Editors

Springer

# Springer Handbook of Global Navigation Satellite Systems

**Springer Handbooks** provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook

# of Global Navigation Satellite Systems

# Foreword

Satellite navigation has become an integral part of our modern-day society and is used by people all over the world. Before 2000, practically only one system was fully operational and available, the American Global Positioning System (GPS). Its Russian counterpart GLONASS, built up during the times of the Cold War in the 1970s and 1980s, had problems with the lifetime of its satellites and decreased to five satellites in the late 1990s. When in 2002 Europe decided to develop its own global satellite system called Galileo, a global race began. Very soon, around 2020, four global satellite navigation systems will be available (GPS – USA, GLONASS – Russia, BeiDou – China, Galileo – Europe), as well as two regional systems (IRNSS/NavIC – India, QZSS – Japan) and more than six augmentation systems. Furthermore, there are probably more to come.

One may wonder whether we need so many systems, yet, who wants to stay on the sidelines in this high-tech area? Satellite navigation with its precise positioning, navigation, and timing (PNT) information is an enabling technology and an important factor in the economic impact of new applications. Precise satellite navigation time is used in the critical infrastructure (telecommunications, power supply, etc.) of many countries, and restricted and encrypted PNT services are a major element in governmental tasks and military applications.

A satellite navigation system is not comparable to other space missions. It does not have a lifetime of, say, 10 years, as is the case with other dedicated space missions that fulfil a specific goal for a limited scientific or technical part of our society. Satellite navigation systems need 10 to 20 years to be built up and are meant to last for many decades in the future. Moreover, they affect the life of each citizen – space for everybody!

In recent years, only a limited number of new textbooks addressing satellite navigation as a whole have become available. The reason is obvious; many systems were under construction, and the authors often had to restrict themselves to the general theory of satellite navigation, to the fundamentals, in order not to write a book that would already be outdated at the moment of publication. Separate books covered satellite navigation receivers, orbit determination, or navigation applications.

With the present book, we have the first *Handbook of Global Navigation Satellite Systems,* aiming to give the reader a full overview of satellite navigation, starting from its fundamentals in the first part and covering in a total of seven parts the entire spectrum of satellite navigation knowledge and applications. Although some global satellite navigation systems are not yet fully completed, the Editors and authors were brave enough to include as much available information as possible.

**Guenter W. Hein**
**Former Head of ESA's EGNOS and Galileo Evolution Dept.**
**& Scientific Consultant of The European Space Agency**

More than 60 authors – all international experts and specialists in their field – have put together the latest state-of-the-art knowledge in the field in approximately 1400 pages. The names of the authors read like the *who is who* in satellite navigation. This is really an exhaustive reference work for one of the key technologies of science and engineering in the future and for those who want to know more about the background for their satellite navigation applications. It must already have been a huge amount of work for the Editors to find the right specialists, to convince them to contribute to such a handbook, to harmonize the different chapters in order to avoid duplications, and last but not least, to describe everything in a consistent way using the same nomenclature. This was a remarkable management exercise with an excellent outcome! Many figures and photographs illustrate the text, completing the handbook as *the* reference and resource in satellite navigation.

It is also excellent that the book is not only published as a hardcover version, but also as an eBook, which will enable the reader to do a quick search in this big exhaustive work. Each of the 41 chapters also contains a list of references from which the interested reader can start to dig even deeper into the topics. Nothing is missing. There are even two annexes that show the different receiver and data formats and outline the various GNSS parameters.

Each of the seven major parts of the book covers distinct aspects of Global Navigation Satellite Systems.

The reader confronted with satellite navigation for the first time can find a very useful, quick overview in Chap. 1. A very clear description and definition of the coordinate reference systems used follows. The chapter on clocks and the relativistic effects on GNSS is excellent; it covers everything from theory to practical

examples of clock data in space. Part A concludes with signal propagation in the atmosphere.

In Part B, the reader already finds a description of all the global, regional, and augmentation systems. The Editors have made great effort to reflect the latest status in the concluding developments of some of these systems.

Part C presents signal processing, receivers, and antennas, and the main effects: multipath and interferences. Even signal generators are described, a topic that is presently not well covered in the open literature.

In Part D, one can read all about the modern achievements in GNSS algorithms and, of course, about the LAMBDA method for the carrier-phase ambiguity resolution developed by one of the Editors in the past 15 years.

Part E entitled *Positioning and Navigation* shows the classical measurement modes of GNSS (absolute and differential positioning). All the new achievements of precise point positioning can be found here, as well the integration of GNSS with inertial navigation systems. The use of GNSS in aviation with its satellite-based augmentation systems and attitude determination is described here. Here, you can also find a description of all GNSS applications on land and sea, as well as in aviation and space.

Part F is dedicated to surveying, geodesy and geodynamics, the first users of GNSS and the most demanding ones in terms of accuracy.

Finally, in Part G *GNSS Remote Sensing and Timing*, some of highly specialized GNSS applications are addressed: tomography, GNSS altimetry, as well as time and frequency transfer.

The list of acronyms and abbreviations and the glossary at the end of the book are very valuable.

There is no doubt that this handbook will quickly become *the* reference manual in satellite navigation – it contains all facets of this high-tech field. The Editors and the many authors have put together an exhaustive book – it is hard to find anything missing. I can only congratulate them for such a fine handbook!

Guenter W. Hein

# Preface

In the mid-1970s, a team of inspired engineers gathered around Brad Parkinson to devise a novel navigation system, which finally became known as NAVSTAR, the Global Positioning System, or briefly GPS. Despite all creativity and visionary thought, the fathers of GPS could hardly imagine that this system would literally change the world. Originally conceived as a means for providing instantaneous positioning and timing to the United States' armed forces around the globe, it was soon realized that GPS would be equally beneficial for a wide range of civil navigation applications and could likewise serve as a system-of-opportunity for diverse types of scientific investigations. The Global Positioning System ultimately became a blueprint for a whole family of space-based navigation systems subsequently established by Russia, China, Europe, and Japan, which all build on the same key principles and technologies.

In response to its widespread use and overall impact, GPS has certainly found due attention and coverage in the popular, educational, and scholarly literature. Numerous textbooks and monographs have been published over the years, but more than 20 years have passed since GPS technology and usage was last summarized in a single comprehensive encyclopedia. Since then, substantial progress has been made and the world of global navigation satellite systems has changed dramatically. Obviously, the number of global navigation satellite systems (GNSS) has increased notably and so has the number of signals and services made available to their users. In parallel, the concepts of GNSS signal and data processing have continuously matured. This has both enabled new levels of performance (in terms of accuracy and timeliness) as well as a wide range of new application areas.

With the above background, we gratefully accepted the publisher's invitation (and challenge) to compile a dedicated *Handbook of Global Navigation Satellite Systems*, which presents a complete and rigorous overview of the fundamentals, methods, and applications of GNSS from today's perspective. After 4 years of work, this endeavor has come to an end, and we are proud to present the result of this work to our readers. With more than 40 chapters and roughly 1400 pages, the new handbook provides an exhaustive, single-source reference work and a state-of-the art description of GNSS as a key technology for science and society at large. Key experts from a broad range of disciplines have contributed to cover the diverse aspects of GNSS and to summarize the respective body-of-knowledge. This includes fundamental principles and technologies but likewise addresses the latest developments in the field. Throughout the handbook, due attention has been given to the new and emerging navigation satellite systems and the way they affect GNSS data processing and utilization.

Overall, the Handbook is structured in seven distinct parts, each comprising a set of four to eight individual chapters with a common range of topics.

Part A starts with a primer on global navigation satellite systems (GNSS), followed by chapters that cover the fundamentals of GNSS. Reference systems that form the backbone of positioning and navigation are discussed, as well as the essentials of GNSS satellite orbits and attitude. These topics are followed by a treatment of radio signals and modulations for GNSS, as well as a chapter on high-performance ground and space clocks that form another GNSS key technology. The part concludes with a description of the physics of atmospheric signal propagation and the changes experienced by GNSS signals when passing through the ionosphere and troposphere.

Part B gives a detailed description of the global and regional navigation satellite systems that are currently operational and/or under development. In addition to GPS, it covers the Russian Global'naya Navigatsionnaya Sputnikova Sistema (GLONASS), the European Galileo system, the Chinese BeiDou System (BDS), the Japanese Quasi-Zenith Satellite System (QZSS), and the Indian Regional Navigation Satellite System (IRNSS/NavIC). The architecture, the navigation signals, the space and control segments, and the services and performances of each system are described as well as their planned evolution. This part also covers the fundamentals and operations of satellite-based augmentation systems (SBASs).

Part C focuses on GNSS user equipment as well related aspects of signal multipath and interference. It discusses the basic architecture of hard and software receivers together with their digital signal processing principles. A dedicated chapter is devoted to GNSS antennas, including design options, performance aspects, and calibration. The multipath environment and its impact on code and phase measurements are described along with relevant mitigation techniques. Sources of GNSS signal interference are examined, and a systematic treatment of jamming and spoofing is provided together with a review of interference detection and mitigation techniques. The part is concluded with an

overview of the different GNSS simulators and a description of their key features.

Part D covers the fundamentals of the GNSS observation equations including the generic algorithms for GNSS parameter estimation and model validation. It starts with the basic observation equations for pseudorange, carrier-phase, and Doppler measurements, and continues with a discussion of linear combinations and their applications. Then the undifferenced GNSS model is developed and used to provide an overview of the various absolute and relative positioning concepts. This is followed by a treatment of the fundamental GNSS estimation, filter, and ambiguity resolution algorithms, together with the corresponding batch and recursive methods for GNSS model validation.

Part E describes different methods of GNSS positioning and navigation together with their various applications. The single-receiver, precise point positioning concept is discussed first, highlighting its adjustment procedure as well as the required models needed to correct for systematic effects. Then the methods of differential positioning are described, including DGNSS, real-time kinematics (RTK) and network RTK. This is followed by a presentation of GNSS attitude determination methods and a discussion of GNSS integration with inertial measurement units. Subsequently, dedicated chapters provide an overview of GNSS applications in land, marine, air, and space environments, along with a discussion of ground-based augmentation systems (GBAS).

Part F describes how GNSS is used in surveying, geodesy, and geodynamics. It starts with an overview of the International GNSS Service (IGS) and a description of the various GNSS products that it offers. For surveying, this part describes how GNSS is used as a tool by the land, engineering, and hydrographic surveyor; for geodesy, it focuses on the role of GNSS in the Global Geodetic Observing System (GGOS), including GNSS-based reference frame implementation, Earth rotation, and sea level monitoring. For geodynamics, it describes the concepts and models used to relate active processes within the Earth to surface deformation observed with GNSS.

Part G, finally, covers GNSS remote sensing and timing. It describes how GNSS tropospheric sensing from ground and space can be used for short-term weather forecasting and long-term climate research. It also describes how GNSS ionospheric sensing contributes to space weather studies and how it helps to mitigate GNSS performance degradation. Furthermore, this part describes the principles of GNSS reflectometry together with methods to retrieve geophysical information from GNSS signals scattered or reflected at the Earth's surface. It concludes with a description of how GNSS is used for accurate time and frequency dissemination and the comparison of distant clocks.

The main body of the book is complemented by an Annex that provides a detailed description of the most widely used GNSS data and product formats. It also offers a summary of relevant physical constants, key parameters of the GNSS constellations, and a compilation of the various GNSS signals. A Glossary covering GNSS-specific terminology is available at the end of the book to provide definitions of common terms that appear in the various chapters.

Overall, we are confident that the Handbook offers an invaluable source of knowledge for scientists, engineers, students, and institutions. It is likewise suited for readers who want to familiarize themselves with GNSS or one of its sub-disciplines and for experienced readers who aim at a deeper understanding of specific aspects. Unlike traditional textbooks, the individual chapters have been written by dedicated expert authors, who were selected based on their experience and background. Each chapter covers a specific aspect of GNSS in a largely self-contained manner and is thus well suited for standalone reading. However, individual chapters are still well connected through cross-references and follow a well-defined and transparent path for readers interested in studying all GNSS aspects in a step-by-step approach. Despite the overall size of the Handbook, space for each topic inevitably remains limited. Care has therefore been taken to complement each chapter with a thoroughly compiled list of bibliographic references covering both background literature and recent developments in the field. These may serve as a starting point for independent research and will enable readers to gain full insight into the numerous details of GNSS technology that cannot be addressed in a single-volume work.

At this stage, we would finally like to thank everyone who helped turn the vision of a new GNSS encyclopedia into reality. This includes, first of all, the more than 60 colleagues and authors who volunteered to contribute their expertise to this project. Despite a wealth of other duties, they all spent endless hours compiling the relevant information, preparing illustrating material, and adapting their work to the never-ending suggestions and change requests of the Editors. Their effort and patience have greatly contributed to achieving an up-to-date, concise, and consistent presentation of the whole world of GNSS in a single publication. We are also grateful to Ms Safoora Zaminpardaz of Curtin University, who assisted in the LaTeX conversion of numerous manuscripts and helped prepare various illustrations for the Handbook. Her assistance has taken substantial work off our shoulders and is thankfully acknowledged.

Our particular appreciation belongs to Ms J. Hinterberg and Ms J. Schwarz of Springer-Verlag, Heidelberg, as well as Ms A. Strohbach of le-tex, Leipzig, and her team for their excellent cooperation and continued support throughout all phases of this work. It was a great pleasure to work with them! Last but not least, we would both like to thank our families, who tolerated, without major complaints, that we stole so many hours from them to work on this project. We are more than grateful for their patience and the continued backing received over the past years.

Peter J.G. Teunissen Perth, Australia
Oliver Montenbruck Munich, Germany

## About the Editors

Peter J.G. Teunissen is Professor of Geodesy and Satellite Navigation at Curtin University (CU), Australia, and Delft University of Technology (TU Delft), The Netherlands. He obtained his Doctorate degree from TU Delft in 1985, following which he received a Constantijn and Christiaan Huygens Fellowship of The Netherlands Organization for the Advancement of Pure Research (NWO). In 1988, he became full Professor at TU Delft and held various academic positions including Vice-Dean of the Faculty of Civil Engineering and Geosciences, Head of the Aerospace Engineering Department, and Science Director of the Delft Institute of Earth Observation and Space Systems. He currently heads the Curtin University GNSS Research Centre, where his research is focused on developing theory, models, and algorithms for high-accuracy geospatial applications of new global and regional satellite navigation systems. He has authored numerous journal papers and textbooks in his field. His pioneering contributions include statistical and numerical methods of integer inference theory, innovative algorithms for multi-GNSS precise parameter estimation, and the early characterization and utilization of the Chinese BeiDou, the Indian IRNSS, and the Russian GLONASS CDMA system. His scientific contributions have been recognized through various awards, including the Bomford Prize, the Steven Hoogendijk Prize, and the Alexander von Humboldt Award. He serves on the Editorial Boards of several journals and is past Editor-in-Chief of the Journal of Geodesy. He has an Honorary Degree from the Chinese Academy of Sciences and is a Fellow of the International Association of Geodesy (IAG), the UK Royal Institute of Navigation (RIN), the US Institute of Navigation (ION), and the Royal Netherlands Academy of Sciences (KNAW).

Oliver Montenbruck is Head of the GNSS Technology and Navigation Group at DLR's German Space Operations Center, Oberpfaffenhofen. He studied Physics and Astronomy and received his diploma from Ludwig Maximilians University Munich in 1987. After joining DLR, he worked as a flight dynamics analyst for geostationary spacecraft as well as other near Earth and deep space missions. He received his PhD from the Technical University Munich in 1991. In 2004, he started teaching at the same university, where he received his habilitation (second doctorate) in 2006 and where he is presently engaged as an Associate Lecturer. His research activities comprise space borne GNSS receiver technology, autonomous navigation systems, spacecraft formation flying, and precise orbit determination. More recently, he has been focusing on the characterization of new satellite navigation systems and multi-GNSS processing. Pioneering contributions in this field included GIOVE and GPS signal investigations based on high gain antenna measurements, the build-up of the Cooperative Network for GNSS Observation (CONGO), the evaluation of triple-frequency signals, as well as the early characterization and utilization of the Chinese BeiDou navigation system. Oliver Montenbruck chairs the Multi-GNSS Working Group of the International GNSS Service (IGS) and coordinates the performance of the MGEX Multi-GNSS Project (MGEX). He has authored various textbooks and numerous technical papers related to his diverse fields of work. His scientific contributions have been recognized through various awards, including the DLR Senior Scientist Award, the Institute of Navigation's (ION) Tycho Brahe Award, and the GPS World Leadership Award.

# Contents

**List of Abbreviations** ..... XXVII

## Part A Principles of GNSS

1 **Introduction to GNSS**
*Richard B. Langley, Peter J.G. Teunissen, Oliver Montenbruck* ..... 3
1.1 Early Satellite Navigation ..... 3
1.2 Concept of GNSS Positioning ..... 5
1.3 Modeling the Observations ..... 10
1.4 Positioning Modes ..... 13
1.5 Current and Developing GNSSs ..... 16
1.6 GNSS for Science and Society at Large ..... 19
**References** ..... 22

2 **Time and Reference Systems**
*Christopher Jekeli, Oliver Montenbruck* ..... 25
2.1 Time ..... 25
2.2 Spatial Reference Systems ..... 31
2.3 Terrestrial Reference System ..... 34
2.4 Celestial Reference System ..... 44
2.5 Transformations Between ICRF and ITRF ..... 46
2.6 Perspectives ..... 55
**References** ..... 56

3 **Satellite Orbits and Attitude**
*Urs Hugentobler, Oliver Montenbruck* ..... 59
3.1 Keplerian Motion ..... 59
3.2 Orbit Perturbations ..... 66
3.3 Broadcast Orbit Models ..... 79
3.4 Attitude ..... 85
**References** ..... 87

4 **Signals and Modulation**
*Michael Meurer, Felix Antreich* ..... 91
4.1 Radiofrequency Signals ..... 91
4.2 Spread Spectrum Technique and Pseudo Random Codes ..... 97
4.3 Modulation Schemes ..... 107
4.4 Signal Multiplexing ..... 113
4.5 Navigation Data and Data-Free Channels ..... 117
**References** ..... 118

5 **Clocks**
*Ron Beard, Ken Senior* ..... 121
5.1 Frequency and Time Stability ..... 122
5.2 Clock Technologies ..... 127
5.3 Space-Qualified Atomic Standards ..... 138
5.4 Relativistic Effects on Clocks ..... 148

5.5 International Timescales ..... 155
5.6 GNSS Timescales ..... 158
**References** ..... 160

6 **Atmospheric Signal Propagation**
*Thomas Hobiger, Norbert Jakowski* ..... 165
6.1 Electromagnetic Wave Propagation ..... 165
6.2 Troposphere ..... 168
6.3 Ionospheric Effects on GNSS Signal Propagation ..... 177
**References** ..... 190

**Part B Satellite Navigation Systems**

7 **The Global Positioning System (GPS)**
*Christopher J. Hegarty* ..... 197
7.1 Space Segment ..... 197
7.2 Control Segment ..... 203
7.3 Navigation Signals ..... 205
7.4 Navigation Data and Algorithms ..... 210
7.5 Time System and Geodesy ..... 216
7.6 Services and Performance ..... 216
**References** ..... 217

8 **GLONASS**
*Sergey Revnivykh, Alexey Bolkunov, Alexander Serdyukov*
*Oliver Montenbruck* ..... 219
8.1 Overview ..... 219
8.2 Navigation Signals and Services ..... 225
8.3 Satellites ..... 232
8.4 Launch Vehicles ..... 237
8.5 Ground Segment ..... 238
8.6 GLONASS Open Service Performance ..... 241
**References** ..... 243

9 **Galileo**
*Marco Falcone, Jörg Hahn, Thomas Burger* ..... 247
9.1 Constellation ..... 248
9.2 Signals and Services ..... 250
9.3 Spacecraft ..... 265
9.4 Ground Segment ..... 269
9.5 Summary ..... 270
**References** ..... 271

10 **Chinese Navigation Satellite Systems**
*Yuanxi Yang, Jing Tang, Oliver Montenbruck* ..... 273
10.1 BeiDou Navigation Satellite Demonstration System (BDS-1) ..... 275
10.2 BeiDou (Regional) Navigation Satellite System (BDS-2) ..... 279
10.3 Performance of BDS-2 ..... 293
10.4 BeiDou (Global) Navigation Satellite System ..... 297
10.5 Brief Introduction of CAPS ..... 298
**References** ..... 301

11 **Regional Systems**
*Satoshi Kogure, A.S. Ganeshan, Oliver Montenbruck* ..... 305
11.1 Concept of Regional Navigation Satellite Systems ..... 306
11.2 Quasi-Zenith Satellite System ..... 306
11.3 Indian Regional Navigation Satellite System (IRNSS/NavIC) ..... 321
**References** ..... 334

12 **Satellite Based Augmentation Systems**
*Todd Walter* ..... 339
12.1 Aircraft Guidance ..... 340
12.2 GPS Error Sources ..... 343
12.3 SBAS Architecture ..... 345
12.4 SBAS Integrity ..... 349
12.5 SBAS User Algorithms ..... 351
12.6 Operational and Planned SBAS Systems ..... 353
12.7 Evolution of SBAS ..... 358
**References** ..... 360

**Part C GNSS Receivers and Antennas**

13 **Receiver Architecture**
*Bernd Eissfeller, Jong-Hoon Won* ..... 365
13.1 Background and History ..... 366
13.2 Receiver Building Blocks ..... 372
13.3 Multifrequency and Multisystem Receivers ..... 391
13.4 Technology Trends ..... 396
13.5 Receiver Types ..... 397
**References** ..... 399

14 **Signal Processing**
*Jong-Hoon Won, Thomas Pany* ..... 401
14.1 Overview and Scope ..... 402
14.2 Received Signal Model ..... 403
14.3 Signal Search and Acquisition ..... 406
14.4 Signal Tracking ..... 413
14.5 Time Synchronization and Data Demodulation ..... 424
14.6 GNSS Measurements ..... 428
14.7 Advanced Topics ..... 434
**References** ..... 440

15 **Multipath**
*Michael S. Braasch* ..... 443
15.1 The Impact of Multipath ..... 444
15.2 Characterizing the Multipath Environment ..... 444
15.3 Multipath Signal Models ..... 448
15.4 Pseudorange and Carrier-Phase Error ..... 450
15.5 Multipath Error Envelopes ..... 450
15.6 Temporal Error Variation, Bias Characteristics and Fast Fading Considerations ..... 453
15.7 Multipath Mitigation ..... 455

15.8 Multipath Measurement ..... 459
15.9 A Note About Multipath Impact on Doppler Measurements ..... 466
15.10 Conclusions ..... 466
**References** ..... 466

16 **Interference**
*Todd Humphreys* ..... 469
16.1 Analysis Technique for Statistically Independent Interference ..... 471
16.2 Canonical Interference Models ..... 476
16.3 Quantization Effects ..... 479
16.4 Specific Interference Waveforms and Sources ..... 481
16.5 Spoofing ..... 485
16.6 Interference Detection ..... 491
16.7 Interference Mitigation ..... 498
**References** ..... 501

17 **Antennas**
*Moazam Maqsood, Steven Gao, Oliver Montenbruck* ..... 505
17.1 GNSS Antenna Characteristics ..... 506
17.2 Basic GNSS Antenna Types ..... 509
17.3 Application-Specific GNSS Antennas ..... 513
17.4 Multipath Mitigation ..... 519
17.5 Antennas for GNSS Satellites ..... 523
17.6 Antenna Measurement and Calibration ..... 527
**References** ..... 531

18 **Simulators and Test Equipment**
*Mark G. Petovello, James T. Curran* ..... 535
18.1 Background ..... 537
18.2 RF-Level Simulators ..... 543
18.3 IF-Level Simulators ..... 546
18.4 Record and Playback Systems ..... 549
18.5 Measurement-Level Simulators ..... 552
18.6 Combining Live and Simulated Data ..... 554
18.7 Other Considerations ..... 556
18.8 Summary ..... 557
**References** ..... 557

**Part D GNSS Algorithms and Models**

19 **Basic Observation Equations**
*André Hauschild* ..... 561
19.1 Observation Equations ..... 561
19.2 Relativistic Effects ..... 564
19.3 Atmospheric Signal Delays ..... 565
19.4 Carrier-Phase Wind-Up ..... 569
19.5 Antenna Phase-Center Offset and Variations ..... 572
19.6 Signal Biases ..... 576
19.7 Receiver Noise and Multipath ..... 578
**References** ..... 579

20 **Combinations of Observations**
*André Hauschild* ..... 583
20.1 Fundamental Equations ..... 583
20.2 Combinations of Single-Satellite and Single-Receiver Observations 586
20.3 Combinations of Multisatellite and Multireceiver Observations ..... 594
20.4 Pseudorange Filtering ..... 601
**References** ..... 603

21 **Positioning Model**
*Dennis Odijk* ..... 605
21.1 Nonlinear Observation Equations ..... 606
21.2 Linearization of the Observation Equations ..... 609
21.3 Point Positioning Models ..... 612
21.4 Relative Positioning Models ..... 623
21.5 Differenced Positioning Models ..... 631
21.6 The Positioning Concepts Related ..... 633
**References** ..... 635

22 **Least-Squares Estimation and Kalman Filtering**
*Sandra Verhagen, Peter J.G. Teunissen* ..... 639
22.1 Linear Least-Squares Estimation ..... 639
22.2 Optimal Estimation ..... 641
22.3 Special Forms of Least Squares ..... 644
22.4 Prediction and Filtering ..... 650
22.5 Kalman Filtering ..... 653
**References** ..... 659

23 **Carrier Phase Integer Ambiguity Resolution**
*Peter J.G. Teunissen* ..... 661
23.1 GNSS Ambiguity Resolution ..... 662
23.2 Rounding and Bootstrapping ..... 666
23.3 Linear Combinations ..... 669
23.4 Integer Least-Squares ..... 673
23.5 Partial Ambiguity Resolution ..... 677
23.6 When to Accept the Integer Solution? ..... 678
**References** ..... 683

24 **Batch and Recursive Model Validation**
*Peter J.G. Teunissen* ..... 687
24.1 Modeling and Validation ..... 687
24.2 Batch Model Validation ..... 689
24.3 Testing for a Bias ..... 692
24.4 Testing Procedure ..... 705
24.5 Recursive Model Validation ..... 710
**References** ..... 717

## Part E Positioning and Navigation

25 **Precise Point Positioning**
*Jan Kouba, François Lahaye, Pierre Tétreault* ..... 723
25.1 PPP Concept ..... 724

25.2 Precise Positioning Correction Models ..... 726
25.3 Specific Processing Aspects ..... 735
25.4 Implementations ..... 741
25.5 Examples ..... 743
25.6 Discussion ..... 746
**References** ..... 747

26 **Differential Positioning**
*Dennis Odijk, Lambert Wanninger* ..... 753
26.1 Differential GNSS: Concepts ..... 753
26.2 Differential Navigation Services ..... 760
26.3 Real-Time Kinematic Positioning ..... 763
26.4 Network RTK ..... 774
**References** ..... 778

27 **Attitude Determination**
*Gabriele Giorgi* ..... 781
27.1 Six Degrees of Freedom ..... 781
27.2 Attitude Parameterization ..... 784
27.3 Attitude Estimation from Baseline Observations ..... 787
27.4 The GNSS Attitude Model ..... 790
27.5 Applications ..... 798
27.6 An Overview of GNSS/INS Sensor Fusion for Attitude Determination 804
**References** ..... 806

28 **GNSS/INS Integration**
*Jay A. Farrell, Jan Wendel* ..... 811
28.1 State Estimation Objectives ..... 812
28.2 Inertial Navigation ..... 813
28.3 Inertial Sensors ..... 815
28.4 Strapdown Inertial Navigation ..... 818
28.5 Analysis of Error Effects ..... 822
28.6 Aided Navigation ..... 824
28.7 State Estimation ..... 824
28.8 GNSS and Aided INS ..... 825
28.9 Detailed Example ..... 828
28.10 Alternative Estimation Methods ..... 835
28.11 Looking Forward ..... 838
**References** ..... 839

29 **Land and Maritime Applications**
*Allison Kealy, Terry Moore* ..... 841
29.1 Land-Based Applications of GNSS ..... 842
29.2 Rail Applications ..... 856
29.3 Maritime Applications ..... 863
29.4 Outlook ..... 873
**References** ..... 873

30 **Aviation Applications**
*Richard Farnworth* ..... 877
30.1 Overview ..... 878

30.2 Standardising GNSS for Aviation ..... 881
30.3 Evolution of the Flight Deck ..... 884
30.4 From the RNP Concept to PBN ..... 886
30.5 GNSS Performance Requirements ..... 888
30.6 Linking the PBN Requirements and the GNSS Requirements ..... 891
30.7 Flight Planning and NOTAMs ..... 897
30.8 Regulation and Certification ..... 897
30.9 Military Aviation Applications ..... 898
30.10 Other Aviation Applications of GNSS ..... 899
30.11 Future Evolution ..... 900
**References** ..... 901

31 **Ground Based Augmentation Systems**
*Sam Pullen* ..... 905
31.1 Components ..... 906
31.2 An Overview of Local Area Approaches ..... 907
31.3 Ground-Based Augmentation Systems ..... 909
31.4 Augmentation via Ranging Signals Pseudolites ..... 928
31.5 Outlook ..... 930
**References** ..... 930

32 **Space Applications**
*Oliver Montenbruck* ..... 933
32.1 Flying High ..... 933
32.2 Spacecraft Navigation ..... 938
32.3 Formation Flying and Rendezvous ..... 951
32.4 Other Applications ..... 957
**References** ..... 959

## Part F Surveying, Geodesy and Geodynamics

33 **The International GNSS Service**
*Gary Johnston, Anna Riddell, Grant Hausler* ..... 967
33.1 Mission and Organization ..... 967
33.2 Components ..... 969
33.3 IGS Products ..... 972
33.4 Pilot Projects and Experiments ..... 976
33.5 Outlook ..... 981
**References** ..... 981

34 **Orbit and Clock Product Generation**
*Jan P. Weiss, Peter Steigenberger, Tim Springer* ..... 983
34.1 Global Tracking Network ..... 984
34.2 Models ..... 985
34.3 POD Process ..... 992
34.4 Estimation Strategies ..... 993
34.5 Software ..... 1000
34.6 Products ..... 1001
34.7 Outlook ..... 1005
**References** ..... 1006

35 **Surveying**
*Chris Rizos* ..... 1011
35.1 Precise Positioning Techniques ..... 1013
35.2 Geodetic and Land Surveying ..... 1023
35.3 Engineering Surveying ..... 1029
35.4 Hydrographic Surveying ..... 1033
**References** ..... 1035

36 **Geodesy**
*Zuheir Altamimi, Richard Gross* ..... 1039
36.1 GNSS and IAG's Global Geodetic Observing System ..... 1039
36.2 Global and Regional Reference Frames ..... 1044
36.3 Earth Rotation, Polar Motion, and Nutation ..... 1054
**References** ..... 1059

37 **Geodynamics**
*Jeff Freymueller* ..... 1063
37.1 GNSS for Geodynamics ..... 1064
37.2 History and Establishment of GNSS Networks for Geodynamics ..... 1067
37.3 Rigid Plate Motions ..... 1071
37.4 Plate Boundary Deformation and the Earthquake Cycle ..... 1073
37.5 Seismology ..... 1078
37.6 Volcano Deformation ..... 1088
37.7 Surface Loading Deformation ..... 1091
37.8 The Multi-GNSS Future ..... 1099
**References** ..... 1100

**Part G GNSS Remote Sensing and Timing**

38 **Monitoring of the Neutral Atmosphere**
*Gunnar Elgered, Jens Wickert* ..... 1109
38.1 Ground-Based Monitoring of the Neutral Atmosphere ..... 1110
38.2 GNSS Radio Occultation Measurements ..... 1120
38.3 Outlook ..... 1132
**References** ..... 1133

39 **Ionosphere Monitoring**
*Norbert Jakowski* ..... 1139
39.1 Ground-Based GNSS Monitoring ..... 1140
39.2 Space-Based GNSS Monitoring ..... 1144
39.3 GNSS-Based 3-D-Tomography ..... 1147
39.4 Scintillation Monitoring ..... 1148
39.5 Space Weather ..... 1152
39.6 Coupling with Lower Geospheres ..... 1156
39.7 Information and Data Services ..... 1159
**References** ..... 1159

40 **Reflectometry**
*Antonio Rius, Estel Cardellach* ..... 1163
40.1 Receivers ..... 1164
40.2 Models ..... 1167

40.3 Applications ..... 1172
40.4 Spaceborne Missions ..... 1182
**References** ..... 1183

41 **GNSS Time and Frequency Transfer**
*Pascale Defraigne* ..... 1187
41.1 GNSS Time and Frequency Dissemination ..... 1187
41.2 Remote Clock Comparisons ..... 1191
41.3 Hardware Architecture and Calibration ..... 1197
41.4 Multi-GNSS Time Transfer ..... 1201
41.5 Conclusions ..... 1203
**References** ..... 1204

**Annex A: Data Formats** ..... 1207
**Annex B: GNSS Parameters** ..... 1233
**About the Authors** ..... 1241
**Detailed Contents** ..... 1251
**Glossary of Defining Terms** ..... 1275
**Subject Index** ..... 1303

# List of Abbreviations

## A

| | |
|---|---|
| A-GNSS | assisted GNSS |
| A-PNT | alternative positioning navigation and timing |
| ABAS | aircraft based augmentation system |
| AC | analysis center |
| ACES | atom clock ensemble in space |
| ADC | analog-to-digital converter |
| ADEV | Allan deviation |
| ADF | automatic direction finding |
| ADOP | ambiguity dilution of precision |
| ADS | automatic dependent surveillance |
| AEP | architecture evolution plan |
| AFS | atomic frequency standard |
| AFSCN | air force satellite control network |
| AGC | automatic gain control |
| AGGA | advanced GPS/GLONASS ASIC |
| AIUB | Astronomical Institute of the University of Bern |
| AKM | apogee kick motor |
| AltBOC | alternative BOC |
| AM | amplitude modulation |
| ANTEX | antenna exchange (format) |
| AOCS | attitude and orbit control system |
| APL | airport pseudolite |
| APV | approach with vertical guidance |
| ARP | antenna reference point |
| ARW | angular random walk |
| ASIC | application specific integrated circuit |
| ATV | automated transfer vehicle |
| AUT | antenna under test |
| AWGN | additive white Gaussian noise |

## B

| | |
|---|---|
| BAW | bulk acoustic wave |
| BC | Barker code |
| BCH | Bose–Chaudhuri–Hocquenghem (code) |
| BCRS | barycentric celestial reference system |
| BDS | BeiDou Navigation Satellite System |
| BDT | BeiDou time |
| BGD | broadcast group delay |
| BIH | Bureau International de l'Heure |
| BIPM | Bureau International des Poids et Mesures |
| BLUE | best linear unbiased estimation |
| BLUP | best linear unbiased prediction |
| BNR | bias-to-noise ratio |
| BOC | binary offset carrier |
| BPSK | binary phase-shift keying |

## C

| | |
|---|---|
| CAPS | Chinese Area Positioning System |
| CASM | coherent adaptive sub-carrier modulation |
| CBOC | composite binary offset carrier |
| CCD | code-carrier divergence |
| CCIR | Comité Consultatif International des Radiocommunications |
| CDGNSS | carrier-phase differential GNSS |
| CDMA | code division multiple access |
| CEP | circular error probable |
| CFIT | controlled flight into terrain |
| CGCS | China Geodetic Coordinate System |
| CIO | celestial intermediate origin |
| CL | long code |
| CM | moderate-length code |
| CMC | code-minus-carrier |
| CMCU | clock monitoring and comparison unit |
| CMOS | complementary metal oxide semiconductor |
| CMS | constrained maximum success-rate |
| CNAV | civil navigation message |
| CODE | Center for Orbit Determination in Europe |
| COG | center-of-gravity |
| CoM | center-of-mass |
| CoN | center-of-network |
| CONUS | conterminous United States |
| COO | cell-of-origin |
| CORS | continuously operating reference station |
| COSPAS | Cosmicheskaya Sistema Poiska Avariynyh Sudo (space system for search of distress vessels and airplanes) |
| COTS | commercial-off-the-shelf |
| CPT | coherent population trapping |
| CPU | central processing unit |
| CRC | cyclic redundancy check |
| CRF | celestial reference frame |
| CRPA | controlled radiation pattern antenna |
| CRS | celestial reference system |
| CS | Commercial Service |
| CS | control segment |
| CSAC | chip scale atomic clock |
| CSK | code shift keying |
| CTP | conventional terrestrial pole |

## D

| | |
|---|---|
| DAB | digital audio broadcast |
| DC | data center |
| DCB | differential code bias |
| DCFBS | digital cesium beam frequency standard |
| DD | double-difference |

| | |
|---|---|
| DDM | delay-Doppler-map |
| DEM | digital elevation model |
| DGNSS | differential GNSS |
| DH | decision height |
| DIODE | DORIS immediate orbit on-board determination |
| DLL | delay lock loop |
| DLR | Deutsches Zentrum für Luft- und Raumfahrt |
| DMA | Defense Mapping Agency |
| DME | distance measuring equipment |
| DOP | dilution of precision |
| DORIS | Doppler orbitography and radiopositioning integrated by satellite |
| DQM | data quality monitoring |
| DSP | digital signal processor |
| DVB | digital video broadcasting |

## E

| | |
|---|---|
| EAL | Echelle atomique libre (free atomic scale) |
| ECEF | Earth-centered Earth-fixed |
| ECI | Earth-centered inertial |
| ECMWF | European Centre for Medium-Range Weather Forecasts |
| ECOM | Empirical CODE Orbit Model |
| EELV | evolved expendable launch vehicles |
| EGNOS | European Geostationary Navigation Overlay Service |
| EIRP | effective isotropic radiated power |
| EKF | extended Kalman filter |
| EO | Earth observation |
| EPB | equatorial plasma bubble |
| ESA | European Space Agency |
| EUV | extreme ultraviolet |

## F

| | |
|---|---|
| FAA | US Federal Aviation Administration |
| FAR | full ambiguity resolution |
| FBR | front-to-back ratio |
| FCC | Federal Communications Commission |
| FDMA | frequency division multiple access |
| FE | front end |
| FEC | forward error correction |
| FFT | fast Fourier transform |
| FK5 | Fundamental Katalog 5 |
| FLDR | flicker drift |
| FLFR | flicker frequency (noise) |
| FLL | frequency lock loop |
| FLPH | flicker phase (noise) |
| FMS | flight management system |
| FNBW | first-null beam width |
| FOC | full operational capability |
| FOG | fiber optic gyroscope |
| FPGA | field programmable gate array |
| FRPA | fixed radiation pattern antenna |
| FTE | flight technical error |

## G

| | |
|---|---|
| GAGAN | GPS-aided GEO Augmented Navigation |
| GAST | Greenwich apparent sidereal time |
| GBAS | ground-based augmentation system |
| GCC | Galileo Control Centre |
| GCRS | Geocentric Celestial Reference System |
| GDGPS | global differential GPS |
| GEO | geostationary Earth orbit |
| GFZ | Deutsches GeoForschungsZentrum |
| GGTO | GPS-to-Galileo time offset |
| GIM | global ionospheric map |
| GIOVE | Galileo In-Orbit Validation Element |
| GIS | geographic information system |
| GIVE | grid ionospheric vertical error |
| GLONASS | Global'naya Navigatsionnaya Sputnikova Sistema (Russian Global Navigation Satellite System) |
| GLST | GLONASS System Time |
| GMS | ground mission segment |
| GNSS | global navigation satellite system |
| GPS | Global Positioning System |
| GPST | GPS Time |
| GPT | global pressure and temperature (model) |
| GRAM | GPS receiver application module |
| GRAS | ground-based regional augmentation system |
| GRAS | GNSS receiver for atmospheric sounding |
| GST | Galileo System Time |
| GTRS | Geocentric Terrestrial Reference System |

## H

| | |
|---|---|
| HDOP | horizontal dilution of precision |
| HEO | highly elliptical orbit |
| HOW | hand-over word |
| HPBW | half-power beam width |

## I

| | |
|---|---|
| I/Q | in-phase/quadrature |
| IAU | International Astronomical Union |
| IB | integer bootstrapping |
| IBLS | integrity beacon landing system |
| ICAO | International Civil Aviation Organization |
| ICD | interface control document |
| ICRF | International Celestial Reference Frame |
| ICRS | International Celestial Reference System |
| IEEE | Institute of Electrical and Electronics Engineers |
| IERS | International Earth Rotation and Reference Systems Service |
| IF | intermediate frequency |
| IFA | inverted-F antenna |
| IGP | ionospheric grid point |
| IGS | International GNSS Service |
| IGSO | inclined geo-synchronous orbit |
| IIP | instantaneous impact point |
| ILS | integer least-squares |

| | |
|---|---|
| ILS | instrument landing system |
| ILS | International Latitude Service |
| IMU | inertial measurement unit |
| INS | inertial navigation system |
| InSAR | interferometric synthetic aperture radar |
| IOD | issue-of-data |
| IODC | issue-of-data clock |
| IODE | issue-of-data ephemeris |
| IONEX | ionosphere exchange (format) |
| IOP | intensity optical pumping |
| IOT | in-orbit test |
| IOV | in-orbit validation |
| IPP | ionospheric pierce point |

# 1. Introduction to GNSS

Richard B. Langley, Peter J.G. Teunissen, Oliver Montenbruck

This chapter is a primer on global navigation satellite systems (GNSSs). It assumes no prior knowledge of the systems or how they work. All of the key concepts of satellite-based positioning, navigation, and timing (PNT) are introduced with pointers to subsequent chapters for further details. The chapter begins with a history of PNT using satellites and then introduces the concept of positioning using measured ranges between a receiver and satellites. The basic observation equations are then described along with the associated error budgets. Subsequently, the various GNSSs now in operation and in development are briefly overviewed. The chapter concludes with a discussion of the relevance and importance of GNSS for science and society at large.

## 1.1 Early Satellite Navigation

We will introduce the basic concepts of the Navstar Global Positioning System (GPS) and the other global navigation satellite systems (GNSSs) in operation and under development but it will be helpful if we first view them in a historical perspective. Determining the positions of points on the Earth's surface using observations of distant objects has been carried out for hundreds of years. Reflecting mirrors on mountaintops gave way to using high-altitude flares and rockets. And, of course, celestial navigation using observations of the Sun, stars, and planets has been used for centuries. However, it was only with the dawning of the space age that it became possible to develop a global system for high accuracy positioning and navigation.

Sometimes we refer to these systems as space-based systems. They can be broadly classified into optical techniques and radio techniques. Both kinds of system were pioneered in the late 1950s and 1960s.

Optical techniques are those techniques that utilize the visible part of the electromagnetic spectrum and in addition to astronomical positioning using a theodolite or sextant, include ground-based imaging of orbiting satellites and satellite laser ranging (SLR). Although still an important source of information for satellite orbit determination and surveillance, imaging of satellites against background stars for geodetic positioning has been superseded by other techniques. However, SLR still plays a prominent role in geodetic positioning and celestial mechanics.

Several radio systems were developed for satellite tracking and orbit determination. In the United States, these systems included radar, the Goddard Space Flight Center Range and Range Rate (GRARR) system, and NASA's Minitrack system [1.1]. In addition to their role in orbit determination, the systems were utilized for tracking camera calibration and directly for geode-

tic positioning. The US Army's Sequential Collation of Range (SECOR) system, on the other hand, was developed specifically for positioning purposes.

But the most successful satellite-based positioning system and one that overlapped with the development of GPS, was Transit [1.2, 3]. Also known as the US Navy Navigation Satellite System, Transit was the world's first satellite-based positioning system to operate globally. The system evolved from the efforts to track the Soviet Union's Sputnik I, the first artificial Earth-orbiting satellite. By measuring the Doppler frequency shift of the 20 MHz radio signals received from the satellite at a known location, the orbit of the satellite could be worked out. And shortly thereafter, researchers determined that if the orbit of a satellite was known, then the position of a receiver could be determined from the shift. That realization led to the development of Transit, with the first experimental satellite being launched in 1959. Initially classified, the system was made available to civilians in 1967 and was widely used for navigation and precise positioning until it was shut down in 1996. The Soviet Union developed a similar system called Tsikada and a special military version called Parus [1.4, 5]. These systems are also assumed to be no longer in use – at least for navigation.

A series of Transit prototype and research satellites was launched between 1959 and 1964 with the first fully operational satellite, Transit 5-BN-2, launched on 5 December 1963. The first Oscar-class Transit satellite (NNS O-1, Fig. 1.1), was brought into orbit on 6

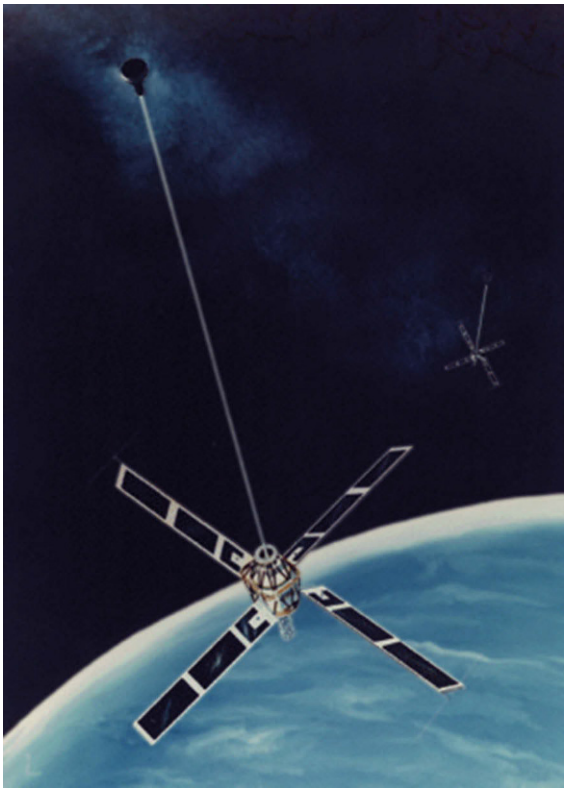

**Fig. 1.1** US Navy Transit navigation satellite of the *Oscar* series (named after the phonetic code word for the letter *O*, or *operational*) (courtesy of US Navy)

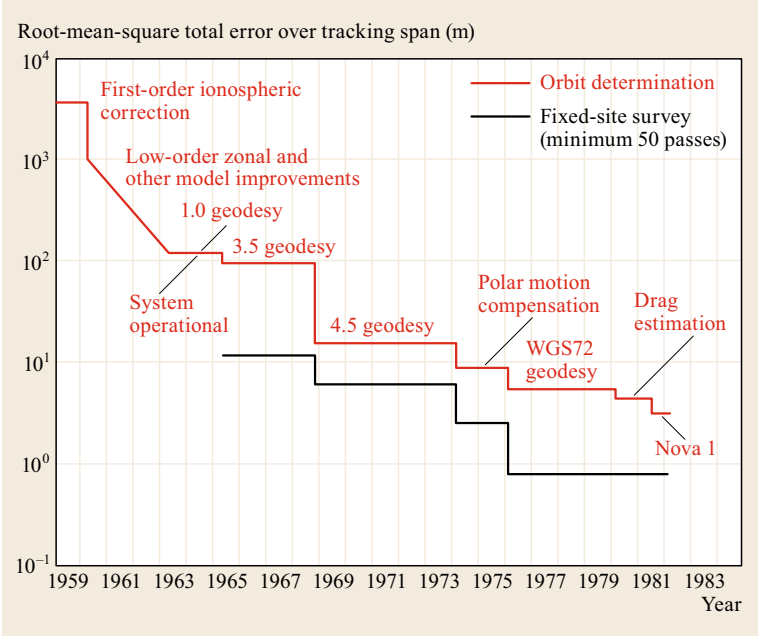

**Fig. 1.2** Accuracy improvements over time with US Navy Transit satellites (after [1.3])

October 1964 and 24 operational satellites were subsequently launched. The last pair of Transit satellites, NNS O-25 and O-31, was launched on 25 August 1988.

Transit navigation required the measurements of the satellite signal's Doppler shift for a complete pass that could take up to about 18 min from horizon to horizon. At the conclusion of the pass, the latitude and longitude of the receiver, the position fix, could be determined. With five operational satellites, the mean time between fixes at a mid-latitude site was around 1 h. Eventually, as the orbits of the satellites became better determined, two-dimensional (2-D) position fix accuracies of several tens of meters were possible from a single satellite pass. By recording data from a number of passes over a few days from a fixed site on land, three-dimensional (3-D) accuracies better than one meter were possible and Doppler-based control points for mapping were established in many countries and the Canadian north, in particular, saw significant use of Transit for geodetic purposes.

The Transit satellites used signals on two different frequencies (150/400 MHz) to cancel out ionospheric delays, a concept that was later inherited by GPS and the other GNSSs. Besides its main use as a navigation system, Transit also provided early contributions to geodesy and helped to establish a new global reference frame (Fig. 1.2).

Transit was decommissioned at the end of 1996 with the advent of GPS and its superior performance. And the equivalent Russian satellite Doppler systems have essentially been replaced by the Global'naya Navigatsionnaya Sputnikova Sistema (Russian Global Navigation Satellite System, GLONASS), the second fully operational GNSS. These new systems were based on the concept of range measurements rather than Doppler observations and used a different constellation design offering continuous coverage. These new concepts enabled a notable increase in accuracy as well as instantaneous positioning around the globe.

## 1.2 Concept of GNSS Positioning

### 1.2.1 Ranging Measurements

GNSS signals are electromagnetic waves propagating at the speed of light. Signal frequencies in the radio spectrum between about 1.2 and 1.6 GHz (a part of the so-called L-band) have been selected for these signals since these enable measurements of adequate precision, allow for reasonably simple user equipment and do not suffer from attenuation in the atmosphere under common weather conditions. At the given frequencies, GNSS signals have a wavelength of about 19–25 cm. Similar to early radio navigation systems such as Transit, GNSSs provide signals on at least two different frequencies for compensation of ionospheric delays in their measurements.

A distinct feature of all GNSS signals is the modulation of the harmonic radio wave (termed the *carrier*) with a characteristic pseudorandom noise (PRN) code. This code is essentially a binary sequence of zeros and ones with no obvious pattern or regularity. The sequence is transmitted at a rate of typically 1–10 MHz, where higher rates imply a higher processing effort but promise more precise measurements. The PRN code is continuously repeated at intervals of a few milliseconds to seconds and facilitates measurements of the signal transmission time. In most GNSSs, the PRN sequence also serves as a unique fingerprint, which allows the receiver to distinguish individual satellites transmitting on the same frequency.

On top of the ranging code, the signal is also modulated with a low rate (e.g., 50 bits/s) navigation data stream (known as the broadcast navigation message) that provides information on the orbit of the transmitting satellite and the offset of its local clock from the GNSS system time.

The basic measurement made by a GNSS receiver is the time $\tau$ required for the GNSS signal to propagate from a satellite to the receiver. This can be obtained by tracking the PRN code modulation of the signal as illustrated in Fig. 1.3. Within the receiver, a local copy of the PRN sequence is generated, which is continuously compared and aligned with the signal received

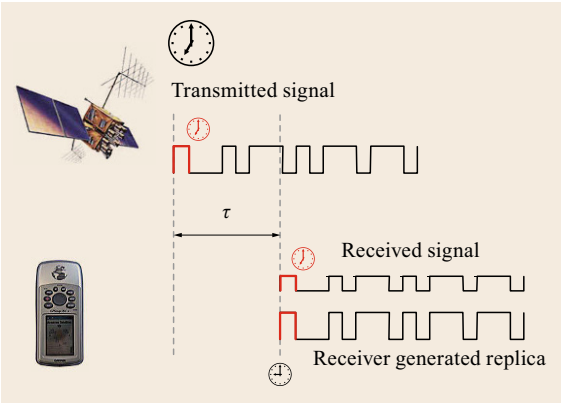

**Fig. 1.3** Basic principle of pseudorange measurements

from the satellite. This *tracking loop* provides continuous measurements of the instantaneous code phase and hence the transmission time corresponding to the currently received signal (Chap. 13). By comparing this time with the local receiver time, the signal propagation time, and – upon multiplication by the speed of light – the distance or range from receiver to satellite are obtained.

Overall, the GNSS signals enable three basic types of measurements:

- *Pseudorange*: A measure of the difference between the receiver clock at signal reception and the satellite clock at signal transmission (scaled by the speed of light). Except for the asychronicity of the two clocks and some other delays, the pseudorange measures the satellite–receiver distance, the precision of which is in the dm-range.
- *Carrier phase*: A measure of the instantaneous beat phase and the accumulated number of zero-crossings obtained after mixing with a reference signal of the nominal frequency. Changes in carrier phase over time reflect the change in (pseudo)range but are substantially ($\approx 2$ orders) more precise. In case of interrupted tracking the accumulated cycle count is lost and the carrier-phase measurements exhibit a cycle slip.
- *Doppler*: The change in the received frequency caused by the Doppler effect is a measure of the range-rate or line-of-sight velocity.

Pseudorange, carrier-phase, and Doppler observations provide the basic measurements for computing position and velocity as well as the offset of the receiver time with respect to the GNSS system time scale.

They are complemented by information on the orbit and clock offsets of the individual GNSS satellites, which is transmitted as part of the broadcast navigation message and allows the receiver to compute the position and velocity of the transmitting satellite at the signal transmission time. To provide such information with adequate accuracy, the GNSS operator must be able to determine and to predict the satellite orbit (Chap. 3) ahead of time, so that it can be uploaded to the satellite for subsequent broadcasting to the users. Likewise GNSS relies on highly stable onboard clocks, whose time offsets can be accurately predicted. Rubidium or cesium atomic frequency standards or even hydrogen masers are used for this purpose (Chap. 5), which deviate by only $10^{-13}$ to $10^{-14}$ from their nominal frequency over time scales of a day.

Before addressing pseudorange- and carrier-phase-based positioning in more detail, we first discuss the basic principles of range-based positioning using distance measurements.

### 1.2.2 Range-Based Positioning

As mentioned, the basic measurement made by a GNSS receiver is the time $\tau_\mathrm{r}^\mathrm{s}$ required for the GNSS signal to propagate from a satellite antenna s to a receiver antenna r. Since the signal travels at the speed of light, $c$, this time interval can be converted to a distance or range, simply by multiplying it by $c$

$$\rho_\mathrm{r}^\mathrm{s}(t) = c\tau_\mathrm{r}^\mathrm{s} \,. \tag{1.1}$$

Let us assume that the clock in the receiver is synchronized with the clock in the satellite, and that the atmosphere (ionosphere and troposphere), which slightly delays the arrival of the signal and about which we will talk later, does not exist. Furthermore, let us assume there is no measurement noise; that is, no random perturbation to the measurement, something that invariably affects all measurements to a greater or lesser degree. Under these ideal and simplified circumstances, the observation equation for the observed range takes the form

$$\begin{aligned}\rho_\mathrm{r}^\mathrm{s}(t) &= ||\boldsymbol{r}_\mathrm{r}(t) - \boldsymbol{r}^\mathrm{s}(t-\tau)|| \\ &= \Big[(x_\mathrm{r}(t) - x^\mathrm{s}(t-\tau))^2 + (y_\mathrm{r}(t) - y^\mathrm{s}(t-\tau))^2 \\ &\quad + (z_\mathrm{r}(t) - z^\mathrm{s}(t-\tau))^2\Big]^{-\frac{1}{2}} ,\end{aligned} \tag{1.2}$$

with $\boldsymbol{r}_\mathrm{r} = (x_\mathrm{r}, y_\mathrm{r}, z_\mathrm{r})^\top$ being the unknown position vector of the receiver antenna (possibly moving and therefore a function of time) and $\boldsymbol{r}^\mathrm{s} = (x^\mathrm{s}, y^\mathrm{s}, z^\mathrm{s})^\top$ that of the satellite (known from the navigation message transmitted by the satellite). Typically, both vectors are referred to an Earth-centered, Earth-fixed (ECEF) coordinate frame. Examples of such frames include versions of the World Geodetic System (WGS) 84 and the International Terrestrial Reference Frame (ITRF) (Chaps. 2 and 36).

With a single range measurement (1.2), we would know that the position of the receiver antenna must lie somewhere on a sphere, centered on the satellite, with a radius equal to the measured range; call it $\rho_\mathrm{r}^1$. If we simultaneously make a range measurement to a second satellite, then our receiver must also lie on a sphere, of radius $\rho_\mathrm{r}^2$, centered on this satellite. The two spheres will intersect, with the loci of intersection points forming a circle. Our receiver must lie somewhere on this circle, which is therefore called a line of position. A third simultaneous range measurement, $\rho_\mathrm{r}^3$, gives us a third sphere, which intersects the other two at just two points. One of these points can be immediately dismissed as being the location of our receiver, since it lies far out in space. So, the simultaneous measurement of the ranges to three satellites is sufficient to determine

a position fix in three dimensions – at least in principle (Fig. 1.4).

Computationally, the receiver position solution $(x_r, y_r, z_r)^\top$ of the simultaneous range equations

$$\begin{aligned}\rho_r^1 &= \sqrt{(x_r - x^1)^2 + (y_r - y^1)^2 + (z_r - z^1)^2}\\ \rho_r^2 &= \sqrt{(x_r - x^2)^2 + (y_r - y^2)^2 + (z_r - z^2)^2}\\ \rho_r^3 &= \sqrt{(x_r - x^3)^2 + (y_r - y^3)^2 + (z_r - z^3)^2}\end{aligned} \tag{1.3}$$

is usually obtained through an iterative linearization approach. Switching to vector formalism $\boldsymbol{p} = [\rho_r^1, \rho_r^2, \rho_r^3]^\top$ and dropping the indices, the system (1.3) of three nonlinear range equations can be approximated to the first order as

$$\boldsymbol{p} = \boldsymbol{p}_0 + \mathbf{A}\Delta\boldsymbol{x}\,, \tag{1.4}$$

where $\boldsymbol{p}_0$ is the vector of computed range values based on given satellite coordinates $(x^i, y^i, z^i)$, $i = 1, 2, 3$, and an initial estimate $\boldsymbol{x}_0 = (x_{r,0}, y_{r,0}, z_{r,0})^\top$ of the receiver's position. Furthermore,

$$\mathbf{A} = \begin{pmatrix} \frac{\partial\rho_r^1}{\partial x_r} & \frac{\partial\rho_r^1}{\partial y_r} & \frac{\partial\rho_r^1}{\partial z_r} \\ \frac{\partial\rho_r^2}{\partial x_r} & \frac{\partial\rho_r^2}{\partial y_r} & \frac{\partial\rho_r^2}{\partial z_r} \\ \frac{\partial\rho_r^3}{\partial x_r} & \frac{\partial\rho_r^3}{\partial y_r} & \frac{\partial\rho_r^3}{\partial z_r} \end{pmatrix} \tag{1.5}$$

with $\partial p_r^i/\partial x_r = (x_{r,0} - x^i)/\rho_{r,0}^i$ $(i = 1, 2, 3)$, is the design matrix, and $\Delta\boldsymbol{x} = \boldsymbol{x} - \boldsymbol{x}_0$ is the increment to the initial vector of receiver coordinates that is to be determined. Note that the matrix $\mathbf{A}$ reflects the relative geometry of the satellites and the receiver. Solving for $\Delta\boldsymbol{x}$, we have

$$\Delta\boldsymbol{x} = \mathbf{A}^{-1}(\boldsymbol{p} - \boldsymbol{p}_0) = \mathbf{A}^{-1}\Delta\boldsymbol{p} \tag{1.6}$$

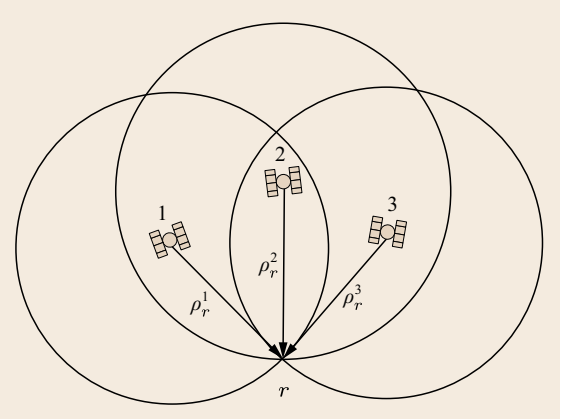

**Fig. 1.4** Positioning through intersecting spheres

and then

$$\boldsymbol{x} = \boldsymbol{x}_0 + \Delta\boldsymbol{x}\,. \tag{1.7}$$

Depending on the closeness of the approximate ranges, $\boldsymbol{p}_0$, to the measurements, $\boldsymbol{p}$, several iterations are, in general, required to arrive at final values for $\boldsymbol{x}$.

### 1.2.3 Pseudorange Positioning

So far we assumed that the clock in the GNSS receiver was synchronized with the clocks in the satellites. This assumption, however, is fallacious. When a GNSS receiver is switched on, its clock will in general be mis-synchronized with respect to the satellite clocks, by an unknown amount. Furthermore, the clocks in the satellites are synchronized with each other and to a master time scale, called the system time, only to within about a millisecond. The range measurements the receiver makes are biased by the receiver and satellite clock errors, $dt_r$ and $dt^s$, and are therefore referred to as *pseudo*ranges

$$p_r^s = \rho_r^s + c\,(dt_r - dt^s)\,. \tag{1.8}$$

A timing error of a millisecond would result in an error in position of about 300 km, clearly an intolerable amount. It would be possible to better synchronize the satellite clocks by frequently sending them adjustment commands from the ground, but it has been found that clocks actually keep better time if they are left alone and the readings of the clock corrected. The GNSS operators monitor the satellite clocks and determine the offsets and drifts with respect to system time. These parameters are subsequently uploaded to the satellites and transmitted as part of a navigation message broadcast by the satellites. A GNSS receiver uses these satellite clock offset values to correct the measured pseudoranges.

However, we then still have the receiver clock error $dt_r$ to deal with. Because of this error, the three spheres with radii equal to the measured pseudoranges corrected for the satellite clock offsets will not intersect at a common point. But, if the receiver clock error $dt_r$, can be determined, then the pseudoranges can be corrected and the position of the receiver determined. The situation, compressed into two dimensions, is illustrated in Fig. 1.5.

So now we actually have four unknown quantities or parameters in our pseudorange observation equation

$$p_r^s = \rho_r^s + c dt_r\,. \tag{1.9}$$

They are the three coordinates of the receiver antenna position $(x_r, y_r, z_r)$ and the receiver clock offset $dt_r$.

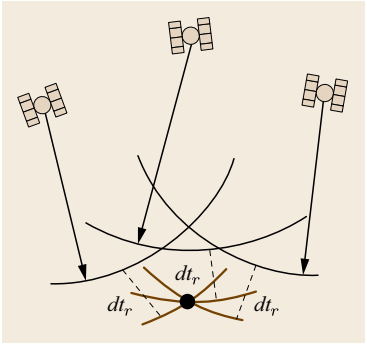

**Fig. 1.5** Determination of receiver clock offset $dt_r$ and true user position (intersection of *brown lines*) from the intersection of spheres centered on the satellites. Pseudoranges are shown by arcs of *black lines*

We thus need at least four simultaneous pseudoranges to estimate the three receiver coordinates and the receiver clock offset (measured in units of distance). With $\boldsymbol{x} = (x_r, y_r, z_r, dt_r)^\top$ and the four-by-four design matrix

$$\mathbf{A} = \begin{pmatrix} \frac{\partial \rho_r^1}{\partial x_r} & \frac{\partial \rho_r^1}{\partial y_r} & \frac{\partial \rho_r^1}{\partial z_r} & 1 \\ \frac{\partial \rho_r^2}{\partial x_r} & \frac{\partial \rho_r^2}{\partial y_r} & \frac{\partial \rho_r^2}{\partial z_r} & 1 \\ \frac{\partial \rho_r^3}{\partial x_r} & \frac{\partial \rho_r^3}{\partial y_r} & \frac{\partial \rho_r^3}{\partial z_r} & 1 \\ \frac{\partial \rho_r^4}{\partial x_r} & \frac{\partial \rho_r^4}{\partial y_r} & \frac{\partial \rho_r^4}{\partial z_r} & 1 \end{pmatrix} \tag{1.10}$$

the same iterative procedure as described before can then be applied.

What if signals from more than four satellites are available? Because of the unmodeled errors (e.g., atmospheric delays) as well as the residual errors in the modeled terms, it is beneficial to use simultaneous pseudoranges to all $m$ available satellites for estimating the receiver coordinates and clock offset. This requires use of a nonlinear least-squares (or related Kalman filter) estimation procedure (Chap. 22)

$$\Delta \boldsymbol{x} = (\mathbf{A}^\top \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^\top \mathbf{W} \Delta \boldsymbol{p} \,, \tag{1.11}$$

where $\mathbf{A}$ now has dimensions of $m \times 4$ and $\mathbf{W}$ is a weight matrix, which reflects the uncertainty in the observations and any correlations that may exist among them. This weight matrix may be written as

$$\mathbf{W} = \mathbf{Q}_{pp}^{-1} \,, \tag{1.12}$$

in which $\mathbf{Q}_{pp}$ is the covariance matrix of the pseudorange errors. In general, the solution of a nonlinear problem must be iterated to obtain the result. However, if the linearization point is sufficiently close to the true solution, then only one iteration is required (Chaps. 21 and 22). The processing of measurements can take place in real time within the receiver or the raw measurements can be stored for postprocessing by a standalone computer.

### 1.2.4 Precision of Position Solutions

The precision with which the receiver's coordinates and clock offset can be determined is described by the covariance matrix of the solution $\Delta \boldsymbol{x}$. This covariance matrix, denoted as $\mathbf{Q}_{xx}$, follows, with (1.12), from applying the error propagation law, also known as the variance propagation law, to (1.11) as

$$\begin{aligned} \mathbf{Q}_{xx} &= [(\mathbf{A}^\top \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^\top \mathbf{W}] \\ &\quad \cdot \mathbf{Q}_{pp} \cdot [(\mathbf{A}^\top \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^\top \mathbf{W}]^\top \\ &= (\mathbf{A}^\top \mathbf{Q}_{pp}^{-1} \mathbf{A})^{-1} \,. \end{aligned} \tag{1.13}$$

The diagonal elements of this matrix are the estimated receiver coordinate and clock-offset variances, and the off-diagonal elements (the covariances) indicate the degree to which these estimates are correlated. This equation represents a fundamental relationship widely used for actual measurement analysis as well as for experiment and system design studies. It allows one to examine the effect a particular design (through design matrix $\mathbf{A}$) or measurement capability (through measurement covariance matrix $\mathbf{Q}_{pp}$) will have on specified parameters without actually making any measurements.

In GNSS-related studies, for example, we might use the equation to answer a variety of questions:

- What is the behavior of the estimated parameter covariance matrix as a function of particular satellite configurations?
- How do various model errors propagate into the receiver coordinates as a function of satellite configurations?
- What is the tolerance value that a particular model error should not exceed to achieve a desired positioning accuracy?

#### User Equivalent Range Error

Such analyses simplify if we assume that the measurement and residual model errors are uncorrelated and the same for all observations with a particular standard deviation ($\sigma$). Then $\mathbf{Q}_{pp} = \sigma^2 \mathbf{I}_m$ (in which $\mathbf{I}_m$ is the identity matrix of order $m$) and the expression for the covariance matrix of $\boldsymbol{x}$ simplifies to

$$\mathbf{Q}_{xx} = \sigma^2 (\mathbf{A}^\top \mathbf{A})^{-1} \,. \tag{1.14}$$

When we combine satellite clock and ephemeris error, atmospheric error, receiver noise, and multipath – all expressed in units of distance – we obtain a quantity

known as the total *user equivalent range error* (UERE), which we can use for $\sigma$. UERE can further be divided into two parts [1.6], namely:

- The *signal-in-space (user) range error* (SISRE or SISURE), which comprises errors related to the space and control segment (primarily broadcast satellite orbit and clock errors), and
- The *user equipment error* (UEE), which includes the remaining contributions specific to the user's receiver and environment.

The total UERE can then be written as

$$\mathrm{UERE} = \sqrt{\mathrm{SISRE}^2 + \mathrm{UEE}^2}\,. \tag{1.15}$$

An overview of key contributions to the UERE budgets is provided in Table 1.1. The given values are mainly for illustration, since it is difficult to provide universally valid error bounds in most cases. Among others, UEE contributions may differ widely among individual receivers and sites. In the case of GPS single-frequency positioning, the total UERE is typically in the neighborhood of a few meters, with the actual value dominated by ionospheric and multipath effects [1.7]. Dual-frequency positioning, with the capability to remove almost all of the ionospheric delay from the pseudorange observations, can result in even smaller UEREs.

### Dilution of Precision

A simple scalar indicator of the overall quality of the least-squares solution is given by the square root of the sum of the parameter estimate variances

$$\begin{aligned}\sigma_\mathrm{G} &= \sqrt{\sigma_\mathrm{E}^2 + \sigma_\mathrm{N}^2 + \sigma_\mathrm{U}^2 + \sigma_{dt}^2} \\ &= \sigma\ \mathrm{tr}\,\{(\mathbf{A}^\top\mathbf{A})^{-1}\}\,,\end{aligned} \tag{1.16}$$

**Table 1.1** Representative magnitudes of individual contributions to the GNSS user equivalent range error (after [1.8–10]) for estimates of the individual contributions

| Error source | Contribution $1\sigma$ (m) |
|---|---|
| **SISRE** | |
| Broadcast satellite orbit | 0.2–1.0 |
| Broadcast satellite clock | 0.3–1.9 |
| Broadcast group delays | 0.0–0.2 |
| **UEE** | |
| Unmodeled ionospheric delay | 0–5 |
| Unmodeled tropospheric delay | 0.2 |
| Multipath | 0.2–1 |
| Receiver noise | 0.1–1 |
| **UERE** | **0.5–6** |

in which $\sigma_\mathrm{E}^2$, $\sigma_\mathrm{N}^2$, and $\sigma_\mathrm{U}^2$ are the variances of the east, north, and up components of the receiver position estimate, respectively, and $\sigma_{dt}^2$, is the variance of the estimated receiver clock offset. If the solution algorithm is parameterized in terms of geocentric Cartesian coordinates, it is a straightforward procedure to transform the solution variance matrix to the local coordinate frame to get the north, east, and up components.

The elements of matrix $\mathbf{A}^\top\mathbf{A}$ are a function of the receiver–satellite geometry and as the trace of its inverse is typically greater than 1, it amplifies $\sigma$, or dilutes the precision, of the position determination. This scaling factor is therefore usually called the geometric dilution of precision (GDOP). The GDOP becomes the position-DOP (PDOP), if one leaves out the contribution of the receiver clock, and it further reduces to the horizontal-DOP (HDOP), if one also leaves out the contribution of the up-component. In a likewise manner one can obtain the vertical-DOP (VDOP).

It turns out that DOP values depend on the volume of the polyhedron formed by the tips of the receiver–satellite unit vectors. The larger the volume, the smaller the DOPs. If the tips lie in a plane, the DOP factors are infinitely large. In fact, no position solution is possible with this receiver–satellite geometry as the matrix $\mathbf{A}^\top\mathbf{A}$ is singular: the solution cannot distinguish between an error in the receiver clock and an error in the position of the receiver. DOP values are smaller and hence solution errors are smaller when the satellites used in computing the solution are spread out in the sky.

High DOP values can sometimes occur even for all-in-view receivers operating at mid-latitudes. In some environments, such as heavily forested areas or urban canyons, a GNSS receiver's antenna may not have a clear view of the whole sky because of obstructions. If it can only receive GNSS signals from a small region of the sky, the DOPs will be large, and position accuracy will suffer. Being able to track more satellites can help in such situations, and a multi-GNSS receiver may provide acceptable accuracies. New receiver technology permitting use of weaker GPS signals, even those present inside buildings, will also be beneficial.

While DOP and UERE are highly useful concepts to understand GNSS positioning errors and their dependence on the geometric distribution of tracked satellites as well as individual pseudorange error sources, readers should keep in mind that the common rule-of-thumb

$$\text{Navigation error} = \mathrm{DOP} \times \mathrm{UERE} \tag{1.17}$$

is only a rough approximation and limited to random error propagation. Efforts to better account for system-

atic and random errors and to arrive at a more realistic description of real postioning errors are, for example, presented in [1.11].

### 1.2.5 GNSS Observation Equations

So far, we have been working with a rather simplified version of the pseudorange observation equation (1.8) and (1.9). In actuality, however, there are a number of additional error sources that must be taken into consideration and modeled in the observation equation. We therefore have to modify the pseudorange observation equation as follows

$$p_{\mathrm{r}}^{\mathrm{s}} = \rho_{\mathrm{r}}^{\mathrm{s}} + c(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + T_{\mathrm{r}}^{\mathrm{s}} + I_{\mathrm{r}}^{\mathrm{s}} + e_{\mathrm{r}}^{\mathrm{s}} \,. \tag{1.18}$$

Here, $dt_{\mathrm{r}}$ and $dt^{\mathrm{s}}$ are the receiver and satellite clock offset from GNSS system time as before, $T_{\mathrm{r}}^{\mathrm{s}}$ is the neutral atmosphere (troposphere) propagation delay, $I_{\mathrm{r}}^{\mathrm{s}}$ is the ionospheric propagation delay, and $e_{\mathrm{r}}^{\mathrm{s}}$ represents unmodeled errors including receiver noise, multipath, and other small effects (Chaps. 13–15). For a more detailed discussion of the basic pseudorange observation equation, see Chap. 19.

The carrier-phase observation equation is similar to the pseudorange equation

$$\varphi_{\mathrm{r}}^{\mathrm{s}} = \rho_{\mathrm{r}}^{\mathrm{s}} + c(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + T_{\mathrm{r}}^{\mathrm{s}} - I_{\mathrm{r}}^{\mathrm{s}} + \lambda M_{\mathrm{r}}^{\mathrm{s}} + \epsilon_{\mathrm{r}}^{\mathrm{s}} \,. \tag{1.19}$$

In addition to the previously defined terms, $\lambda$ is the carrier wavelength, $M_{\mathrm{r}}^{\mathrm{s}} = N_{\mathrm{r}}^{\mathrm{s}} + \delta_{\mathrm{r}} - \delta^{\mathrm{s}}$ is the sum of the integer carrier-phase ambiguity $N_{\mathrm{r}}^{\mathrm{s}}$ (in cycles) and the instrumental receiver and satellite phase delays $\delta_{\mathrm{r}} - \delta^{\mathrm{s}}$ (in cycles), $\epsilon_{\mathrm{r}}^{\mathrm{s}}$ represents unmodeled phase errors including receiver noise, multipath, and other small effects.

Several terms in the carrier-phase observation equation are nominally identical to those in the pseudorange observation equation, including the geometric range, receiver and satellite clock offsets, and the tropospheric propagation delay. The magnitude of the ionospheric term in both equations is the same, however its sign is negative in the carrier-phase equation. This relates to the fact that the phase of the carrier is advanced during the signal's passage through the ionosphere, as opposed to the pseudorange, which suffers a delay. And the ionospheric phase advance is frequency dependent like the pseudorange delay. For a more detailed discussion of the basic carrier-phase observation equation, see Chap. 19.

The receiver or postprocessing software will use the above forms of the observation equations to compute the receiver coordinates or any other relevant GNSS parameters. Models exist for describing the neutral atmosphere propagation delay, and the ionospheric propagation delay can be corrected using the coefficients of a model included in the broadcast navigation message or by combining simultaneous pseudorange or carrier-phase measurements made on two transmitted frequencies (Chaps. 38 and 39).

## 1.3 Modeling the Observations

To accurately determine the receiver coordinates or any other relevant GNSS parameters, we must model the right-hand sides of the observation equations (1.18) and (1.19) to match as accurately as possible the receiver's observations of the satellites. This requires knowledge of the satellites' positions at the time of signal transmission, the offset of their clocks, the atmospheric propagation delays, ambiguities for the carrier-phase observations, plus perhaps some smaller contributions such as instrumental delays. If the available information is not sufficiently accurate, we may be able to estimate residual effects from the observations themselves and so better match the right-hand and left-hand sides of the equations.

In the next few sections, we will overview some of the information required for a receiver or external software to process GNSS observations. More detailed descriptions are provided in subsequent chapters of the Handbook.

### 1.3.1 Satellite Orbit and Clock Information

The predicted position of a satellite's antenna phase center can be derived from the Keplerian-like orbit parameters given in the broadcast navigation message. The predicted offset of the active satellite clock from system time is also derived from the navigation message. The combined accuracy of these terms, SISRE, is typically 0.5–2 m for current global and regional navigation satellite systems. For GPS, the Global Positioning Systems Directorate has reported that the annual root-mean-square signal-in-space range error (SISRE) across all healthy satellites dropped from 1.6 m in 2001 to 0.7 m in 2014 [1.12] and further improvement has been made after replacing the old Block IIA satellites with the latest generation of Block IIF satellites in early 2016. SISRE values of about 0.5 m can also be expected for Galileo based on the performance of the preoperational constellation in the 2015/2016 timeframe. The

performance of GLONASS, the second fully operational GNSS, is presently about three times worse but likewise expected to improve with the ongoing modernization of the space and ground segments.

Significantly more accurate satellite orbit and clock information is available from various sources, such as satellite-based augmentations systems, the international GNSS service, and private service providers, for both real-time and postprocessing applications (Chaps. 3, 33, and 34).

### 1.3.2 Atmospheric Propagation Delay

GNSS signals travel through the Earth's atmosphere to receivers on or near the ground (Chap. 6). The signals are refracted, changing their velocity – both speed and direction of travel. Measured pseudoranges and carrier phases are biased by meters to tens of meters. The biases are determined by the integrated effect of the refractive index – the ratio of the speed of propagation of an electromagnetic wave in a vacuum to that in a medium – all along the signal raypath. In general, the refractive index will be a function of the characteristics of the medium including the type and densities of the medium's constituents as well as the frequency of the wave and possibly external factors such as ambient magnetic fields.

The atmospheric propagation delays can be separated into those due to the electrically neutral atmosphere and those due to the ionosphere (Fig. 1.6).

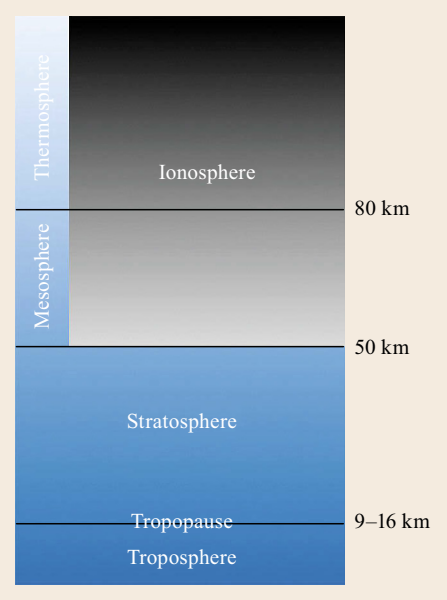

**Fig. 1.6** Structure of the Earth's atmosphere

#### Neutral Atmosphere

The neutral atmosphere is that part of the atmosphere that is electrically neutral and stretches from ground level up to a height of 50 km and beyond (Chap. 6). It is what we colloquially refer to as the air. Air is made up of nitrogen, oxygen, carbon dioxide, as well as some other atoms and molecules including water vapor. With the inclusion of water vapor, we refer to the medium as moist air. The refractive index $n$ of a parcel of moist air is a function of its temperature, the partial pressures $P_\mathrm{d}$ of the dry constituents (nitrogen, oxygen, etc.) and the partial pressure $e$ of water vapor

$$n = n(T, P_\mathrm{d}, e) \; . \tag{1.20}$$

Note that air is essentially a nondispersive medium, with $n$ independent of frequency throughout most of the radio spectrum and including the frequencies used by all GNSSs. This also means that the effect on pseudoranges is identical to that on carrier-phase measurements.

At sea level, values of the refractive index of air are close to 1.0003, becoming smaller with increasing height. A more useful quantity is refractivity, $N = 10^6(n-1)$, with sea level values near 300. Since the bulk of the neutral atmospheric effect occurs in the lowest-most part of the atmosphere – the troposphere – the effect is often termed the tropospheric propagation delay.

How much delay is imparted to a GNSS signal by the neutral atmosphere? This depends on the location and height of the receiver as well as weather conditions and also the elevation angle (and, to a lesser degree, azimuth) at which the signal arrives at the receiver. The total delay experienced by the received signal is referred to as the slant delay. It is modeled by mapping the delay of a hypothetical signal arriving from directly overhead – the zenith direction – to the actual signal slant path using a mapping function (also called an obliquity factor). Typically, at sea level, zenith delay is about 2.4 m, rising to more than 24 m at an elevation angle of 5°.

Various neutral atmosphere delay models exist. Many receivers use the Radio Technical Commission for Aeronautics (RTCA) MOPS (Minimum Operational Performance Standards model) [1.13] (a slightly simplified version of the University of New Brunswick's UNB3 model, the predecessor to UNB3m [1.14, 15]) mandated for use by satellite-based augmentation system (SBAS) user equipment. Several more sophisticated models exist (Chap. 6). No model is perfect, though, and there is some advantage in estimating residual delays from the GNSS data itself.

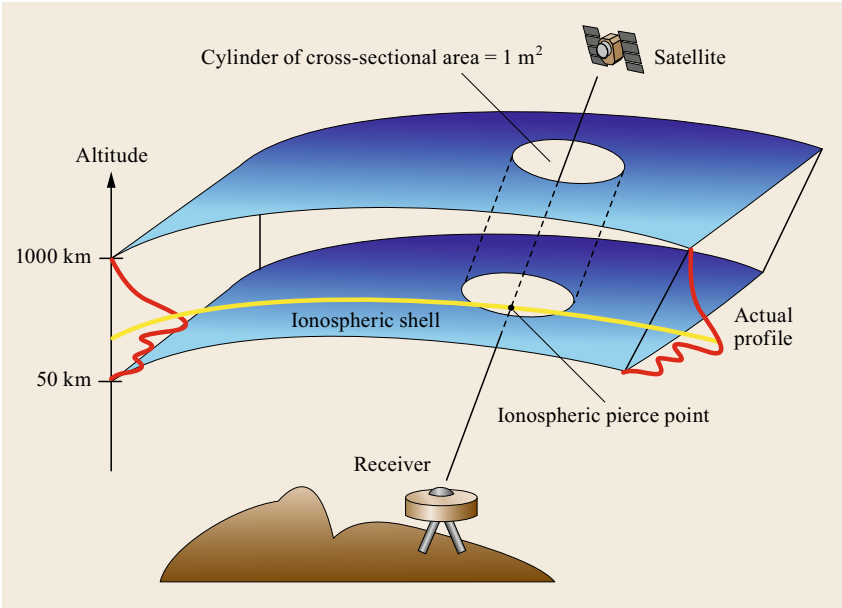

**Fig. 1.7** The thin-shell approximation of the ionosphere (after [1.16])

### Ionosphere

The ionosphere is that region of the Earth's atmosphere in which ionizing radiation (principally from solar extreme ultraviolet (EUV) and x-ray emissions) cause electrons to exist in sufficient quantities to affect the propagation of radio waves (Sect. 6.3). It extends from about 50–1000 km or more, above which we have the plasmasphere (also known as the protonosphere).

The ionosphere is a dispersive medium for radio waves: the refractive index is a function of frequency. It also means that pseudorange and carrier-phase observations are affected differently, with a phase refractive index and a pseudorange (group delay) refractive index. This results in an ionospheric delay for pseudoranges (increased value) and an ionospheric phase advance for carrier-phase measurements (decreased value). In addition to the radio frequency of the signal, the refractive indices are a function of electron density. The Earth's magnetic field also plays a minor role.

Again, it is the integrated effect of ionospheric refractive index all along the raypath that determines the pseudorange delay and the carrier-phase advance. It turns out that, to first order, the magnitudes of the pseudorange delay and the carrier-phase advance are the same; they just differ in sign. To an excellent approximation, the magnitude, $I$, in m is given by

$$I = 40.3\frac{\mathrm{TEC}}{f^2}\,, \tag{1.21}$$

where TEC is the total electron content and is the total number of electrons in a column of one-meter-square cross-section centered on the signal raypath and stretching from the receiver to the satellite. In this equation, TEC is given in electrons/m$^2$, and the frequency, $f$, is given in Hz. Typical TEC values measured near the Earth's surface range from about $10^{16}$ to $10^{19}$ with the actual value depending on geographic location, local time, season, solar EUV flux, and magnetic activity. And, as with neutral atmosphere delays, we have slant and zenith delays, corresponding to slant and zenith TEC.

Since the ionospheric effect is to a very good approximation inversely proportional to the square of the frequency, by linearly combining simultaneous measurements (either pseudoranges or carrier phases) on two frequencies such as the GPS L1 and L2 frequencies, an observable virtually free of ionospheric effects can be constructed and used for position determinations (Sect. 20.2.3). This approach does require, however, a dual- or multifrequency receiver.

If only single-frequency observations are available, then the sum of the pseudorange and phase measurement can be taken to eliminate the ionospheric delay, or alternatively a model can be used to account for the ionospheric biases as much as possible. The GPS navigation message includes values of the parameters of a simple ionospheric model known as the broadcast or *Klobuchar* model [1.17], named after its developer *Jack Klobuchar*. This model permits an estimate of the zenith ionospheric delay to be computed at a receiver's location at a particular time of day and is driven by recent solar conditions as interpreted by the GPS control

segment. The zenith delay is then mapped into a slant delay assuming a thin shell model for the ionosphere, where all of the electron content is assumed to occur in a shell at a particular height above the Earth's surface (Fig. 1.7). The broadcast model assumes a shell height of 350 km.

A Klobuchar-like model is also used within the BeiDou system, while a version of the NeQuick model [1.18] has been selected as an alternative for the Galileo system. NeQuick describes the 3-dimensional electron density distribution as a function of a small set of ionospheric activity parameters provided in the navigation message and an extensive set of static, seasonal coefficients. The ionospheric slant delay is then obtained by integrating the electron density along the ray path between satellite and receiver. While computationally more demanding, the NeQuick model requires a smaller set of broadcast parameters and achieves an improved overall correction performance compared to the GPS Klobuchar model [1.10].

## 1.4 Positioning Modes

There are a variety of GNSS positioning (and navigation) modes of differing degrees of complexity and precision and accuracy. These range from the standard single-frequency pseudorange-based approach used by most consumer receivers including those in mobile phones to high-integrity methods for safety-of-life applications to sophisticated multifrequency carrier-phase-based techniques capable of centimeter to subcentimeter accuracies for demanding applications like machine control and scientific studies. In this section, we will briefly outline some of the approaches with deeper discussions appearing in later chapters (Chaps. 21, 23, 26, and 35).

### 1.4.1 Precise Point Positioning

Precise point positioning (PPP) is an advanced version of the single-point positioning (SPP) technique that we discussed earlier. PPP (Chap. 25) uses carrier-phase measurements as the primary observable with pseudorange measurements playing a secondary role. The PPP processing algorithm is similar to that for pseudorange-measurement positioning, except that effects down to the centimeter-level and lower must be modeled or estimated. This means that satellite constellation precise orbits and clock offsets (Chap. 34) must be used such as those provided by the International GNSS Service (IGS). Typically, a dual-frequency GNSS receiver is used with dual-frequency code and phase measurements linearly combined to remove first-order ionospheric effects. The carrier-phase ambiguities are estimated (resolving them to integer values if possible) as well as residual tropospheric propagation delay after applying an a priori model. Subtle effects, such as Earth tides, ocean tide loading, satellite and receiver antenna offsets, and carrier-phase windup are also modeled.

The performance of PPP can be measured in terms of accuracy, precision, convergence period (the time required for a position solution to converge below a certain accuracy threshold), availability, and integrity. Best effort PPP is generally bias free, so there is little difference between accuracy and precision statistics. PPP can provide few-centimeter-level 1-sigma accuracies in each coordinate (north, east, and up) for a static site after convergence whereas decimeter-level accuracies can be achieved for a moving platform or a static site with data processed in *kinematic mode* (independent epoch-by-epoch position fixes). Accuracies, although good, may not be sufficient for some applications. The convergence period for achieving a decimeter-level solution is typically up to about 30 min under normal conditions with some newer procedures (multifrequency, multiconstellation) achieving convergence periods of 20 min or less. Continuous availability of accurate PPP fixes depends on the environment. Signal blockages by trees and buildings can reduce availability but multiconstellation observations can be a big help in this regard. Integrity measures for PPP are currently limited.

PPP can be used for processing data from either static (stationary) sites or kinematic (moving) platforms

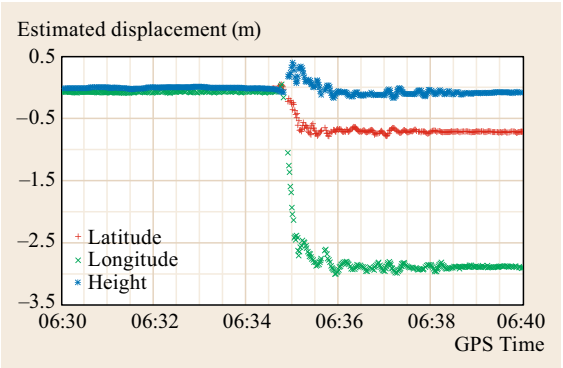

**Fig. 1.8** Estimate of co-seismic displacement at IGS station CONZ following the 8.8 magnitude Chilean earthquake of 27 February 2010 (after [1.19])

and its uses include establishing and updating reference-station coordinates for crustal-deformation monitoring (Fig. 1.8), precise orbit determination of low-Earth-orbiting satellites, ocean buoy positioning for tsunami detection with main commercial applications in precision farming, seafloor mapping, marine construction, and airborne mapping. Application of PPP is expanding to atmosphere remote sensing, precise time transfer, land surveying, construction, and military uses.

### 1.4.2 Code Differential Positioning

The advantage of differential positioning (Chap. 26) over SPP is that with differential techniques certain effects are eliminated or largely reduced (e.g., orbit errors and atmospheric delays with dependence on the spatial correlation). There are two basic kinds of code differential positioning: measurement domain (typically covering a local/regional area and known as differential GPS/GNSS or DGPS/DGNSS) and state-space domain (typically covering a wide area and known as wide-area GPS/GNSS or WADGPS/WADGNSS). The best example of a measurement-domain DGPS is that implemented by coast guard agencies around the world for maritime navigation (Sect. 29.4). The best example of state-space-domain DGPS is that of SBASs, the first of which was the US Federal Aviation Administration's (FAA's) Wide Area Augmentation System (WAAS). SBAS is discussed in Sect. 1.5 and in detail in Chap. 12.

The measurement domain techniques provide composite measurement corrections to the user without estimating individual error components whereas state-space domain techniques provide individual error corrections such as satellite orbit and clock and ionospheric propagation delay. These corrections are determined at reference stations and transmitted to users using radio beacons.

The combined corrections account for navigation message satellite orbit and clock error, tropospheric propagation delay, ionospheric propagation delay and, in the past, GPS Selective Availability. A user requires a GNSS receiver with an integrated beacon receiver or a separate beacon receiver connected to the GNSS receiver by a serial communications link such as RS-232. The corrections are datum dependent. In North America, user-computed positions will be in the North American Datum (NAD) 83 system, not WGS 84.

Position accuracy generally degrades with increasing distance from the beacon transmitter site. Official accuracy is stated as 10 m (horizontal at 95%) within the coverage area but typically, the error of a DGPS position is 1–3 m. Accuracy will be affected by user multipath and DOP. The error is often seen as a bias in positioning, resulting in a position offset. The scatter of the coordinates is likely to remain close to constant. A general rule of thumb is an additional 1 m error per 100 km. However, accuracy is worse during strong ionospheric disturbances due to gradients.

### 1.4.3 Differential Carrier Phase

Differential carrier-phase positioning is a classic technique dating to the early 1980s. The procedure combines data from one (or more) reference stations with user data (Chap. 26). Observations on the same satellite at the same epoch are differenced between receivers (single difference) and then single differences are differenced between pairs of satellites (double difference). This procedure eliminates residual satellite and receiver clock errors, and reduces satellite orbit error and atmospheric propagation delay errors (Chap. 20). Accuracies at the decimeter level and better can be obtained. In principle, a similar approach could be taken using pseudoranges (alone) but with much lower resulting accuracies. See Chap. 26 for a more detailed description.

#### Single Differencing

Let us take a look at the differencing operations in detail starting with single differencing. Differencing carrier-phase measurements on one satellite $s$ from two receivers, 1 and 2, gives us

$$\varphi_{12}^{s} = \rho_{12}^{s} + cdt_{12} + T_{12}^{s} - I_{12}^{s} + \lambda M_{12}^{s} + \epsilon_{12}^{s} \,, \qquad (1.22)$$

where $\varphi_{12}^{s} = \varphi_{2}^{s} - \varphi_{1}^{s}$ is the between-receiver single-difference carrier phase, with a similar notational convention for the terms on the right-hand side (1.22). Note that the satellite clock error has disappeared because it is identical for both receivers. Likewise, the satellite phase bias disappeared from $M_{12}^{s} = \delta_{12} + N_{12}^{s}$.

Differencing measurements made on two satellites, $s$ and $t$, with receiver 1 gives us

$$\varphi_{1}^{st} = \rho_{1}^{st} + cdt^{st} + T_{1}^{st} - I_{1}^{st} + \lambda M_{1}^{st} + \epsilon_{1}^{st} \,, \qquad (1.23)$$

where $\varphi_{1}^{st} = \varphi_{1}^{t} - \varphi_{1}^{s}$ is the between-satellite single-difference carrier phase. Note that the receiver clock error has disappeared because it is identical for measurements made on all satellites at the same epoch. Likewise, the receiver phase bias disappeared from $M_{1}^{st} = \delta^{st} + N_{1}^{st}$.

#### Double Differencing

If we difference carrier-phase measurements between receivers and then difference the resulting values between satellites, we have the double-difference observ-

able

$$\varphi_{12}^{st} = \rho_{12}^{st} + T_{12}^{st} - I_{12}^{st} + \lambda N_{12}^{st} + \epsilon_{12}^{st} \,, \tag{1.24}$$

where $\varphi_{12}^{st} = \varphi_2^{st} - \varphi_1^{st} = \varphi_{12}^{t} - \varphi_{12}^{s}$. Note that both receiver and satellite clock error have disappeared as well as the corresponding instrumental phase biases. As a result, the real valued parameters, $M_{12}^{s}$ in (1.22) and $M_1^{st}$ in (1.23), have been replaced by the integer parameter $N_{12}^{st}$ in (1.24).

In processing double differences (between a pair of receivers and a pair of satellites), we must model the double-difference geometric range, the double-difference tropospheric delay, the double-difference ionospheric effect (which can be neglected in case of sufficiently short baselines), and the double-difference phase ambiguity, here now an integer. Least squares or a Kalman filter approach is used to estimate the coordinates of the user receiver along with the *nuisance* parameters in a similar approach to that used for processing undifferenced pseudorange or carrier-phase observations. Redundancy in the system of observation equations is used to check the validity of the assumed models (Chaps. 22 and 24).

The integer ambiguities $N_{12}^{st}$ for all satellite pairs in an observation set are estimated together with the coordinates of the user receiver and (optionally) a residual tropospheric delay error. The ambiguities are initially estimated as floating-point numbers (the so-called *float solution*); procedures are available for fixing some or all of the ambiguities at their correct integer values (the so-called *fixed solution*) (Chap. 23). Successful ambiguity resolution depends on several factors including baseline length (shorter is better), the number of satellites in view (more is better), continuous tracking of satellites, low dilution of precision values, the degree of multipath (less is better), the number of frequencies observed (two are better than one), and length of observing session (longer is better). With modern receivers and techniques, ambiguity resolution can be carried out with just a few tens of seconds of observations, even if the user receiver is in motion (*on the fly*). Fixed solutions generally provide more accurate results. A common ambiguity fixing technique is LAMBDA (Least-squares Ambiguity Decorrelation Adjustment) [1.20] (Chap. 23).

### Real-Time Kinematic Positioning

In real-time kinematic (RTK) positioning, a GNSS reference station transmits carrier-phase and pseudorange data over a radio link to a roving station. Either single- or dual-frequency GNSS receivers can be used, with the dual-frequency systems typically affording faster ambiguity resolution and higher positioning accuracies over longer distances. The receivers must incorporate data radios (or be wired to external radios), typically operating in the very high frequency (VHF, 30–300 MHz) or ultrahigh frequency (UHF, 300 MHz and 3 GHz) parts of the radio spectrum. The reference station transmits pseudorange and carrier-phase measurements and ancillary data. Radio Technical Commission for Maritime Services (RTCM) SC-104 2.x or 3.x [1.21] data protocols are typically used although proprietary data formats also exist.

Transmission modes vary and include narrowband frequency modulation (FM) with frequency-shift-keying and packetized data transmission. Both 2 and 35 W transmitters are commonly available and for these licensing is typically required. However, license-free, low-power transmitters can also be used. In any case, VHF/UHF data links are limited to line of sight and transmitting and receiving antennas should be as high as possible. The maximum theoretical range is given by [1.22, 23]

$$d(\mathrm{km}) = 3.57\sqrt{k}\left[\sqrt{h_\mathrm{t}(\mathrm{m})} + \sqrt{h_\mathrm{r}(\mathrm{m})}\right]. \tag{1.25}$$

with $h_\mathrm{t}$ and $h_\mathrm{r}$ the height of transmitter and receiver, respectively, and where $k$ varies with refractivity (typically between 1.2 and 1.6); for example, for a transmitting antenna at 30 m above the terrain and a receiving antenna at 2 m, the maximum range is 28 km. Any obstructions along the propagation path will affect the signal's range. Whether or not a received signal can be successfully used depends on several factors including receiver sensitivity.

Reference station data can also be transmitted via the Internet using, e.g., the Network Transportation of RTCM Internet Protocol (NTRIP; [1.24]) and accessed by a hardwire or wireless link such as a mobile phone.

To reduce latency effects, transmission protocols typically use data differences with reconstruction of reference station data at the rover. Cycle slips must be detected and corrected in real time and ambiguities must be resolved quickly, even if the receiver is in motion (*on the fly*). Several techniques exist. Use of GLONASS data in addition to GPS data can result in greater availability, faster ambiguity fixing, and higher positioning accuracies.

PPP–RTK, a combination or merging of PPP with state-space RTK can have significant advantages in ambiguity resolution, in convergence time, and in accuracy and practical systems have been implemented by industry and research organizations (Chaps. 25 and 26). All individual GNSS error components, derived from the RTK monitoring network, are determined and delivered using state-space representation (SSR). These include orbits, clocks, code (pseudorange) biases, ionosphere

(for single-frequency receivers), troposphere, and carrier-phase biases. In principle, the concept can be applied to small, regional, and global networks. RTCM and IGS have active committees developing standards for PPP–RTK and real-time PPP for delivering prototype research and commercial services.

## 1.5 Current and Developing GNSSs

GNSSs and regional navigation satellite systems (RNSSs) commonly consist of three components:

- The *space segment* comprises a constellation of satellites orbiting above the Earth's surface that transmit ranging signals on at least two frequencies in the microwave part of the radio spectrum.
- The *control segment* is responsible for maintaining the health of the system by monitoring the broadcast signals and computing and uploading to the satellites required navigation data. It consists of a group of globally (or locally)-dispersed monitoring stations, ground antennas for communicating with the satellites, and a master control station with a backup facility at a different location.
- The *user segment* consists of GNSS receiving equipment both civil and military. This includes receivers on the ground, at sea, in the air, and even in space.

GNSS constellations typically adopt a specific orbital configuration: MEO (medium-altitude Earth orbit) satellites for global coverage; IGSOs (inclined geosynchronous orbits) and GEOs (geostationary orbits) as supplements in regional systems.

MEO satellites are often evenly distributed in inclined near-circular orbits overequally spaced orbital planes, forming a constellation known as a *Walker* constellation [1.25]. The geometry of a specific Walker constellation is described by the triplet $t/p/f$, where $t$ denotes the total number of satellites, $p$ the number of equally spaced planes, and $f$ the phase difference between the adjacent orbital planes. To determine the angle between satellites in adjacent planes, the parameter $f$ should be multiplied by $360°/t$. A simple Walker constellation of eight satellites in two orbital planes is illustrated in Fig. 1.9.

Currently, there are six GNSSs/RNSSs in operation. The four GNSSs are: GPS (US), GLONASS (Russia), BeiDou (China), and Galileo (EU); and the two RNSSs: QZSS (Japan) and IRNSS/NavIC (India). For an overview summary, see Table 1.2.

### 1.5.1 Global Navigation Satellite Systems

#### GPS

The Global Positioning System (GPS; Chap. 7) is the US GNSS, which provides free positioning and timing services worldwide. It was originally developed for the US military and was made free for civilian purposes very early in the experimental phase of GPS. The launch of the first Block I Navstar GPS satellite occurred on 22 February 1978, followed by the declaration of the Initial Operating Capability in December 1993 with 24 operational satellites in orbit, and the Full Operational Capability in June1995. GPS is maintained by the US government and is freely accessible by anyone with a GPS receiver. GPS provides two different positioning services: the Precise Positioning Service (PPS) on the GPS L1 (1575.42 MHz) and L2 (1227.6 MHz) frequencies both containing an encrypted precision (P) code ranging signal (known as the Y-code) with a navigation data message for authorized users, and the Standard Positioning Service (SPS) on the GPS L1 frequency containing a coarse/acquisition (C/A) code and a navigation data message for civilian users. The GPS modernization program began in 2005 with the launch of the first IIR-M satellite. Since that moment on, two new signals have been transmitted: L2C for civilian users and a new military signal (M-code) at the L1 and L2 frequencies to provide better jamming resistance than the Y-code. Moreover, a new radio frequency link L5 (1176.45 MHz) for civilian users has been introduced. This signal, available since

the launch of the Block IIF satellites (beginning in May 2010) will be interoperable with that of Galileo, QZSS, and IRNSS/NavIC.

### GLONASS

The former Soviet Union developed the *Global'naya Navigatsionnaya Sputnikovaya Sistema* or GLONASS (Chap. 8). The first GLONASS satellite was launched on 12 October 1982. By early 1996, a fully operational constellation of 24 satellites was in orbit. Unfortunately, the full constellation was short lived. Russia's economic difficulties following the dismantling of the Soviet Union hurt GLONASS. By 2002 the constellation had dropped to as few as seven satellites, with only six available during maintenance operations. With support of the Russian government, GLONASS was reborn, and on 8 December 2011, full operational capability (FOC) was again achieved and has been subsequently maintained.

The GLONASS satellites are categorized into three different generations: first generation GLONASS I/II (started in 1982), second generation GLONASS-M (started in 2003), and third generation GLONASS-K (started in 2011). All GLONASS satellites launched since December 2005 have been GLONASS-M satellites with the exception of two GLONASS-K1 satellites, launched on 26 February 2011 and 30 November 2014. GLONASS uses frequency division multiple access (FDMA) for its signals. Originally, the system transmitted the signals within two bands: Ll, 1602–1615.5 MHz, and L2, 1246–1256.5 MHz, at frequencies spaced by 0.5625 MHz at L1 and by 0.4375 MHz at L2. GLONASS-K satellites include, for the first time, code division multiple access (CDMA) signals accompanying the legacy FDMA signals. GLONASS-K1 as well as the latest GLONASS-M satellites transmit a CDMA signal on a new L3 frequency (1202.025 MHz).

### Galileo

The Galileo system (Chap. 9) is a joint initiative of the European Commission (EC) and the European Space Agency (ESA). The first two In-orbit Validation (IOV) satellites were launched on 21 October 2011, and the

third and fourth IOV satellites were launched on 12 October 2012. The first two full-operational-capability satellites, were launched on 22 August 2014, into wrong orbits due to an upper rocket stage anomaly. Up to the end of 2015, six further satellites have been launched. In all, when the constellation is fully developed, there will be 30 Galileo satellites with 24 designated as primary and six spares.

Galileo satellites transmit three levels of service in three frequency bands using CDMA. The Open Service (OS) and the Public Regulated Service (PRS) are transmitted in the E1 frequency band centered on 1575.46 MHz (the same as the GPS L1 frequency) and the PRN ranging codes are modulated onto the carrier using binary offset carrier (BOC) techniques with each satellite, like GPS, assigned separate codes. The Commercial Service (CS) signal and the PRS are transmitted in the E6 frequency band centered on 1278.75 MHz using binary phase-shift keying (BPSK) and BOC modulation, respectively. Data and data-less (pilot) signals are transmitted in the E5 frequency band centered on 1191.795 MHz using BOC modulation. Data and pilot signals are also available on E1 and E6. The signals are separated into an E5a and an E5b component and either can be tracked separately or together. The various signals also contain navigation messages supplying the necessary information for acquiring Galileo signals and for determining receiver positions and time.

#### BeiDou

China fielded a demonstration regional satellite-based navigation system known as BeiDou (Chinese for the *Big Dipper* asterism and pronounced *bay-dough*) following a program of research and development that began in 1980 (Chap. 10). The initial constellation of three GEO satellites was completed in 2003. A fourth GEO satellite was launched in 2007. The initial regional BeiDou system (BeiDou-1) has been replaced by a global system known as BeiDou-2 (or simply BeiDou and formerly known as Compass). The BeiDou Navigation Satellite System (BDS) as it is officially now known will eventually include five GEO satellites, 27 MEO satellites, and five IGSO satellites. BeiDou-2 was declared operational for use in China and surrounding areas on 27 December 2011. FOC for this area was declared on 27 December 2012. The system will provide global coverage by 2020. As of February 2016, 21 BeiDou satellites have been launched. Some of the BeiDou satellites launched from 30 March 2015 onward are a new version termed BeiDou Phase 3 or simply BeiDou-3.

The satellites transmit two levels of service, an open service and an authorized service primarily for the Chinese government and military using three frequency bands. The bands and the central frequencies for the satellites now in use, the BeiDou-2 satellites, are B1 at 1561.098 MHz, B2 at 1207.14 MHz, and B3 at 1268.52 MHz. BeiDou-3 will transmit modernized signals in the L1/E1 and L5/E5 bands as well as the BeiDou B3 band. For compatibility it is also foreseen that they will transmit the B1 open service signal of the BeiDou-2 system.

### 1.5.2 Regional Navigation Satellite Systems

#### QZSS

The Quasi-Zenith Satellite System (QZSS; Chap. 11) will use multiple satellites in inclined orbits, placed so that one satellite always appears near zenith above Japan, well known for its high-rise cities where the signals from GPS satellites can be easily blocked. The design provides high-accuracy satellite positioning service covering almost all of the country, including urban canyons and mountainous terrain. The IGSO satellites will be supplemented with one GEO satellite. The start of full QZSS service is planned for 2018. QZSS Phase One is validating technological enhancement of GPS availability, performance, and application using the first QZSS satellite, Michibiki. Michibiki was launched on 11 September 2010 and is in full operation. Phase Two will demonstrate full system capability using at least three QZSS satellites, including Michibiki. Future plans call for a seven-satellite constellation.

The satellites will generate and transmit their own signals, compatible with modernized GPS signals. QZSS also transmits GPS corrections and availability data, the L1-SAIF (Submeter-class Augmentation with Integrity Function) signal, and so is also considered as a satellite-based augmentation system satellite. Altogether, Michibiki transmits six signals with structures similar to and compatible with GPS and Galileo signals: L1-C/A (1575.42 MHz), L1C (1575.42 MHz); L2C (1227.6 MHz), L5 (1176.45 MHz), L1-SAIF 1575.42 MHz), and LEX (L-band Experiment, 1278.75 MHz) a QZSS experimental signal for a high precision (3 cm level) service, sharing the frequency of the Galileo E6 signal.

#### IRNSS/NavIC

The Indian government has developed the Indian Regional Navigation Satellite System (IRNSS) as an independent system serving India and the surrounding area (Chap. 11). In April 2016, IRNSS was renamed to NavIC, a Hindi word for sailor or navigator as well as an acronym for *Navigation with Indian Constellation*. The area of coverage is from 30° south to 50° north in latitude and 30° east to 130° east in longi-

**Table 1.3** An overview of the SBASs

| System | WAAS | SDCM | EGNOS | MSAS | GAGAN |
|---|---|---|---|---|---|

| Nominal number of satellites | 3 | 3 | 4 | 1 | 3 |
| Longitudes | 133° W, 107° W, 98° W | 16° W, 95° E, 167° E | 15.5° W, 5° E, 25° E, 31.5° E | 145° E | 55° E, 83° E, 93.5° E |
| Date of being operational | July 2003 | – | October 2009 | September 2007 | February 2014 |
| Origin | USA | Russia | Europe | Japan | India |
| Service area | CONUS, Alaska, Canada, Mexico | Russia | Europe | Japan | India |
| Frequency (MHz) | L1 1575.42<br>L5 1176.45 | L1 1575.42 | L1 1575.42<br>L5 1176.45 | L1 1575.42 | L1 1575.42<br>L5 1176.45 |

tude. IRNSS provide two types of service: the SPS, which is an open service for all users, and the Restricted Service (RS), which is an encrypted service available only to authorised users. IRNSS is expected to provide a real-time pseudorange-based position accuracy of better than 20 m in the primary service area. The IRNSS constellation consists of three GEO satellites as well as two pairs of IGSO satellites.

The first satellite in the constellation, an IGSO satellite, IRNSS-1A, was launched on 1 July 2013. The second IGSO satellite, IRNSS-1B, was launched on 4 April 2014. The first GEO satellite, IRNSS-1C, was launched on 15 October 2014. IRNSS-1D, the third IGSO satellite, was launched on 28 March 2015. The constellation was completed by launches of IRNSS-1E, 1F, and 1G in 2016. The satellites transmit navigation signals at 1176.45 and 2492.028 MHz in the L- and S-bands respectively. The SPS and RS are transmitted on both frequencies. The SPS uses BPSK modulation while the RS uses BOC modulation with data and pilot channels.

### 1.5.3 Satellite-Based Augmentation Systems

In addition to the GNSS/RNSSs, there are also SBASs, which use geostationary communications satellites to provide differential correction data and integrity information to GNSS users in real time using a *bent path* from a ground station through the satellite to a user's equipment. The systems use a state-space-domain approach in which corrections for GNSS satellite orbit and clock data along with ionospheric propagation delays are provided.

Currently, four SBASs are in full operation: the FAA's WAAS, the European Geostationary Navigation Overlay Service (EGNOS), Japan's Multifunctional Transport Satellite (MTSAT) Satellite-based Augmentation System (MSAS), and India's GPS-aided GEO Augmented Navigation System (GAGAN). In addition, Japan's Quasi-Zenith Satellite System has an augmentation component as already mentioned. Russia's System for Differential Correction and Monitoring (SDCM) is currently in development. See Table 1.3 for an overview and Chap. 12 for a detailed description of SBASs.

## 1.6 GNSS for Science and Society at Large

GNSS is used for many types of applications, covering the mass market, professional and safety-critical applications as well as a whole range of scientific applications (Chaps. 29, 30, and 32). There are therefore literally hundreds of applications of GNSS, from the everyday to the exotic. And with the advent of next generation GNSSs, many more applications are expected to emerge.

According to a recent market study [1.26], the global GNSS market is expected to grow from roughly 50B Euros in 2013 to more than 100B Euros in 2023, when considering only the core revenue, i. e., the value of the chipsets sold. Enabled revenues covering the entire end-user equipment are projected to even grow from 200B Euros to almost 300B Euros in the same period. As illustrated in Fig. 1.10, the GNSS market is clearly

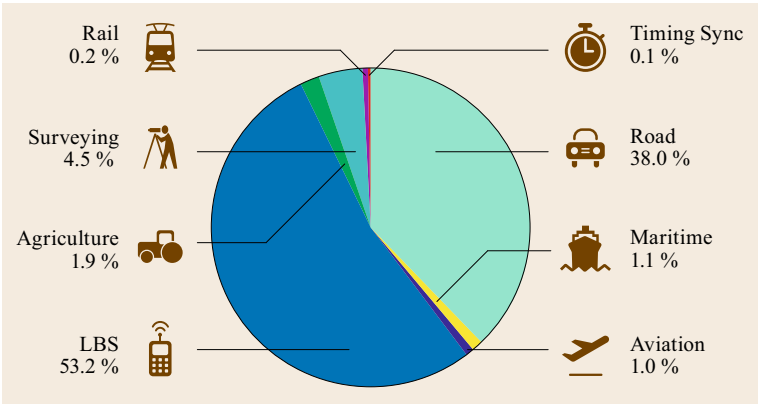

**Fig. 1.10** Distribution of cumulative global revenue from GNSS chipset sales projected for the 2013–2023 period (after [1.26], courtesy of European GNSS Agency)

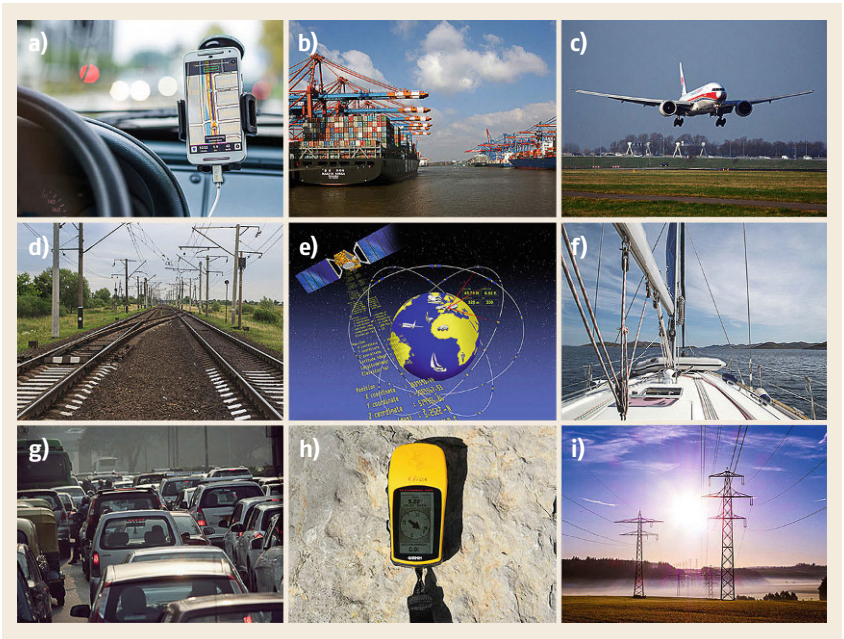

**Fig. 1.11a–i** Examples of everyday GNSS applications; from car navigation, to the landing of aircraft, to electrical power grid maintenance. (Photos courtesy of pixabay.com **(a–d)**, **(f–i)** and ESA, J. Huart **(e)**)

dominated by personal navigation devices (covered by location based services, LBS) and in-car navigation systems, which constitute more than 90% of the global core revenue. High-precision and specialized GNSS equipment for surveying and agriculture as well as maritime and aviation use, in contrast, contributes less than 10% of the overall chipset sales.

By far the most common use of GNSS is for navigation, which includes navigation for people who are hiking and geocaching (a treasure-hunting game); navigation of cars and other vehicles; ocean navigation for marine vessels and channel dredging; and aircraft control, as in approach and landing at airports (Fig. 1.11). Some of these applications, requiring higher accuracy, involve the use of carrier-phase measurements. GNSS is also used for tracking of people, vehicles, vessels, aircraft, and assets, where GNSS-determined positions are reported via a supplementary communication channel such as that provided by a mobile phone.

One of the earliest high-precision applications of GNSS was in surveying and geodesy (Chaps. 35 and 36) (Fig. 1.12). Through the use of carrier-phase measurements, accurate coordinates of lot boundaries and geodetic markers can be established. Later on these carrier-phase-based techniques found their way into machine control, attitude determination, and precision agriculture [1.27]. Because GNSS also provides precise time (Chap. 41), it is also used to synchronize timing systems worldwide, permitting very accurate time-tagging of financial trades, for example. GNSS timing is widely used in the telecommunication industry including synchronization of mobile phone networks. It is also

**Fig. 1.12a–i** Examples of high-precision GNSS applications; from surveying and geodesy to machine guidance and precision agriculture (Photos courtesy of Position Partners ((**a**), *left*); Leica Geosystems ((**a**), *right*); M. Gottlieb, University NAVSTAR Consortium (UNAVCO) (**b**); pixabay.com (**c**,**f**) TU Delft (**d**); B. Morris (**e**); Trimble (**g**); V. Janssen (**h**); Deere & Co. (**i**))

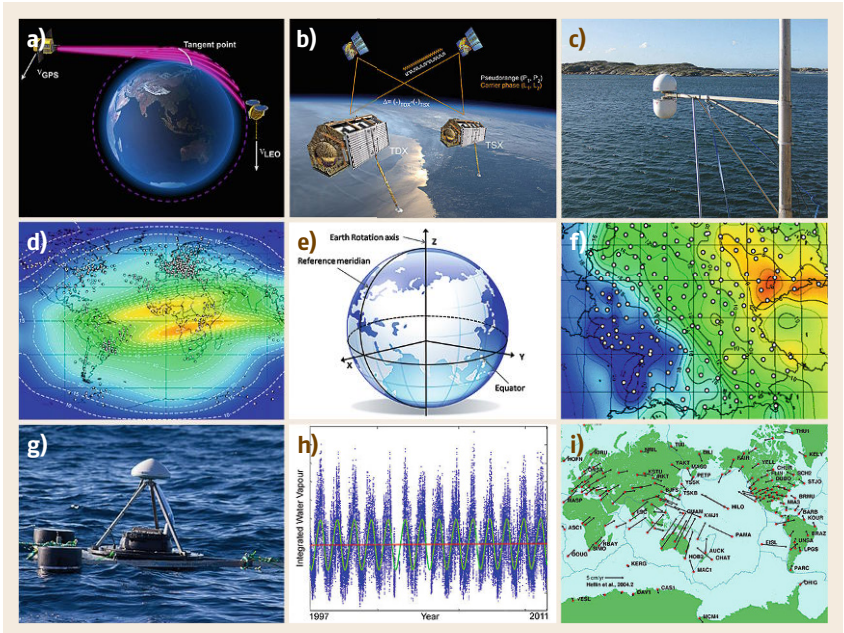

**Fig. 1.13a–i** Examples of scientific GNSS applications; from atmospheric sensing and reference frame studies to tectonic monitoring (Photos courtesy of UCAR 2007 (**a**); P. Kuss, DLR, NASA (**b**); J. Löfgren (**c**); N. Jakowski, DLR (**d**); J. Legrand & C. Bruyninx, ROB (**e**); G. Dick, GFZ (**f**); IMOS (**g**); G. Elgered, Chalmers (**h**); NASA, JPL-Caltech (**i**))

used for electrical power grids [1.28] to synchronize the phase of alternating current and for power-line fault isolation.

GNSSs are also important for Earth system studies and global environmental Earth observation (Fig. 1.13). Advanced GNSS receivers are operated continuously or periodically at geophysically interesting sites (Chap. 37). Long-term tectonic plate motion is measured using GNSS [1.29] and networks of receivers are used to assess Earth surface activities for monitoring landslide and volcano activity or the study of land uplift following the last ice age. By monitoring crustal motions with extensive GNSS networks of continuously operating tracking stations, researchers have the long-term goal of being able to make accurate earthquake predictions, and thereby save lives.

GNSSs are also an invaluable instrument for atmospheric sensing (Chaps. 38 and 39). As GNSS signals are affected by their passage through the ionosphere and the lower atmosphere, an appropriate analysis of the received signals can be used to map the ionosphere's variable electron content [1.30] and the amount of water vapor in the troposphere [1.31]. Several national weather services use GNSS-determined water-vapor measurements to improve their weather forecasts. And GNSSs also help us to understand the processes taking place in the ionosphere. This is important as bad weather in the ionosphere may severely disturb our communication, navigation, and power systems. By looking at the effects that earthquakes and tsunamis have on ionospheric electron density [1.32, 33], GNSS ionospheric sensing may become an important component in tsunami warning systems as well.

During the last few years, GNSS data has also proven its potential for climate monitoring. Several studies have demonstrated the potential of both ground-based and radio occultation GNSS data for the accurate measurement of atmospheric water-vapor content and temperature structure [1.34, 35]. Determination of global temperature trends are important when it comes to the question of global warming. And since GNSS also provides an accurate positioning tool for investigating how ice masses move and change, it also contributes to gaining a better understanding of the linkage between global warming and the melting of our glaciers and the shrinkage of the Arctic ice cover.

*Acknowledgments.* Some of the material in this chapter stems from the authors lectures on GNSS over the years and the beneficial input of past and present students, research associates, and other colleagues. Some of it is also drawn from the first author's long running Innovation column in GPS World magazine.

# 2. Time and Reference Systems

Christopher Jekeli, Oliver Montenbruck

Geodesy is the science of the measurement and mapping of the Earth's surface, and in this context it is also the science that defines and realizes coordinates and associated coordinate systems. Geodesy thus is the foundation for all applications of global navigation satellite system (GNSS). This chapter presents the reference systems needed to describe coordinates of points on the Earth's surface or in near space and to relate coordinate systems among each other, as well as to some *absolute* system, visually, a celestial system. The topic is primarily one of geometry, but the geodynamics of the Earth as a rotating body in the solar system plays a fundamental role in defining and transforming coordinate systems. Therefore, also the fourth coordinate, time, is critical not only as the independent variable in the dynamical theories, but also as a parameter in modern geodetic measurement systems. Instead of expounding the theory of geodynamics and celestial mechanics, it is sufficient for the purpose of this chapter to describe the corresponding phenomena, textually, analytically and illustratively, in order to give a sense of the scope of the tasks involved in providing accurate coordinate reference systems not just to geodesists, but to all geoscientists.

## 2.1 Time

Everyone experiences time, but when pressed no one can explain exactly what it is. Mathematically it can be defined as a coordinate in a fourth dimension (as did Einstein), or more traditionally, it is the independent variable in our theories of motion. Indeed, the only reason that we perceive time is that things change. We have relatively easy access to *units* of time because many of the changes that we observe are periodic. If the changing phenomenon varies with uniform period, then the associated *time scale* is uniform. Clearly, a desirable property of a description and realization of time is that its scale should be uniform at least in the local frame. However, very few observed dynamical systems have rigorously uniform time units. In the past, Earth's rotation provided the most suitable and evident phenomenon to represent the time scale, with the unit being a (solar) day [2.1]. It has been recognized for a long time, however, that Earth's rotation is not uniform (it is varying at many different scales: daily, bi-weekly, monthly, etc., and even slowing down over geologic time [2.2, p. 607]). In addition to scale or units, an origin must be defined for a time system, that is, a zero-point, or an epoch, at which a value of time is specified. Finally, whatever system of time is defined, it should be accessible and, thereby, realizable, thus creating a time *frame*. This distinction between a system and a frame is explained in greater detail with respect to spatial coordinates in Sect. 2.2.2.

Prior to 1960, a second of time was defined as 1/86 400 of a mean solar day (Sect. 2.1.3). Today (since 1960), a fundamental time scale is defined by the natural oscillation of the cesium atom and all time systems can be referred or transformed to this scale. Specifically, the SI (*Système International*) second is defined as follows [2.3, 4]:

> *The second is the duration of* 9 192 631 770 *periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium* 133 *atom.*

This definition has been refined to specify that the atom should be at rest (i. e., at temperature 0 K) and at mean sea level, thus independent of ambient radiation effects and relativistic gravitational changes. Corrections are applied to actual measurements to comply with these requirements. The value of the SI second was set to the previously (in 1956) adopted value of a second of *ephemeris time* (ET) (Sect. 2.1.1), defined as 1/31 556 925.9747 of a mean tropical (solar) year, being computed for the epoch, 1 January 1900, on the basis of Newcomb's theory of motion of the Earth around the Sun [2.5].

Although the SI second now defines the fundamental time unit, one still distinguishes between systems of time that have different origins and even different scales depending on the application. Dynamic time is the independent variable in the most complete theory of the dynamics of the solar system. It is uniform by definition. Mean solar time, or universal time (UT), is the time scale based on Earth's rotation with respect to the Sun and is used for general civilian time keeping. Finally, sidereal time is defined by Earth's rotation with respect to the celestial sphere. Within this section, the various types of dynamic, atomic, and sidereal time scales are described in further detail.

### 2.1.1 Dynamic Time

Newtonian (ephemeris time) and relativistic (barycentric and terrestrial time (TT), etc.) concepts of *dynamic time* generally refer to the time variable in the equations of motion describing the dynamical behavior of the massive bodies of our solar system. As such, with respect to the theory of general relativity, the dynamic time scale refers to a coordinate system and thus represent a coordinate time (Chap. 5). Common choices include the *barycentric* reference system (origin at the center of mass of the solar system) or the *geocentric* reference system. The corresponding time scales are thus designated as *barycentric coordinate time* (TCB) and *geocentric coordinate time* (TCG). Note that acronyms for time systems generally follow the corresponding French names, for example, *temps-coordonnée barycentrique* for Barycentric Coordinate Time. Dynamic time defined in this way is the fourth coordinate and transforms according to the theory of general relativity as the fourth coordinate from one point in space–time to another.

On the other hand, dynamic time has also been defined as a *proper time*, the time associated with the frame of the observer that a uniformly running clock would keep and that describes observed motions in that frame. Depending on the frame of the observer, it is designated, for example, *terrestrial dynamic time* (TDT), or *barycentric dynamic time* (TDB). In 1991, the International Astronomical Union (IAU) renamed TDT simply *terrestrial time*, referring to proper time at the geoid (approximately mean sea level). However, in 2000 the IAU further recommended, due to uncertainties in the realization of the geoid, that TT be redefined as differing from TCG by a constant, specified rate. Its relation to a proper time then more precisely depends on the location and velocity of the observer's clock in the ambient gravitational field. Mathematical connections to the coordinate times, TCB and TCG, and to TDB may be found in Chap. 5 of this Handbook as well as in [2.6, Chap. 10]. The realization of TT is atomic time (Sect. 2.1.2), that is, its scale is the SI second. For calculations of Earth orientation (Sect. 2.5.1), the difference between TT and TDB is usually neglected.

Prior to 1977, the dynamic time was called *ephemeris time*. ET was based on the time variable in the theory of motion of the Sun relative to the Earth – Newcomb's ephemeris of the Sun. This theory suffered from the omission of relativistic theory, the dependence on adopted astronomical constants that, in fact, show a time dependency (such as the *constant* of aberration). It also omitted the effects of other planets on Earth's orbit. The new dynamic time described above was constrained to be consistent with ET at their boundary; specifically,

$$\mathrm{TT} = \mathrm{ET} \ \text{at} \ 1977 \ \text{January} \ 1.0003725 \ \left(1^{\mathrm{d}}\ 0^{\mathrm{h}}\ 00^{\mathrm{m}}\ 32.184^{\mathrm{s}},\ \text{exactly}\right). \tag{2.1}$$

The extra fraction in this epoch was included since this would make the point of continuity between the systems exactly January 1.0, 1977, in International Atomic Time (TAI) (Sect. 2.1.2).

The basic unit of dynamic time is the *Julian Day*, equal to 86 400 SI seconds, which is close to our usual day based on Earth rotation, but is uniform by definition. The origin of dynamic time, designated by the *Julian date*, or *Julian epoch*, J0.0, is defined to be Greenwich noon, 1 January 4713 BC. Julian days, by convention, start and end when it is noon (dynamic

time) in Greenwich, England, representing midday in the usual meaning of a day starting and ending at midnight. Furthermore, there are exactly 365.25 Julian days in a *Julian year*, or exactly 36 525 Julian days in a *Julian century*. With the origin as given above, the Julian date, J1900.0, corresponds to the Julian day number, 2 415 021.0, being Greenwich noon, January 1, 1900; and the Julian date, J2000.0, corresponds to the Julian day (JD) number 2 451 545.0, being Greenwich noon, January 1, 2000 (Fig. 2.1). Thus, the date with Julian day number 2 451 545.0 is also January 1.5, 2000. Note that January 0.5, 2000 is really Greenwich noon on December 31, 1999 (or December 31.5, 1999). For practical reasons, a *modified* Julian day number

$$\mathrm{MJD} = \mathrm{JD} - 2\,400\,000.5\,, \tag{2.2}$$

is also defined relative to a new origin, which counts days as starting at midnight in Greenwich.

### 2.1.2 Atomic Time Scales

*Atomic time* refers to the time scale defined and realized by the oscillations in energy states of the cesium-133 atom, as defined in the introduction of this section. The SI second thus is the unit that defines the atomic time scale [2.3, 7]. Atomic time was not realized until 1955 with the development of standardized atomic clocks (Chap. 5). From 1958 through 1968, the *Bureau International de l'Heure* (BIH) in Paris maintained the atomic time scale. The origin, or zero point, for atomic time has been chosen officially as $0^{\mathrm{h}}\,0^{\mathrm{m}}\,0^{\mathrm{s}}$, January 1, 1958.

*International Atomic Time* was officially introduced in January 1972. It was determined and subsequently defined that on $0^{\mathrm{h}}\,0^{\mathrm{m}}\,0^{\mathrm{s}}$, January 1, 1977 (TAI), the ET epoch was $0^{\mathrm{h}}\,0^{\mathrm{m}}\,32.184^{\mathrm{s}}$, January 1, 1977 (ET); thus, in accord with (2.1),

$$\mathrm{TAI} = \mathrm{TT} - 32.184\,\mathrm{s}\,. \tag{2.3}$$

TAI is realized today by the *Bureau International des Poids et Mesures* (BIPM), which combines data from over 400 high-precision atomic clocks around the world in order to maintain the SI-second scale as accurately as possible. TAI is published and accessible as a correction to each time-center clock, but rather in terms of *coordinated universal time* (UTC, Sect. 2.1.3), which is civilian atomic time adjusted to be close to a time scale based on Earth's rotation.

In the United States, the official atomic time clocks are maintained by the US Naval Observatory (USNO) in Washington, DC, and by the National Institute of Standards and Technology (NIST) in Boulder, CO, USA. Within each such center several cesium beam clocks are running simultaneously and averaged. Other centers participating in the realization of TAI include observatories in Paris, Greenwich, Moscow, Tokyo, Ottawa, Wettzell, Beijing, and Sydney, among over 70 others. The comparison and amalgamation of the clocks of participating centers around the world are accomplished by LORAN-C, satellite transfers (GNSS playing the major role; Chap. 41), and actual clock visits. Time offsets of individual laboratories and their uncertainties are reported in the monthly issues of the BIPM Circular T [2.8]. Worldwide synchronization for many of the national laboratories is at the level of a few tens of nanoseconds or better [2.9]. Since atomic time is computed from many clocks, it is also known as a *paper clock* or a *statistical clock*.

### 2.1.3 Sidereal and Universal Time, Earth Rotation

*Sidereal time* represents the rotation of the Earth with respect to the celestial sphere and reflects the actual rotation rate of the Earth, plus effects due to the small motion of the spin axis relative to space (precession and nutation, Sect. 2.5.1). It is the angle on the equator between a particular terrestrial meridian and the *vernal equinox*, ♈, which is the point on the celestial sphere where the Sun crosses the equator in Spring

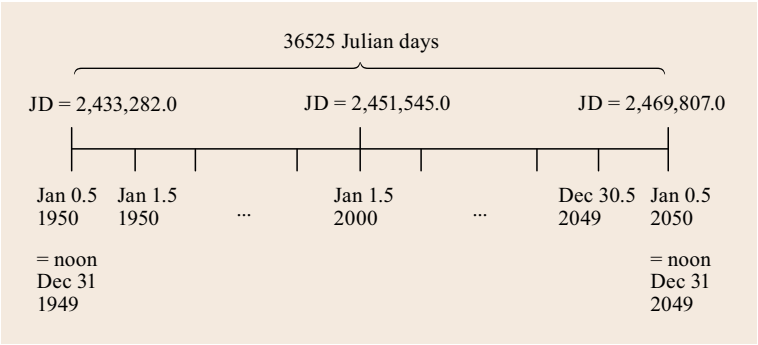

**Fig. 2.1** Julian Day numbers and their relation to our current conventional calendar

as viewed by the Northern Hemisphere of the Earth. Inasmuch as the equator has the same dynamics as the spin axis, one distinguishes between apparent (or, true) and mean sidereal time, the latter having the effects of nutation removed. The amplitude of this effect is about 15.8″, which corresponds to about 1 s of time using the conversion, 15° = 1 h. *Greenwich apparent sidereal time* (GAST) is the angle from the true (or, instantaneous) equinox to the Greenwich meridian (Fig. 2.2).

Due to the precession of the spin axis and thus the vernal equinox on the equator, sidereal time includes a small rotation rate (about $7.1 \cdot 10^{-12}$ rad/s) that is not due to Earth rotation. For this reason, a new origin point, σ, has been introduced and adopted in the late 1990s that better serves the determination of Earth's rotation rate. This so-called nonrotating origin is also called the celestial intermediate origin (CIO) as explained in Sect. 2.5.2. A new angle, $\theta$, called the Earth rotation angle (ERA), now represents true Earth rotation (Fig. 2.2). The angle $\alpha(\Upsilon) = \theta - \text{GAST}$, also called the equation of origins (EO), today (2015) has a significant value of about −12′ due to the accumulated precession since J2000. Expressions for evaluating the EO at arbitrary epochs are provided in [2.6, 10].

UT is the time scale used for general civilian time keeping and is based approximately on the diurnal motion of the Sun. However, the Sun, as viewed by a terrestrial observer does not move uniformly on the celestial sphere. To create a uniform time scale requires the notion of a fictitious, or *mean Sun*, and the corresponding time is known as *mean solar time* (MT). UT is defined as mean solar time on the Greenwich meridian. The basic unit of UT is the *mean solar day*, being the time interval between two consecutive transits of the mean Sun across the meridian. The mean solar day has 24 mean solar hours and 86 400 mean solar seconds.

In comparison to sidereal time, the following approximate relations hold

$$\begin{aligned}&1 \text{ mean solar day}\\ &= 24^{\text{h}}\,03^{\text{m}}\,56.5554^{\text{s}} \text{ in sidereal time}\,,\end{aligned} \tag{2.4}$$

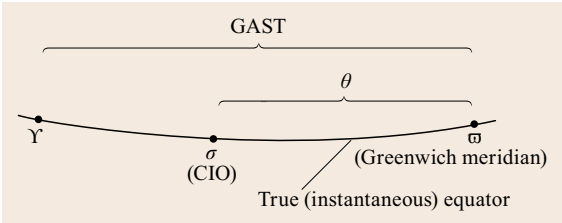

**Fig. 2.2** Relationship between GAST and the Earth rotation angle, $\theta$, relative to the true vernal equinox, Υ

$$\begin{aligned}&1 \text{ mean sidereal day}\\ &= 23^{\text{h}}\,56^{\text{m}}\,04.0905^{\text{s}} \text{ in solar time}\,.\end{aligned} \tag{2.5}$$

A mean solar day is longer than a sidereal day because in order for the Sun to return to the observer's meridian, the Earth must rotate an additional amount due to its orbital advance (Fig. 2.3). Thus, also Earth's rotation rate is *not* equal to $2\pi/86\,400$ rad/s if s is a solar second. Instead, the rate is, according to (2.5),

$$\omega_{\oplus} = 7.292115 \cdot 10^{-5} \text{ rad/s}\,. \tag{2.6}$$

To determine $\omega_{\oplus}$ (and its variations) from measurements by terrestrial observers, one must account for the fact that the observer's reference meridian is associated with a fixed pole, with respect to which the Earth's spin axis moves (polar motion, Sect. 2.5.3). In addition, Earth's rotation is affected by other irregularities of periodic and secular character (such as seasonal effects and the exchange of angular momentum between the Earth and Moon) that are lumped into so-called *length-of-day variations*. Universal time as a scale derived from Earth's rotation has thus been separated into:

UT0: Universal Time determined from observations with respect to the meridian fixed to the reference pole;
UT1: Universal Time determined with respect to the meridian attached to the spin axis;
UT2: Universal Time UT1 corrected for seasonal variations.

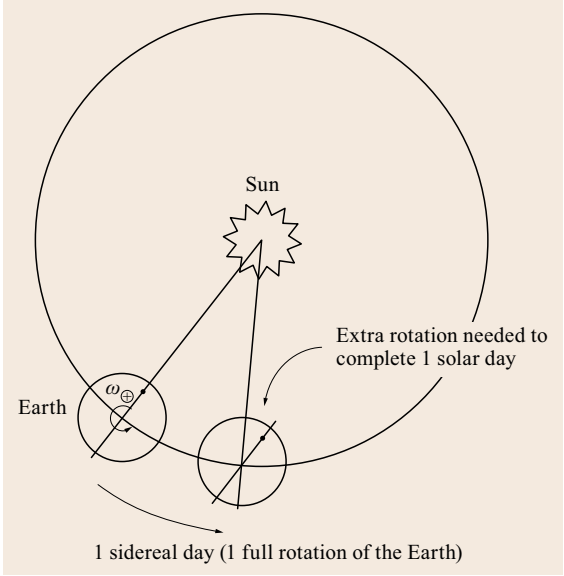

**Fig. 2.3** Geometry of sidereal and solar days

UT2 is the best approximation of UT to a uniform time, although it is still affected by small secular variations. However, as a matter of practical utilization it has now been replaced by an atomic time scale (UTC, see below).

In terms of the SI second, the mean solar day is given by

$$1^{\mathrm{d}}\,(\mathrm{MT}) = 86\,400\,\mathrm{s} - \frac{\Delta\tau}{n}\,, \tag{2.7}$$

where

$$\Delta\tau = \mathrm{UT1} - \mathrm{TT} \tag{2.8}$$

is the difference over a period of $n$ days between UT1 and dynamic time. The length-of-day variation is the time-derivative of $\Delta\tau$. From observational records over the centuries it has been found that the secular variation in the length of a day (rate of Earth rotation) currently is approximately +1.4 ms per century [2.2, p. 607].

All civilian clocks in the world are now set with respect to an atomic time standard since atomic time is much more uniform than solar time and more easily realized through time transfer by satellite signals. Yet, there is still a desire (particularly, in the astronomic community) that civil time should correspond to solar time; therefore, a new atomic time was defined that approximates UT. This atomic time is called *Coordinated Universal Time* (UTC) and implemented in accord with Recommendation TF.460 of the International Telecommunication Union (ITU) [2.11]:

> *UTC is the time scale maintained by the BIPM, with assistance from the IERS, which forms the basis of a coordinated dissemination of standard frequencies and time signals. It corresponds exactly in rate with TAI but differs from it by an integral number of seconds. The UTC scale is adjusted by the insertion or deletion of seconds (positive or negative leap seconds) to ensure approximate agreement with UT1.*

Initially, UTC was adjusted so that $|\mathrm{UT2} - \mathrm{UTC}| < 0.1\,\mathrm{s}$. As of 1972, the requirement for the correspondence between UTC and UT was relaxed to

$$|\mathrm{UT1} - \mathrm{UTC}| < 0.9\,\mathrm{s}\,. \tag{2.9}$$

The adjustments, called *leap seconds*, are introduced either January 1 or July 1 of any particular year.

Up to 2015, leap seconds have, on average, been introduced approximately once every 1.5 years (Table 2.1). Following an earlier adjustment in July 2012, the UTC – TAI amounts to −36 s since mid 2015. The history of UTC relative to TAI and other time scales is schematically shown in Fig. 2.4 based on tabulated data of the United Sates Naval Observatory (USNO) in [2.12]. The decision to introduce new leap seconds is taken by the *International Earth Rotation and Reference Systems Service* (IERS) and announced within the IERS Bulletin C.

**Table 2.1** UTC leap seconds introduced since 1972. The table provides the integer seconds difference between UTC and TAI along with the starting date of applicability (after [2.12])

| Since | UTC – TAI (s) | Since | UTC – TAI (s) |
|---|---|---|---|
| 1 Jan 1972 | −10 | 1 Jan 1988 | −24 |
| 1 Jul 1972 | −11 | 1 Jan 1990 | −25 |
| 1 Jan 1973 | −12 | 1 Jan 1991 | −26 |
| 1 Jan 1974 | −13 | 1 Jul 1992 | −27 |
| 1 Jan 1975 | −14 | 1 Jul 1993 | −28 |
| 1 Jan 1976 | −15 | 1 Jul 1994 | −29 |
| 1 Jan 1977 | −16 | 1 Jan 1996 | −30 |
| 1 Jan 1978 | −17 | 1 Jul 1997 | −31 |
| 1 Jan 1979 | −18 | 1 Jan 1999 | −32 |
| 1 Jan 1980 | −19 | 1 Jan 2006 | −33 |
| 1 Jul 1981 | −20 | 1 Jan 2009 | −34 |
| 1 Jul 1982 | −21 | 1 Jul 2012 | −35 |
| 1 Jul 1983 | −22 | 1 Jul 2015 | −36 |
| 1 Jul 1985 | −23 | 1 Jan 2017 | −37 |

The lengthening of a day by about 1.4 ms per century as measured by Earth's slowing rate of rotation implies that the UT1 clock continues to run more and more behind the TAI clock. It has been determined that the mean solar day today is actually about 86 400.0027 SI seconds long, since the SI second was originally identified with the ET second based on the motion of the mean Sun at Newcomb's time in the nineteenth century. Indeed, 86 400 SI seconds exactly equaled a mean solar day in 1820, or 1.95 centuries (cy) ago. This disparity between the scales of the defined SI second and the current mean solar day has an accumulative effect that adds, on the average, about $1.4\,\mathrm{ms/d/cy} \times 1.95\,\mathrm{cy}$, or about 1 s to UT1 during the course of a year; hence, the introduction of the leap seconds. The difference, $\mathrm{DUT1} = \mathrm{UT1} - \mathrm{UTC}$, is broadcast along with UTC so that users can determine UT1.

The relationships among the various atomic time scales are illustrated along with dynamic time in Fig. 2.4. There is current debate [2.13–15] about the need to maintain the small difference between UTC and UT1 considering the technical inconveniences and inefficiencies (if not outright difficulties) this imposes on the many modern civilian telecommunications systems and other networks that rely on a precise time scale.

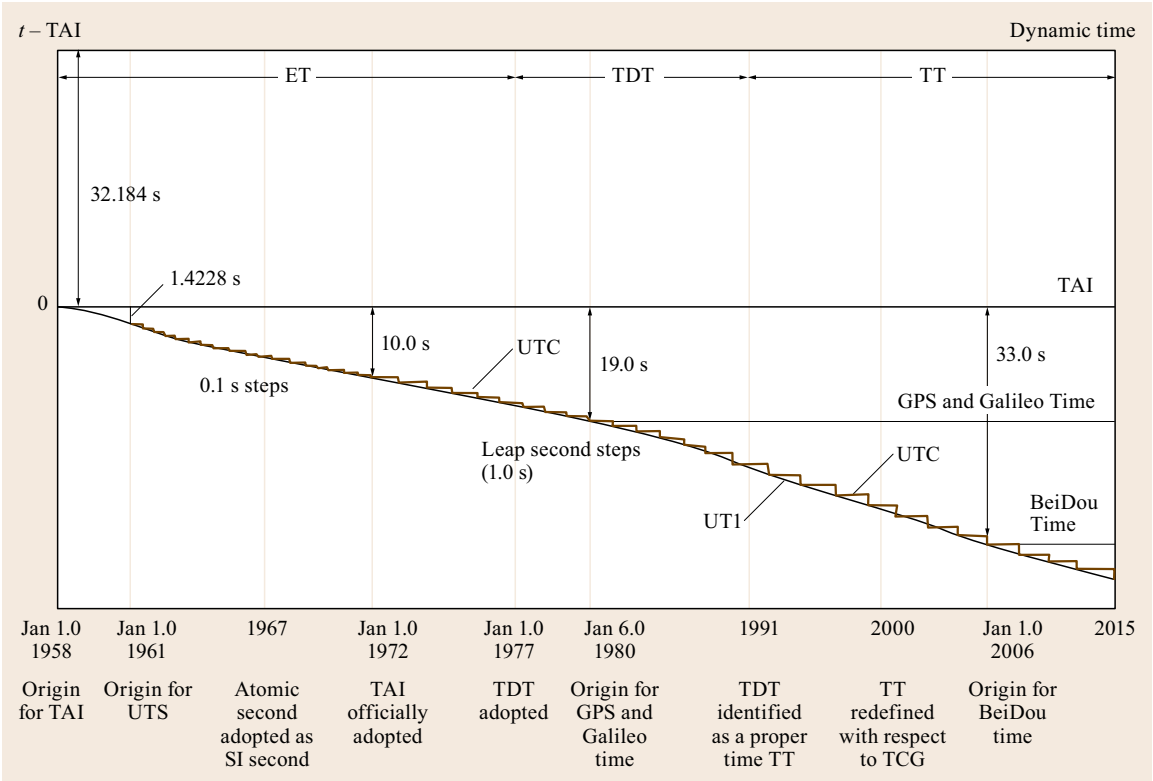

**Fig. 2.4** Relationships between atomic time scales and dynamic time (indicated leap seconds are schematic only). For the acronyms, see the text

### 2.1.4 GNSS System Times

Satellite navigation systems provide user coordinates derived from distance measurements that are based on the propagation time of the transmitted signals. Thus, all these systems rely on very accurate clocks and time standards. To meet the needs of internal time synchronization and dissemination, each GNSS maintains a specific *system time*. The time systems of the four global navigation satellite systems, Global Positioning System (GPS), GLONASS, Galileo, and BeiDou, are all based on the SI second and atomic time similar to TAI. However, they are realized by different clock ensembles and have different origins and offsets with respect to TAI [2.16].

*GPS time* (GPST) is the system time employed by the United States' Global Positioning System. Since 1990, it is formed as a *composite clock* from atomic clocks within the GPS Control Segment (including both the Master Control Station and the Monitoring Stations) as well as the atomic frequency standards onboard the GPS satellites [2.17, 18]. Each of these clocks contributes to the resulting time scale with a specific weight based on the observed variance of the respective clock [2.19]. Using common view time transfer, GPS time is steered to deviate by at most 1 μs [2.20] from UTC(USNO), that is, the realization of UTC maintained by the United States Naval Observatory. In practice, the GPS – UTC(USNO) offset is much smaller than the specified range and achieves representative values at the level of 20 ns [2.21]. In order to provide GPS users with access to UTC, a forecast value of the offset between both time scales is transmitted as part of the navigation message.

The origin of GPS time, as noted in Fig. 2.4, is January 6.0, 1980 UTC(USNO). However, GPS time is not adjusted by leap seconds to slow down with UT and it is thus permanently offset (late) by a constant amount from TAI

$$t\,(\mathrm{GPS}) = \mathrm{TAI} - 19\,\mathrm{s}\,. \tag{2.10}$$

At the same time, it is offset from (ahead of) UTC by varying amounts depending on the number of introduced leap seconds. Note that (2.10) describes only the nominal (integer second) offset between GPS time and

TAI, but neglects additional fractional offsets (typically at the level of tens of nanoseconds) related to different realization of the two time scales.

*GLONASS Time* (GLST) is the only GNSS time scale that actually follows the ITU recommendation [2.11] to align a disseminated time scale with UTC. Its origin is chosen as January 1.0, 1996 in the UTC(SU) time system, that is, the Russian (formerly Soviet Union, SU) realization of UTC maintained by the Institute of Metrology for Time and Space in Moscow. Besides incorporating leap seconds, GLST is always 3 h ahead of UTC because of the time zone difference between Greenwich and Moscow. Thus,

$$t\,(\mathrm{GLONASS}) = \mathrm{UTC} + 3\,\mathrm{h}\,. \tag{2.11}$$

Again, this relation does not account for fractional second offsets resulting from the independent realization of both time scales. GLST is obtained from an ensemble of hydrogen-masers in the GLONASS ground segment and synchronized to UTC(SU) using two-way time transfer with a specified tolerance of 1 µs [2.22]. Following a consolidated effort to improve the alignment of GLST with UTC, the difference of the two time scales has improved from several hundred ns [2.23] to a few tens of ns as of the second half 2014 [2.24].

Both the *Galileo System Time* (GST, [2.25, 26]) and *BeiDou time* (BDT; [2.27]) exhibit a constant offset from TAI. The origin for Galileo time, for consistency, is defined to be identical to that of GPS Time, but the origin for the BeiDou time system has been chosen as January 1.0, 2006 UTC. Thus,

$$t\,(\mathrm{Galileo}) = \mathrm{TAI} - 19\,\mathrm{s}\,, \tag{2.12}$$

$$t\,(\mathrm{BeiDou}) = \mathrm{TAI} - 33\,\mathrm{s}\,. \tag{2.13}$$

Both time scales are generated from atomic clocks in the respective control segments and steered to UTC via time transfer and clock comparison with other UTC laboratories. GST is specified to differ by less than 50 ns ($2\sigma$) from UTC [2.25, 28] while a maximum offset of 100 ns applies for BeiDou [2.23, 29].

Similar to Galileo, continuous time scales with a fixed −19 s offset from TAI are also adopted by the Japanese Quasi-Zenith Satellite System (QZSS) and the Indian Regional Satellite Navigation System (IRNSS/NAVIC).

## 2.2 Spatial Reference Systems

To establish coordinates of points requires that we set up a coordinate system with origin, orientation, and scale defined in such a way that all users have access to these. Before the establishment of GNSS, the most accessible reference for coordinates from a global perspective was the celestial sphere of stars that were used not only for charting and navigation, but also served as a fundamental system to which other terrestrial coordinate systems could be oriented. Still today, the celestial reference system is used for that purpose and may be thought of as the ultimate in reference systems. At the next level, we define coordinate systems attached to the Earth with various origins (and perhaps different orientations and scale). Thus, there are two fundamental tasks: (1) to establish an external coordinate system of the local universe that presumably remains fixed in the sense of no rotation; and (2) to establish a coordinate system attached to the rotating and orbiting Earth, and in so doing to find the relationship between these two systems.

### 2.2.1 Coordinate Systems

The Cartesian system of coordinates, $x, y, z$, is certainly the easiest from a mathematical perspective and it plays a central role in defining modern reference systems. However, because the Earth is nearly spherical and by extension our geocentric view of the heavens takes on a spherical character, spherical coordinates are essential as many geodetic concepts rely on directions and distances. Indeed, the latitude/longitude concept will always have the most direct appeal for terrestrial applications (surveying, near-surface navigation, positioning, and mapping). Figure 2.5 shows the relationship between the Cartesian coordinates and *spherical coordinates*, comprising latitude, $\phi$, longitude, $\lambda$, and radius, $r$, and given by

$$\begin{aligned} x &= r\cos\phi\cos\lambda\,,\\ y &= r\cos\phi\sin\lambda\,,\\ z &= r\sin\phi\,. \end{aligned} \tag{2.14}$$

The inverse relationship is

$$\begin{aligned} \phi &= \tan^{-1}\left(\frac{z}{\sqrt{x^2+y^2}}\right),\\ \lambda &= \tan^{-1}\left(\frac{y}{x}\right),\\ r &= \sqrt{x^2+y^2+z^2}\,. \end{aligned} \tag{2.15}$$

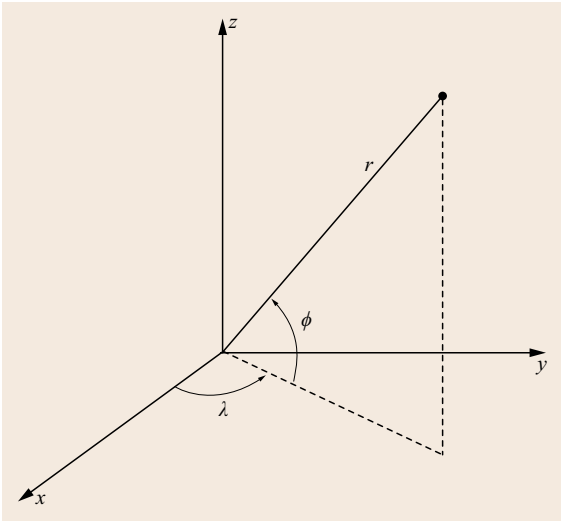

**Fig. 2.5** Spherical coordinates

Already by the middle of the eighteenth century, it was established by measurements that the Earth is flattened at the poles and assumes an elliptical shape [2.30], specifically an *ellipsoid* of revolution, defined as the surface generated by rotating an ellipse about its minor axis. It is also known as a *spheroid* (to distinguish it from a tri-axial ellipsoid). Essential parameters of the ellipsoid are its size and shape that may be defined by the semi-major and semi-minor axis lengths, $a$ and $b$ (Fig. 2.6). Other shape parameters include the flattening

$$f = \frac{a-b}{a} \,, \tag{2.16}$$

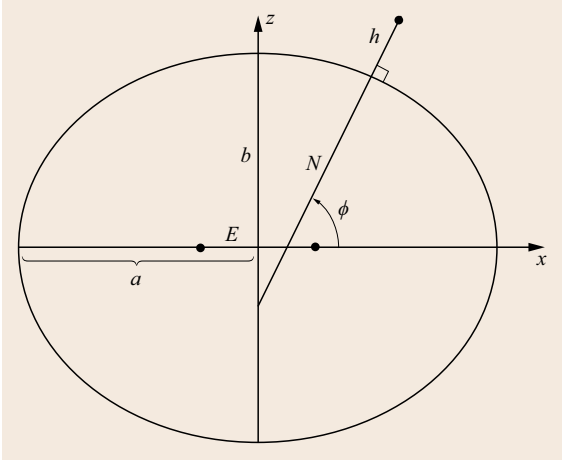

**Fig. 2.6** Ellipsoidal geometry and geodetic coordinates. *Dots* on the $x$-axis denote focal points of the ellipse, which represents the meridian plane

the first and second eccentricities

$$e^2 = \frac{a^2-b^2}{a^2} \quad \text{and} \quad e'^2 = \frac{a^2-b^2}{b^2} \,, \tag{2.17}$$

as well as the linear eccentricity $E = ae$.

With respect to an ellipsoid with given parameters, the *geodetic coordinates* are defined as illustrated in Fig. 2.6 and include the geodetic latitude, $\varphi$, the geodetic longitude, $\lambda$ (not shown, but identical to the spherical longitude), and the geodetic height, $h$, along the line that is normal, or perpendicular, to the ellipsoid. The relationship between geodetic coordinates and the global Cartesian coordinates is

$$\begin{aligned} x &= (N+h)\cos\varphi\cos\lambda \,, \\ y &= (N+h)\cos\varphi\sin\lambda \,, \\ z &= \left[N\left(1-e^2\right)+h\right]\sin\varphi \,, \end{aligned} \tag{2.18}$$

where

$$N = \frac{a}{\sqrt{1-e^2\sin^2\varphi}} \,. \tag{2.19}$$

is the radius of curvature of the ellipsoid in the direction perpendicular to the elliptical meridian plane.

An inverse relationship can be formulated for $z \neq 0$ that requires a numerical iteration on the geodetic latitude,

$$\varphi = \tan^{-1}\left[\frac{z}{\sqrt{x^2+y^2}}\left(1+\frac{e^2 N\sin\varphi}{z}\right)\right] , \tag{2.20}$$

where the initial latitude that assumes the point is on the ellipsoid ($h = 0$),

$$\varphi^{(0)} = \tan^{-1}\left[\frac{z}{\sqrt{x^2+y^2}}\left(1+\frac{e^2}{1-e^2}\right)\right] , \tag{2.21}$$

serves to yield convergence to micro-arcsecond accuracy within three iterations for heights less than 20 km. The height then follows from

$$h = \left(\sqrt{x^2+y^2}\right)\cos\varphi + z\sin\varphi \; - a\sqrt{1-e^2\sin^2\varphi} \,, \tag{2.22}$$

and the longitude is given by the second equation of (2.15).

A noniterative relationship is derived by [2.31] based on the solution to a quartic equation; see also [2.32]. The performance and computational efficiency of different analytical and iterative algorithms

for the conversion of Cartesian to geodetic coordinates is, furthermore, compared in [2.33].

A number of ellipsoids have been established on the basis of geodetic measurements, extending historically from surveyed arc lengths along meridians to modern best fits to mean sea level using satellite altimetry. One of the earliest ellipsoids was computed by Airy in 1830, having semi-major axis, $a = 6\,377\,563.396\,\mathrm{m}$, and flattening, $f = 1/299.324964$. The current internationally adopted ellipsoid is part of the Geodetic Reference System of 1980 (GRS80) and has parameter values given by

$$a_{\mathrm{GRS80}} = 6\,378\,137\,\mathrm{m}\,,$$
$$f_{\mathrm{GRS80}} = \frac{1}{298.257222101}\,. \tag{2.23}$$

The equatorial radius was determined from satellite altimetry and the flattening was derived from the second-degree zonal harmonic coefficient (dynamic form factor, $J_2$) of the Earth's gravitational potential [2.34]. The parameter values of other ellipsoids determined and used in the past may be found in [2.30]. The parameter estimates of the best fitting, or mean Earth ellipsoid (MEE) in the mean tide system are [2.35]

$$a_{\mathrm{MEE}} = 6\,378\,136.72 \pm 0.1\,\mathrm{m}\,,$$
$$f_{\mathrm{MEE}} = \frac{1}{298.25231 \pm 0.00001}\,. \tag{2.24}$$

The GRS80 values are constants, while the MEE values are estimates with a standard deviation and do not constitute an accepted reference ellipsoid. When publishing geodetic coordinates, $\varphi, \lambda, h$, it is always important to specify the associated ellipsoid on which they depend.

*Local coordinates* in the vicinity of a point P are Cartesian with the third axis along the ellipsoid normal as illustrated in Fig. 2.7. For a right-handed system, the first axis points East and the second North. However, a left-handed system, such as North-East-Up, is also common. Local coordinates $(u, v, w)^\top$ of a point Q in a system centered at P are related to the global Cartesian coordinate differences $(\Delta x, \Delta y, \Delta z)^\top$ of Q with respect to P according to

$$\begin{pmatrix} u \\ v \\ w \end{pmatrix} = \mathbf{E} \begin{pmatrix} \Delta x \\ \Delta y \\ \Delta z \end{pmatrix} \tag{2.25}$$

with

$$\mathbf{E} = \begin{pmatrix} -\sin\lambda & +\cos\lambda & 0 \\ -\sin\varphi\cos\lambda & -\sin\varphi\sin\lambda & +\cos\varphi \\ +\cos\varphi\cos\lambda & +\cos\varphi\sin\lambda & +\sin\varphi \end{pmatrix}. \tag{2.26}$$

Here, the latitude $\varphi$ and longitude $\lambda$ refer to the reference point P. The inverse relationship is obtained by premultiplying both sides by the transpose of the rotation matrix since it is orthogonal.

The elevation angle $E$ of Q relative to P and the corresponding azimuth angle $A$ (measured clockwise from North to East) are given by

$$\tan A = \frac{u}{v}$$
$$\sin E = \frac{w}{\sqrt{u^2 + v^2 + w^2}}\,. \tag{2.27}$$

These formulas relate global Cartesian coordinate differences, as might be obtained by GNSS, to local determinations of angles and distances. If those angles are referenced to the local plumb line, rather than the ellipsoidal normal, one needs to account for this *deflection of the vertical*. For a distance of 1 km and a vertical deflection of 30″, the effect on the global Cartesian coordinate differences is of the order of a few centimeters or decimeters.

*Celestial coordinates* refer to the location of objects (e.g., stars) projected onto the *celestial sphere*. By definition, the celestial sphere has no particular radius as the coordinates define only directions. The center of the sphere is defined to be at the origin of a Cartesian coordinate system, and the celestial coordinates are called declination ($\delta$) and right ascension ($\alpha$), analogous to latitude and longitude. As such, the relationship to Cartesian coordinates is the same as in (2.14) and (2.15) with unit radius ($r = 1$). The origins for declination and right ascension require particular definitions associated with a reference system. This is discussed further in Sect. 2.4.

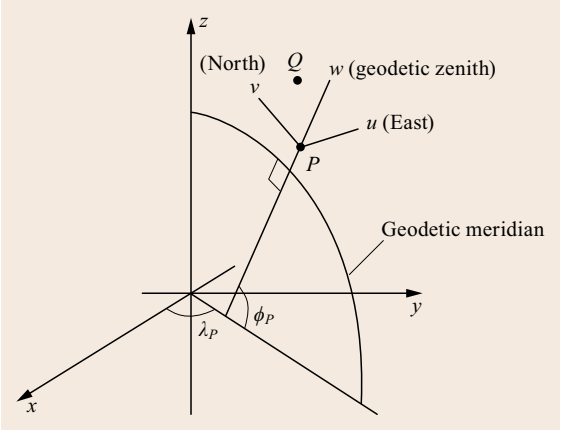

**Fig. 2.7** Local Cartesian coordinates, $u, v, w$

### 2.2.2 Reference Systems and Frames

There is an important conceptual difference between a reference system for coordinates and a reference frame that applies throughout the discussion of coordinate systems in geodesy. Loosely recognized in defining and creating geodetic datums in the past, it was formalized by [2.36] (see also [2.37, Chap. 9] and [2.6]):

- A *reference system* is a set of prescriptions and conventions together with the modeling required to define at any time a triad of coordinate axes.
- A *reference frame* realizes the system by means of coordinates of definite points that are accessible directly by occupation or by observation.

A simple example of a reference system is the set of three mutually orthogonal axes that are aligned with the Earth's spin axis, a prime (Greenwich) meridian, and a third direction orthogonal to these two in the right-handed sense. That is, a system defines how the axes are to be established (e.g., orthogonality), what theories or models are to be used (e.g., what is meant by a spin axis), and what conventions are used (e.g., how the prime meridian is to be chosen). A simple example of a frame is a set of points globally distributed whose coordinates are given mutually consistent numbers in the reference system. That is, a frame is the physical realization of the system defined by actual coordinate values of actual points in space that are accessible to anyone. A frame cannot exist without a system, and a system is of no practical value without a frame.

Although the explicit difference between frame and system was articulated fairly recently in geodesy, the concepts have been embodied in the terminology of a *geodetic datum* that can be traced to the eighteenth century and earlier [2.30]. Indeed, the definition of a datum today refers specifically to the conventions that establish how a coordinate system is attached to the Earth – its origin, its orientation, and its scale. In this sense, the definition of a datum has not changed. The meaning of a datum within the context of frames and systems is explored in more detail in Sect. 2.3.2.

## 2.3 Terrestrial Reference System

Geodetic control at local, regional, national, and international levels has been revolutionized by the advent of satellite systems, particularly GNSS that provide accurate positioning capability to terrestrial observers at all scales, where, of course, the GPS has had the most significant impact. The terrestrial reference systems and frames for geodetic control have evolved correspondingly over the last few decades. Countries and continents around the world are revising, redefining, and updating their fundamental networks to take advantage of the high accuracy, the ease of establishing and densifying the control, and critically important, the uniformity of the accuracy and the connectivity of the control that can be achieved basically in a global setting.

### 2.3.1 Traditional Geodetic Datums

The traditional *geodetic datum* was defined somewhat loosely by today's standards as a set of constants and prescriptions that specify a coordinate system for the purpose of geodetic control [2.38]. Because of the fundamental differences in respective measurement techniques, control was divided between horizontal and vertical datums.

*Horizontal datums* (Fig. 2.8) required the definition of an origin point (a marker on the Earth's surface with defined geodetic latitude and longitude; or, equivalently, a constraint within a network that essentially fixed the origin), as well as a mapping surface, an ellipsoid with defined parameters. Orientation of the ellipsoid was defined to be parallel to the astronomic system of the celestial sphere (Sect. 2.4). It was realized by accurate measurements of azimuth with respect to celestial north and by accounting for the deflection of the vertical in astronomic determinations of coordi-

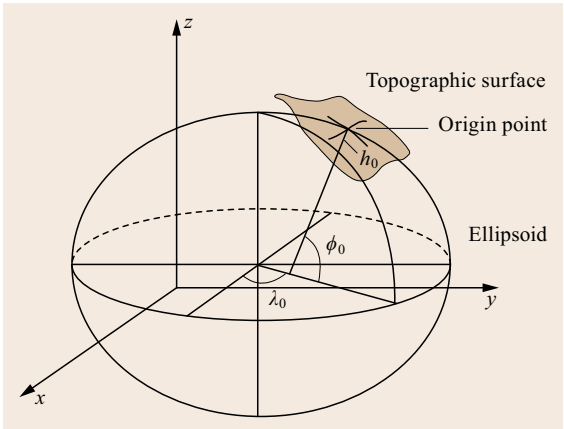

**Fig. 2.8** Traditional horizontal geodetic datum. Geodetic surveys on the topographic surface relative to an origin point are reduced to a mapping surface, the ellipsoid, with proper preservation of its orientation relative to an astronomic system

nates. A *vertical datum* (Fig. 2.9) was similarly defined by the height at an origin point and prescriptions for the reference surface through that point and the associated heights relative to the surface.

In the United States, horizontal control was established in the latter half of the nineteenth century for the Eastern United States and advanced with the westward economic expansion to create the *North American Datum of 1927* (NAD27) with origin point at Meades Ranch in the centrally located state of Kansas. In 1983, the horizontal datum was redefined to be geocentric (origin at the now practically accessible center of mass of the Earth by tracking Earth-orbiting satellites), referred to the GRS80 ellipsoid, and readjusted with the inclusion of satellite Doppler observations and other space techniques such as very long baseline interferometry (VLBI [2.39, 40]). The new *North American Datum of 1983* (NAD83), already incorporating three-dimensional coordinates, assumed a fully three-dimensional character with each new realization that was adjusted by including continuously operating reference stations (CORS [2.41]). The CORS network is a cooperative endeavor among the US government (National Geodetic Survey) and academic and private institutions that creates precise geodetic control throughout the United States and several worldwide stations using GNSS data. New realizations of NAD83 were adjusted as the CORS network expanded and were designated NAD83(CORS93), NAD83(CORS94), and NAD83(CORS96). Including also additional regional high-accuracy GPS networks that were adjusted to fit the NAD83(CORS96) frame, it became the geometric part of the National Spatial Reference System, designated NAD83(NSRS2007). This was readjusted in 2011, yielding the realization NAD83(2011) with coordinates and their velocities (Sect. 2.3.4) given for the epoch $t_0 = 2010.0$. The reference system definition is currently (2015) in revision to bring the realization closer to the International Terrestrial Reference Frame (ITRF) (Sect. 2.3.2).

The vertical datum in the United States similarly evolved from an adjustment of coast-to-coast leveling networks constrained to zero height at various tide-gauge stations at mean sea level. This *National Geodetic Vertical Datum of 1929* (NGVD29) was replaced in 1988 with a readjustment of existing and new leveling data and a tie to the *International Great Lakes Datum of 1985* (IGLD85) whose origin is a single point on the St. Lawrence River in the province of Québec, resulting in the *North American Vertical Datum of 1988* (NAVD88). Vertical control in the United States and Canada is now undergoing a fundamental redefinition to eliminate continent-wide error trends by defining the reference, not by any particular origin point, but by a model for the Earth's gravity potential. This new *geopotential reference system* already exists for Canada as of 2013, and is scheduled to be in place for the United States by the early 2020s.

Similar progress in geodetic control is occurring in other regions of the world, for example, in Europe and South America, where in some cases progress is more difficult due to the varied and heterogeneous datums established in the pre-satellite era.

While geodetic control is now essentially three-dimensional within a single reference system and frame, such as NAD83(NSRS2007), vertical datums continue to be vitally important since they define a different kind of height, one that is based on gravity potential, rather than pure geometry. The geopotential-based heights are needed for any application in hydrology since they indicate the natural flow of water.

The conversion between ellipsoidal heights, $h$, obtained from coordinates in the modern geodetic reference system and heights, $H$, in a vertical datum requires a model for the *geoid undulation*, or *geoid height*, $N$, defined as the vertical separation between the geoid and the ellipsoid (Fig. 2.10)

$$N = h - H - N_0 \,. \tag{2.28}$$

The *geoid* is the equipotential surface that closely approximates global mean sea level and the geoid undulation is determined from gravity measurements [2.42]. High-degree and high-order spherical harmonic gravitational potential models such as EGM2008 can provide global geoid undulations with an accuracy of 10 cm or better as shown in [2.43]. In addition, a constant offset, $N_0$, must be determined between the geoid and the ver-

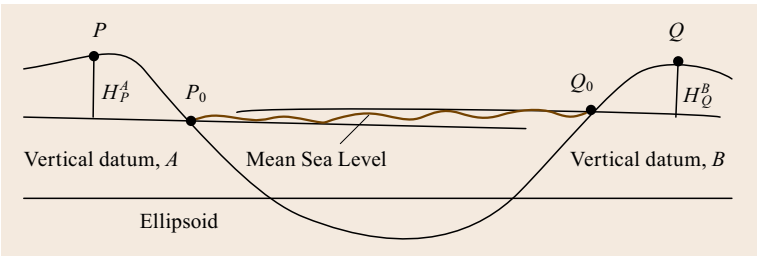

**Fig. 2.9** Traditional vertical geodetic datum, representing an equipotential, or level, surface in Earth's gravity field. Since mean sea level is not truly level, different vertical datums tied to mean sea level are not mutually consistent

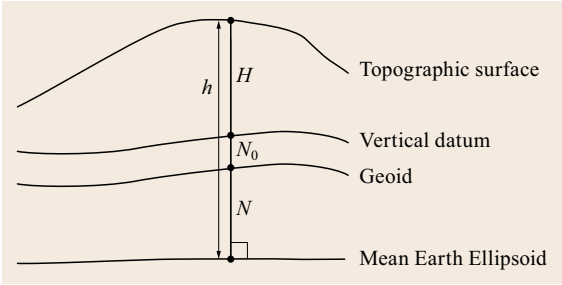

**Fig. 2.10** The relationship between heights with respect to a vertical datum and the ellipsoid

tical datum, as well as a possible difference between the best-fitting MEE and the ellipsoid of the reference system. This offset can reach several decimeters in value.

The geoid undulation itself covers a range of roughly ±100 m with positive peak values in the North Atlantic and Indonesian region and a minimum near the Southern tip of India (Fig. 2.11). GNSS do not have direct access to geoid-related (mean sea level) heights but can only obtain the height with respect to a reference ellipsoid from the navigation solution. For conversion of ellipsoidal heights to mean sea level, a database of precomputed geoid undulations can be used within a GNSS receiver. As an example, [2.44] provides tabular geoid heights on a $10^\circ \times 10^\circ$ longitude/latitude grid. The geoid height at any user location can then be obtained through interpolation using a weighted average of the nearest four grid points with a root-mean-square accuracy of better than 4 m. Higher accuracy would require a finer grid and a more accurate geoid model, such as EGM2008.

### 2.3.2 Global Reference System

The definition of a global terrestrial reference system (or, *terrestrial reference system*, TRS) began in earnest with the advent of Earth-orbiting satellites that enabled a realization of the center of mass and thus a natural origin for the coordinate system. Other names are conventional terrestrial reference system and geocentric terrestrial reference system. The roots of efforts to define a global system, however, can be traced back to the turn of the last century. In 1899, the *International Latitude Service* (ILS) was established by the *International Association of Geodesy* (IAG) to conduct astronomic latitude observations that monitor the motion of Earth's rotation axis relative to the Earth (polar motion, Sect. 2.5.3). By observing and disseminating this motion, latitudes and longitudes obtained by observing the stars could be corrected so that they refer to a fixed global terrestrial system.

In 1960, it was decided at the General Assembly of the *International Union of Geodesy and Geophysics* (IUGG) to adopt as terrestrial pole the average of the

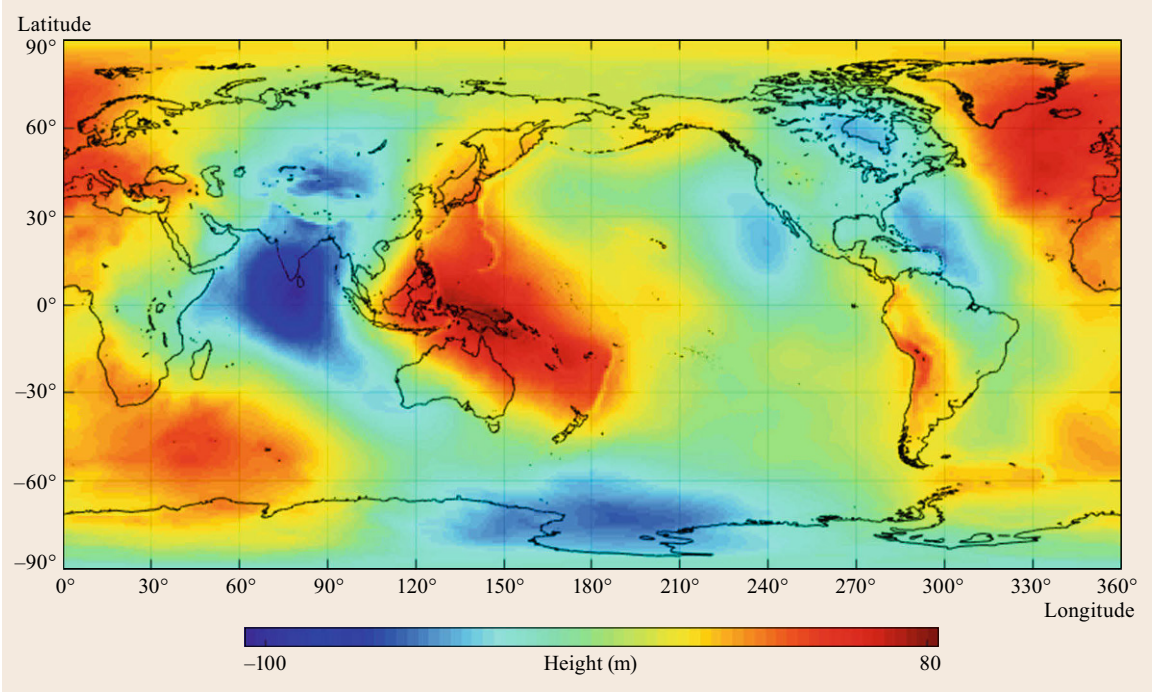

**Fig. 2.11** Geoid heights relative to the Earth ellipsoid (courtesy of Th. Fecher)

positions of the true celestial pole on the Earth during the period 1900–1905 (a 6 year period over which the Chandler period of 1.2 years would repeat five times; Sect. 2.5.3). This average was named the *Conventional International Origin* (CIO).

The global reference meridian, or, origin for longitudes, originally defined astronomically as the meridian through the Greenwich observatory, near London, England, was realized by an average, as implied by the longitudes of many observatories around the world, corrected for polar motion and length-of-day variations.

These early conventions and procedures to define and realize a terrestrial reference system addressed astronomic *directions* only; no attempt was made to define a realizable origin, although implicitly it could be considered as geocentric. In 1984, the BIH, responsible until this time for monitoring the pole and the Greenwich meridian, defined the BIH Conventional Terrestrial System (CTS) (or also BTS) based on satellite laser ranging (SLR), VLBI, and other space techniques. With the inclusion of satellite observations, an (indirectly) accessible geocentric origin of the system could now be defined. New and better satellite and VLBI observations became available from year to year, and the BIH published new realizations of its system: BTS84, BTS85, BTS86, and BTS87. With the orientation of the TRS now defined by geometric satellite and space observations, the origin of geodetic longitudes, to be consistent with its astronomic counterpart (maintained for continuity in time keeping), is now about 102 m to the east of the Greenwich Observatory, which accounts for the local deflection of the vertical [2.45].

In 1988, the functions of monitoring the pole and the reference meridian were turned over to the newly established *International Earth Rotation Service* (IERS). The time service, originally also under the BIH, now resides with the BIPM. The new reference pole realized by the IERS, called the *International Reference Pole* (IRP), was adjusted to fit the BIH reference pole of 1967 – 1968 and presently is consistent with the CIO to within $\pm 0.03''$ (1 m).

The IERS, renamed in 2003 to *International Earth Rotation and Reference Systems Service* (retaining the same acronym), is responsible for defining and realizing both the *International Terrestrial Reference System* (ITRS) and the *International Celestial Reference System* (ICRS). In each case, an origin, an orientation, and a scale are defined among other conventions for the system. The system is then realized as a frame by the specification of these datum parameters and the coordinates of points worldwide. Since various observing systems (analysis centers and techniques) contribute to the overall realization of the reference system and since new realizations are obtained recurrently with improved observation techniques and instrumentation, the transformations among various realizations of the system are of paramount importance. Especially, if one desires to combine data referring to realizations of different reference systems, or to different realizations of the same system, it is important to understand the coordinate relationships so that the data are combined ultimately in one consistent coordinate system.

The ITRS is defined by an orthogonal triad of right-handed, equally scaled axes with the following additional conventions:

1. The *origin* is geocentric, that is, at the center of mass of the Earth (including the mass of the oceans and atmosphere). Because measurement precision has reached the level of detecting variations in the center of mass due to terrestrial mass redistributions, the origin is defined as an average location of the center of mass and referred to an epoch.
2. The *scale* is defined by the SI meter, which is based on an adopted speed of light in vacuum and is connected to the definition of the SI second (Sect. 2.1).
3. The *orientation* is defined by the directions of the IRP and the reference meridian as given for 1984 by the BIH. Since it is now well established that Earth's crust (on which observing stations are located) is divided into tectonic plates that exhibit motion of the order of centimeters per year, it is further stipulated that the time evolution of the orientation of the reference system has no residual global rotation with respect to the crust (*no-net-rotation* condition). That is, even though the points on the crust, through which the system is realized, move with respect to each other, the net rotation of the system with respect to its initial definition should be zero.

The realization of the ITRS is the *International Terrestrial Reference Frame* (ITRF) and requires that three origin parameters, three orientation parameters, and a scale parameter must be identified with actual values. Each new ITRF of the system is named with the year that corresponds to the last available data incorporated in its realization. As of this writing (2015), the latest frame is ITRF2008 [2.46], and ITRF2013 is in preparation. The seven parameters are not observable without conventions (see below) and their specification is formulated by the IERS in terms of constraints imposed on the solution of coordinates from observations. Moreover, the constraints are cast in the form of a seven-parameter similarity transformation (commonly known as *Helmert* transformation) *from* an a priori given frame *to* the realized frame. The seven parameters include three translation parameters, $T_i$, that realize the origin; three

angle parameters, $R_i$, that realize the orientation; and, a scale change parameter, $D$, that realizes the scale

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix}_{\text{to}} = \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{\text{from}} + \begin{pmatrix} T_1 \\ T_2 \\ T_3 \end{pmatrix} + D \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{\text{from}} + \begin{pmatrix} 0 & -R_3 & +R_2 \\ +R_3 & 0 & -R_1 \\ -R_2 & +R_1 & 0 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}_{\text{from}} \tag{2.29}$$

where the translation and rotation parameters are defined in Fig. 2.12. For example, if the origin of an existing frame is known to be the geocenter, then the next realization, based on new observations, can be related to the previous frame by constraining the translation to be zero. The transformation given by (2.29) is a linear approximation where, because of the small values of the transformation parameters, the neglect of second- and higher order terms affects coordinates at the subnanometer level.

Because these datum (transformation) parameters are determined for points on the Earth's crust (*crust-based frame*), and because the Earth as a whole is a dynamic entity, the parameters are associated with an epoch, $t_0$, and, today, are supplemented with rates of change, making the total number of parameters equal to 14. Thus, the $i$-th transformation parameter, $\beta_i$, is a function of time,

$$\beta_i(t) = \beta_{0,i} + \dot{\beta}_{0,i}(t - t_0), \tag{2.30}$$

and the 14 parameters are $\beta_{0,i}$ and $\dot{\beta}_{0,i}$ with $i = 1, \ldots, 7$.

Whether the origin of a coordinate system is implied by a marker on the Earth's surface or accessed via distance measurements to Earth-orbiting satellites, it is defined by a convention, just like all other parts of the coordinate system. As such it is not, a priori, an observable quantity like a distance or an angle. This is the classic *datum defect* problem, well known in all types of surveying, where observations of distances and angles must ultimately be *related* to a point or direction that is fixed or defined by convention.

With satellite techniques, on the other hand, there is the advantage of knowing that the center of mass is the centroid for all orbits. Hence, the center of mass of the Earth serves as a natural origin point that, in theory, is accessible. That is, if the orbit is known, distance observations from points on the Earth's surface to points on the orbit are in a geocentric system, by definition. Due to observational error not all origin realizations, however, are identical as obtained by different analysis centers that, moreover, process different satellite data (such as satellite and lunar laser ranging [2.47, 48], GNSS [2.49], and Doppler data [2.50]). Generally, the most precise methods are based on SLR.

For the first ITRFs in the early 1990s, it was customary to relate all frames realized by particular analysis centers and/or satellite techniques to one of the SLR solutions from the Center for Space Research (CSR) in Austin, Texas, which was considered to be the best solution that accesses the center of mass and thus realizes the origin. The origins of solutions (i. e., realized coordinate systems) from other techniques, such as Doppler and GPS, were related by IERS to the ITRF origin through a translation determined by using stations that are common to both the CSR and the other solutions. For later ITRFs, a weighted average of selected SLR and GPS solutions was used to realize the origin. The origin of ITRF2000 was realized by a weighted average of *the most consistent SLR solutions* submitted to the IERS. With ITRF2005 and ITRF2008, the IERS used a time series over 13 years and 26 years, respectively, of reprocessed SLR data at selected, globally distributed sites to realize the origin.

Similarly, the scale was realized for the early ITRFs by the SLR solutions from the CSR analysis center, with the scale of other solutions transformed accordingly. For later realizations of scale, SLR was combined with VLBI, which accurately determines coordinate

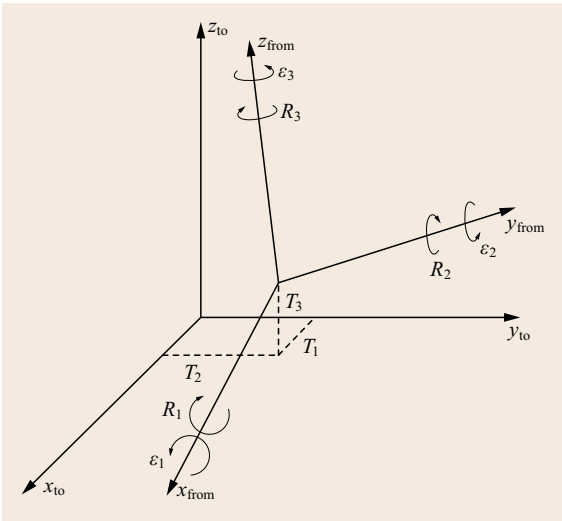

**Fig. 2.12** Transformation parameters between coordinate frames. The similarity transformation (2.29) yields the coordinates of a point in a new frame $\mathcal{R}_{\text{to}}$ that originates from the old frame $\mathcal{R}_{\text{from}}$ through translation of the origin by $-T_i$ ($i = 1, 2, 3$) and a *left*-handed rotation about the $i$-th axis by angle $R_i$. Rotation angles $R_i$ comply with IERS conventions, whereas rotation angles $\varepsilon_i = -R_i$ (corresponding to right-handed rotations), are used by the US National Geodetic Survey

differences of stations separated by large distances (several 1000 km) using observed directions to quasars [2.6, Chap. 4.2.2].

Satellite and space observational techniques contain no information on the absolute longitudinal orientation of a system. This orientation has no obvious natural reference and is completely arbitrary (the Greenwich meridian). One might argue that the orientation of the equatorial plane (or, equivalently, the polar direction), like the center of mass, is a natural reference that is accessible indirectly from astronomic observations, VLBI, and satellite tracking. However, the polar direction is complicated, a result of both polar motion with respect to the Earth's crust (Sect. 2.5.3), and precession and nutation with respect to the celestial sphere (Sect. 2.5.1). Besides this, the stations on the Earth's crust, which ultimately realize the ITRS, are in constant motion due to plate tectonics. Thus, the adopted convention for realizing the orientation of the ITRS is to ensure that each successive realization after 1984 is aligned with the orientation defined by the BIH in 1984 (with some early adjustments for different solutions of the Earth orientation parameters (Sect. 2.5.1)).

The methods of combining different solutions and introducing the constraints needed to address the datum defect (i. e., specifying origin, scale, and orientation) have become increasingly complicated as more data are assimilated and analysis centers employ different weighting schemes to account for the various observational accuracies. Relevant details may be found in the IERS Conventions of 2003 and 2010 and references therein, specifically also publications by [2.51, 52] and their references.

The model for the coordinates of any of the observing stations participating in the realization of ITRS is given by

$$\boldsymbol{x}(t) = \boldsymbol{x}_0 + (t - t_0)\boldsymbol{v}_0 + \sum_i \Delta \boldsymbol{x}_i(t) \,, \tag{2.31}$$

where $\boldsymbol{x}_0$ and $\boldsymbol{v}_0$ are the vectors of the coordinates of the observing station and its velocity, defined for a particular epoch, $t_0$. These are solved on the basis of observed coordinates, $\boldsymbol{x}(t)$, at time, $t$, using some type of observing system (e.g., SLR). The quantities, $\Delta \boldsymbol{x}_i$, are corrections applied by analysis centers to account for various, short wavelength, local geodynamic effects, such as solid Earth tides, ocean loading, and atmospheric loading (Sect. 2.3.5), with the objective of accounting for the nonconstant velocities. Details for the corresponding recommended models are provided by the IERS Conventions 2010 [2.6, Chap. 7]. The coordinate vector, $\boldsymbol{x}_0$, and the linear velocity, $\boldsymbol{v}_0$, for each participating station is provided by IERS as a result of the assimilation of all data, and these represent the consequent realization of ITRS at epoch $t_0$.

In the past, the linear velocity was modeled largely by the NNR-NUVEL1A tectonic plate motion model [2.32, 53, 54]. Thus,

$$\boldsymbol{v}_0 = \boldsymbol{v}_{\mathrm{NUVEL1A}} + \delta \boldsymbol{v}_0 \,, \tag{2.32}$$

where $\boldsymbol{v}_{\mathrm{NUVEL1A}}$ is the velocity given as a set of rotation rates for the major tectonic plates, and $\delta \boldsymbol{v}_0$ is a residual velocity for the station. The major tectonic plates and site velocities predicted from a plate motion model are illustrated in Fig. 2.13. The newest ITRFs (since ITRF2000) appear to indicate significant departures of the station velocities $\boldsymbol{v}_0$ from the NNR-NUVEL1A model [2.55], which, however, does not impact the integrity of the ITRF.

### 2.3.3 Terrestrial Reference Systems for GNSS Users

The various navigation satellite systems have adopted specific reference systems for the provision of orbit information to their users. While the associated realizations may traditionally exhibit small offsets with respect to each other, GNSS providers are making continued effort to align the respective realizations with current versions of the ITRF.

In case of the US Global Positioning System, the World Geodetic System 1984 (WGS84, [2.56]) serves as the basis for orbit determination and broadcast ephemeris generation in the GPS control segment. WGS84 is the equivalent of the ITRS for the US Department of Defense (and includes also a global gravitational model). It is the evolution of previous reference systems, WGS60, WGS66, and WGS72 [2.57]. The corresponding reference frame for WGS84, as originally realized in 1987 on the basis mostly of satellite Doppler observations, agreed approximately with NAD83. The next realization, designated WGS84(G730), made use of observations from 12 GPS stations around the world and was aligned with the ITRF92 to an accuracy of about 20 cm in all coordinates. Here, G730 refers to GPS week 730 (Jan. 1994), the reference epoch of the WGS84 realization. Subsequent versions, known as WGS84(G873), WGS84(G1150) [2.58], and WGS84(G1674) [2.59], achieved continual improvements and are consistent, respectively, with ITRF94, ITRF2000, and ITRF2008 at the level of 10, 2, and 1 cm accuracy.

For the Russian Global'naja Nawigatsionnaja Sputnikowaya Sistema (GLONASS), the PZ-90 (Parametry Zemli – 90) system is employed. PZ-90 follows the same principles as the ITRS and WGS84, but is realized

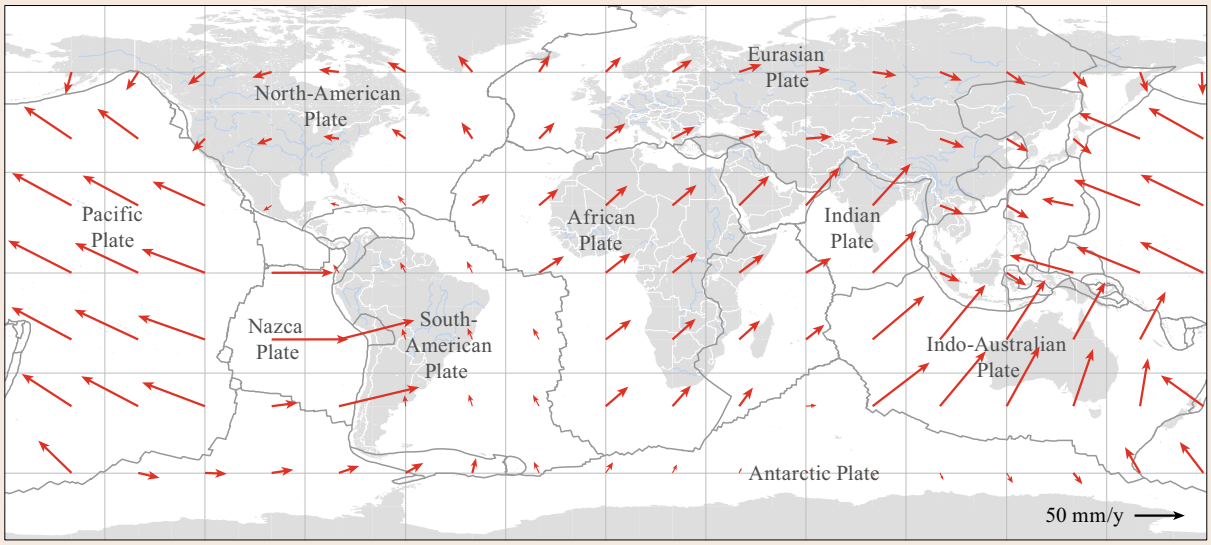

**Fig. 2.13** Tectonic plates and predicted site velocities

through different reference stations and measurements. While the initial release of PZ-90 exhibited meter-level offsets from WGS84, the consitency was notably improved in 2007 with introduction of PZ-90.2 [2.60]. In early 2014, the GLONASS Control Segment finally switched to PZ-90.11 [2.61, 62], which offers a centimeter-level agreement with the latest ITRF versions.

Next to WGS84 and PZ-90, independent reference systems/frames are also employed for the BeiDou (China Geodetic Coordinate System 2000, CGS2000 [2.63]) as well as the European Galileo navigation system (Galileo Terrestrial Reference Frame, GTRF [2.64]).

### 2.3.4 Frame Transformations

The parameters of the Helmert similarity transformation (2.29) are determined in a weighted least-squares adjustment of the transformation model for the differences between coordinates of the same points in two frames. Table 2.2 lists the transformation parameters among the various IERS (and BIH) terrestrial reference frames since 1984. Due to the linear nature of the transformation, the reverse transformation is obtained by simply reversing the signs of the parameters. Also, the parameter values for a transformation between nonsuccessive frames are simply the accumulated values between the frames. However, especially for the later frames, the epoch of their validity must be considered. Rates of the parameters are given only since 1993 and (2.30) yields transformation parameters for other than the listed epoch. Using the last row of Table 2.2 as an example, the translation in $x$ between ITRF2005 and ITRF2008 at the epoch $t = 2000.0$ is given by

$$\begin{aligned} T_1(t) &= T_1(t_0) + \dot{T}_1 \cdot (t - t_0) \\ &= 0.05\,\text{cm} - 0.03\,\text{cm/y} \cdot (-5\,\text{y}) \\ &= 0.20\,\text{cm}\,. \end{aligned} \tag{2.33}$$

On the other hand, each of the determined parameters also has an associated uncertainty (given by the IERS, but not listed in Table 2.2, which should be properly included in any such calculation).

Table 2.3 lists transformation parameters from the original realization of WGS84 to ITRF90 as published by the IERS [2.65], as well as from recent ITRFs to NAD83(CORS96) as published by the National Geodetic Survey [2.67]. There is no origin, scale, and orientation change between NAD83(2011) and NAD83(CORS96). Again, uncertainties in the parameters are not listed. Also, the more recent realizations WGS84 are essentially equivalent to the correspondingly contemporary ITRF (Sect. 2.3.3).

Resolutions 1 and 4 of the 1991 IAG General Assembly [2.68] recommend that regional high-accuracy reference frames be tied to an ITRF, where such frames associated with large tectonic plates may be allowed to rotate with these plates as long as they coincide with an ITRF at some epoch. This procedure was adopted for NAD83, which for the conterminous United States and Canada lies (mostly) on the North American tectonic plate. This plate has global rotational motion estimated

**Table 2.2** Transformation parameters among ITRF and BTS frames for use with the 7/14-parameter Helmert model (2.29) and (2.30). Time-dependent transformation parameters are provided from ITRF93 onward. Based on data from [2.6, 65, 66]

according to the NNR-NUVEL1A model [2.54] by the rates

$$\begin{aligned} \Omega_x &= +0.000258 \cdot 10^{-6}\,\text{rad/y} &&= +0.053\,\text{mas/y} \\ \Omega_y &= -0.003599 \cdot 10^{-6}\,\text{rad/y} &&= -0.742\,\text{mas/y} \\ \Omega_z &= -0.000153 \cdot 10^{-6}\,\text{rad/y} &&= -0.032\,\text{mas/y} \end{aligned} \tag{2.34}$$

which explain the rotation parameter rates between NAD83 and ITRF in Table 2.3.

Coordinates of a control point in any particular frame are listed in terms of the Cartesian vector $\boldsymbol{x}_0$ and a velocity $\dot{\boldsymbol{x}}_0$, both at a given epoch $t_0$ so that at any other epoch the coordinates within that frame are

$$\boldsymbol{x}(t) = \boldsymbol{x}_0 + \boldsymbol{v}_0 (t - t_0)\,. \tag{2.35}$$

Transformation between frames and epochs requires consideration of both the point velocity within a frame and the velocity of the transformation parameters. Thus,

$$\boldsymbol{x}_{\text{from}}(t_0) \xrightarrow{\beta_0} \boldsymbol{x}_{\text{to}}(t_0) \xrightarrow{\dot{x}_0} \boldsymbol{x}_{\text{to}}(t) , \tag{2.36}$$

or, also,

$$\boldsymbol{x}_{\text{from}}(t_0) \overset{\dot{x}_{\text{from}}(t_0)}{\rightarrow} \boldsymbol{x}_{\text{from}}(t) \xrightarrow{\beta(t)} \boldsymbol{x}_{\text{to}}(t) . \tag{2.37}$$

Transformations (2.36) and (2.37) are equivalent if the point and frame velocities are related according to

$$\dot{\boldsymbol{x}}_{\text{to}} = \dot{\boldsymbol{x}}_{\text{from}} + \dot{\boldsymbol{T}} + \dot{\mathbf{D}}\boldsymbol{x}_{\text{from}} + \dot{\boldsymbol{\Omega}}\boldsymbol{x}_{\text{from}} , \tag{2.38}$$

where

$$\boldsymbol{\Omega} = \begin{pmatrix} 0 & -R_3 & +R_2 \\ +R_3 & 0 & -R_1 \\ -R_2 & +R_1 & 0 \end{pmatrix} , \tag{2.39}$$

which is the time derivative (neglecting second and higher order terms) of (2.29).

For most points within a regional frame, such as NAD83, the within-frame velocity of a point is small compared to the velocity of that same point in the ITRF, since, in this example, most of the velocity within the ITRF is due to the motion of the North American plate, and the NAD83 rides along with that plate. However, points on another plate within the NAD83 frame, such as points on the West Coast that are on the Pacific Plate, experience significant motion within the frame.

### 2.3.5 Earth Tides

Because the Earth is not a rigid body, the coordinates of points on its surface change in time in response to forces that deform its crust. The largest of these is due to the gravitational attractions of the Sun and Moon, which not only create the familiar periodic motion of the ocean tides, but also deform any point on (or below) the elastic Earth. The resulting periodic motion is called the *Earth tide* or *body tide*. Furthermore, because of the ocean tides, there is a secondary loading effect that deforms the crust especially at points near coastal areas. These tidal deformations are part of the corrections $\Delta\boldsymbol{x}_i(t)$ in (2.31).

In addition to the tide-induced corrections, there are other environmental effects, such as subsidence or uplift due to natural geophysical effects (earthquakes, post-glacial rebound) or anthropogenic activities (subsurface mineral and water extraction), and due to local hydrological effects (seasonal, secular, and episodic changes). These are site specific and dependent on local models.

The starting point for computing the tidal effect is the *tidal potential*, which accounts for the relative gravitational attraction of the Sun and Moon (other bodies have negligible effect). It is defined as the residual potential after removing the potential associated with the gravitational acceleration that is constant at all material points of the Earth. Assuming that the gravitational effect of a celestial body, $B$ (e.g., the Sun, $\odot$, or Moon, ), may be approximated as that of a point mass at location, $(r_B, \phi_B, \lambda_B)$, in the terrestrial reference system, the principal tidal potential at $(r, \phi, \lambda)$ and time $t$ is given by [2.2, p. 132]

$$V^{(B)}(r,\phi,\lambda,t) = \frac{GM_B}{5r_B}\left(\frac{r}{r_B}\right)^2 \times \sum_{m=0}^{2} \overline{P}_{2,m}(\sin\phi)\,\overline{P}_{2,m}(\sin\phi_B)\cos(mt_B) , \tag{2.40}$$

where $G$ is Newton's gravitational constant, $M_B$ is the mass of the body, $\bar{P}_{2,m}$ is a second-degree, $m$-th order, fully normalized, associated Legendre function [2.42] and

$$t_B = t_\Upsilon^G + \lambda - \alpha_B \tag{2.41}$$

is the hour angle of the body, combining $\lambda$, the Greenwich sidereal time, $t_\Upsilon^G$, and the right ascension, $\alpha_B = t_\Upsilon^G + \lambda_B$, of the body (Fig. 2.16). The coordinates, $r_B, \phi_B, \alpha_B$, and $t_\Upsilon^G$ are functions of time describing both the orbit of the body around the Earth and Earth rotation.

Equation (2.40) separates the long-period tides ($m = 0$) that have annual, semiannual, monthly, and fortnightly periods due to the orbital motion of the Earth and Moon, and the diurnal ($m = 1$) and semidiurnal ($m = 2$) tides due to Earth's rotation. In fact, (2.40) is an approximation that includes only the second-degree harmonics of the potential. Including third-degree harmonics, having the much smaller factor, $(r/r_B)^3$, and Legendre functions, $\bar{P}_{3,m}$, $m = 0, 1, 2, 3$, would introduce terdiurnal periods.

The tidal potential includes a permanent tide potential that is the average over time. Only the $m = 0$ term contributes and is calculated by averaging $\phi_B(t)$ over one orbit assuming $r_B$ is constant [2.69],

$$V^{(B)}_{\text{perm}}(r,\phi) = \frac{3}{8}\frac{GM_B r^2}{r_B^2}\left(3\sin^2\phi - 1\right)\cdot\left(\sin^2\varepsilon - \frac{2}{3}\right) , \tag{2.42}$$

where $\varepsilon$ is the obliquity of the ecliptic (Sect. 2.4). Since the potential is a scalar function, the law of superposition says that the tidal potential due to all bodies is the sum of the individual tidal potentials; thus, $V = V^{☾} + V^{☉}$.

The tidal deformation of points on the Earth derives heuristically from the elasticity of the Earth and *Hooke's law*, which states that a displacement of the end of an elastic spring (the Earth's surface in this case) is linearly proportional to an applied force (the gravitational pull by the body). The gravitational pull (per unit mass) is the gradient of the potential; and, as a vector it creates a three-dimensional deformation in the radial and locally horizontal directions (Fig. 2.7),

$$\begin{pmatrix} \Delta u \\ \Delta v \\ \Delta w \end{pmatrix} = \begin{pmatrix} \ell_2 \dfrac{a}{g_0} \dfrac{\partial V}{r \cos\phi \, \partial\lambda} \\ \ell_2 \dfrac{a}{g_0} \dfrac{\partial V}{r \partial\phi} \\ \dfrac{\mathrm{h}_2}{2} \dfrac{a}{g_0} \dfrac{\partial V}{\partial r} \end{pmatrix} , \tag{2.43}$$

where Earth's equatorial radius, $a$, and an average value of Earth's gravity, $g_0$, are introduced so that the *spring constants*, $h_2$, $\ell_2$, are dimensionless (the subscript refers to the second-degree model of the tidal potential). Indeed, $h_2$ was postulated by A.E.H. Love in 1909 and has become known as a *Love number*. The factor of 2 is included here since Love originally assumed simple proportionality to the tidal potential. In fact, for points on a spherical Earth, $\partial V/\partial r = 2V/a$; see also [2.70] for a definition in terms of vector spherical harmonics that is adopted by the IERS. Likewise, $\ell_2$ is called a *Shida number*, although both are now generically called Love numbers.

The displacements given by (2.43) include a component due to the permanent tide, (2.42); but, such a displacement is time invariant and cannot be observed. Although the IAG in 1984 recommended that station coordinates *not* be corrected for the permanent tidal deformation, the continuing practice is to apply the full tidal effect, thus placing the coordinates in a *tide-free system*, rather than the recommended *mean-tide system*, which only has time-varying components removed [2.6, p. 108].

Nominal values for the Love numbers are [2.6]

$$\mathrm{h}_2 = 0.61 \quad \text{and} \quad \ell_2 = 0.085 \,, \tag{2.44}$$

which yield, with the corresponding astronomical constants for the Moon and Sun, a permanent deformation at the equator of $\Delta w^{(0)} = 5.5\,\mathrm{cm}$ and $\Delta w^{(0)}_{☉} = 2.5\,\mathrm{cm}$. The diurnal variations with respect to these mean values and the simple model above amount to less than 20 cm for the Moon and less than 10 cm for the Sun.

The Love numbers depend strongly on the density and elastic properties of the Earth, including its liquid core, and to a lesser extent on its ellipticity and changes in Earth orientation (nutation and polar motion). In particular, the resonance with the nearly diurnal free wobble (free core nutation, Sect. 2.5.3) is significant and illustrates that the Love numbers are also frequency dependent. The simple model has been extended with various levels of sophistication to account for the deformations observed with VLBI; see [2.70–72], and references therein, and [2.6] that summarizes the recommended formulas.

The secondary effect on station positions, due to ocean loading, depends on the ocean tide model and is computed using a convolution of ocean tide height with a Green's function [2.73]. The effect can be several percent of the body tide effect within continents and several 10% near the coast [2.30]. Another source of variable loading comes from the atmospheric tides resulting from the diurnal heating by the Sun. These mm-to-cm effects can be computed from corresponding atmospheric tidal models based on worldwide barometric data.

The centrifugal acceleration associated with Earth's rotation changes at a point with changes in the direction of the rotation axis with respect to the crust (and thus the terrestrial reference system). This implies a further deformation for an elastic Earth with the periods of polar motion (Sect. 2.5.3). It is called the *pole tide* although the source is not an external gravitational field. The centrifugal acceleration, $\boldsymbol{a}_c = \nabla V_c$, may be associated with a centrifugal potential, $V_c$, whose residual relative to $V_c^{(0)} = 0.5\omega_⊕^2 \left(x^2 + y^2\right)$, is shown by [2.71] to be, in first-order approximation

$$\delta V_c = -\frac{\omega_⊕^2}{2} r^2 \sin 2\phi \left(x_\mathrm{p} \cos\lambda - y_\mathrm{p} \sin\lambda\right) , \tag{2.45}$$

where $x_\mathrm{p}, y_\mathrm{p}$ are the coordinates of the pole in the TRS (Sect. 2.5.3), measured in radians. This has the same form as the second-degree tidal potential (2.42) due to an extraterrestrial body; and, the corresponding crustal deformation is given by (2.43). Since $|x_\mathrm{p}|, |y_\mathrm{p}| \approx 0.2''$ relative to the current mean position, the vertical variation is of the order of 0.6 cm. The effect of ocean loading due to the pole tide, again, is site and ocean-basin model dependent and at the level of a millimeter [2.6, Chap. 7].

## 2.4 Celestial Reference System

Throughout history and today the ultimate reference system for positioning and navigation on and near the Earth, as well as within our solar system is an astronomic system. Its modern manifestation is the *celestial reference system* (CRS). By definition, it is an *inertial* system, which means that it is in free fall in the gravitational field of the universe and does not rotate. It is a system in which the laws of physics in the context of the theory of general relativity hold without requiring corrections for rotations. For geodetic purposes the CRS serves as the primal reference for positioning since it has no dynamics. Conversely, it is the system with respect to which we study the dynamics of the Earth as a rotating body. And, finally, it serves, of course, also as a reference system for astrometry.

The *celestial reference frame* (CRF) is the realization of the CRS based on a set of coordinates of objects on the celestial sphere. For this purpose the origin of the celestial sphere, and thus the CRS, is defined to be the *barycenter* of the solar system, which is the center of mass, as realized by the orbits of the planets. When appropriate or necessary, one also makes the distinction between the CRS and the *geocentric celestial reference system* (GCRS).

The origins, or zero points, of the celestial coordinates, declination and right ascension, have changed definition with a fundamental redefinition of the CRS in 1998. Prior to this time, the definition of the celestial reference system was tied directly to the dynamics of the Earth, whereas, today it is defined almost completely independent of the Earth, although the difference in realizations is defined to be minimal for the sake of continuity. The traditional system refers to two natural directions, the mean direction of Earth's spin axis, or the *north celestial pole* (NCP), and the direction of the *north ecliptic pole* (NEP), which is perpendicular to the mean ecliptic plane defined by Earth's orbit around the Sun (Fig. 2.14).

A point where the ecliptic crosses the celestial equator on the celestial sphere is called an equinox. At the *vernal equinox*, $\Upsilon$, the Sun crosses the celestial equator from south to north as viewed from the Earth. It is the point on the Earth's orbit when Spring starts in the Northern Hemisphere. The angle between the celestial equator and the ecliptic is the *obliquity of the ecliptic*, approximately $\varepsilon = 23.44°$.

The direction of the vernal equinox defines the traditional origin for right ascension and the celestial equator is the origin for declination, as shown in Fig. 2.15. The system of celestial coordinates is also known as the *equatorial right ascension system*. The first and third axes of this system are, respectively, the directions of the vernal equinox and the NCP, which are perpendicular since the vernal equinox lies in the equatorial plane. The second axis is perpendicular to the other two axes so as to form a right-handed system. The intersection of the celestial sphere with the plane that contains both the third axis and a celestial object is called the *hour circle* of the object (Fig. 2.16). The right ascension system is the basis for the celestial reference system, where one must further fix the axes since both the vernal equinox and the NCP are dynamic directions that vary in time due to gravitational effects on Earth's rotational direction and its orbit.

The relationship between the right ascension and longitude on the Earth is illustrated in Fig. 2.16 under the assumption that the terrestrial pole and the NCP have the same direction (Sect. 2.5.1). The name, hour circle, refers to the convention that the right ascension of an object is also given in terms of a sidereal time interval (Sect. 2.1.3), where 15° of right ascension is equivalent to 1 h of sidereal time.

In order to define a reference system, it was necessary to establish the theory of motion of the NCP and the equinox, called the theory of nutation and precession (Sect. 2.5). Moreover, the realization of the reference system was stamped with an epoch for which it was valid; it was typical to determine a new realization every 25 years to reflect the dynamics of the reference system, as well as any updates in the theories

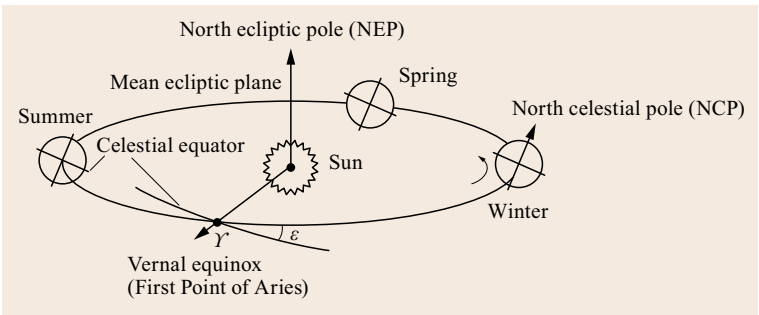

**Fig. 2.14** Mean ecliptic plane (seasons are for the Northern Hemisphere). and natural directions for the celestial reference system

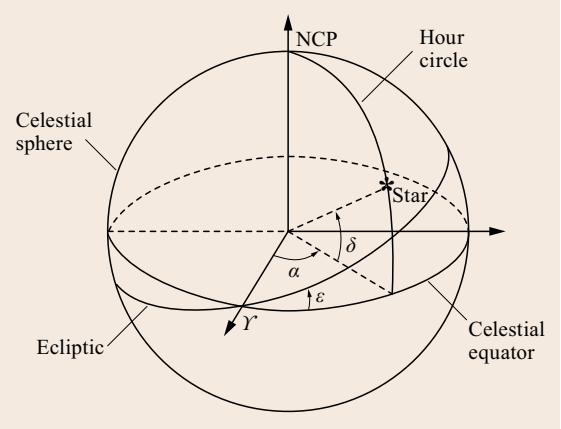

**Fig. 2.15** Celestial coordinates, $\alpha$, $\delta$, in the equatorial right ascension system

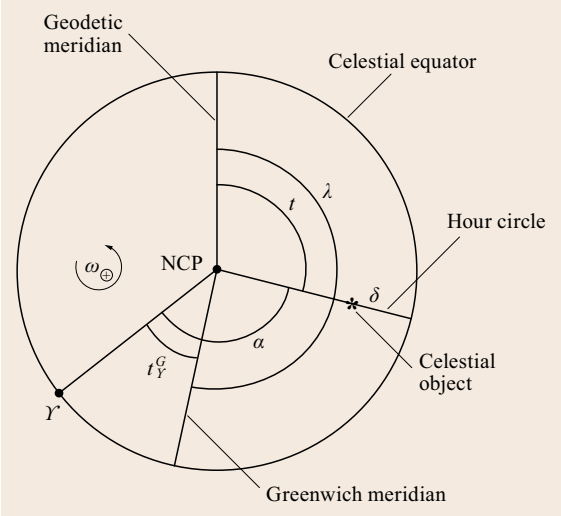

**Fig. 2.16** Relationship between right ascension and longitude (idealized without polar motion). The meridian of a terrestrial point and the Greenwich meridian rotate relative to the vernal equinox due to Earth's rotation rate, $\omega_\oplus$. The hour angle, $t_\Upsilon^G$, is also the Greenwich sidereal time

of motion [2.5, p. 167]. The last such realization was the FK5 (Fundamental Catalog No. 5) of stars referring to the best computed equinox and NCP for the epoch, J2000. The origins of right ascension and declination were determined indirectly from an adjustment of observed coordinates of celestial objects and their proper motions (in other words, the equinox is not observed directly).

The change in definition of the CRS adopted by the International Astronomical Union (IAU) in the 1990s was enabled by the then established history of very accurate observations of quasars (quasi-stellar radio sources) using the technique of Very Long Baseline Interferometry (VLBI, [2.39, Chap. 11.1]). Since these beacons are at such great distances that no proper motion can be detected, that is, they have no perceptible rotation on the celestial sphere, they may be used to define an inertial system.

This new definition of the CRS represents a change as fundamental as that which transferred the origin of the regional terrestrial reference system (i. e., the horizontal geodetic datum) from a monument on Earth's surface to the geocenter. By relying strictly on geometrically defined points on the celestial sphere, the definition of the CRS has changed from a *dynamic* system to a *kinematic* (or geometrical) system. The axes of the celestial reference system are still (close to) the NCP and vernal equinox, but are not defined dynamically in connection with Earth's motion. Rather they are tied to the defining set of quasars whose coordinates are given with respect to these axes. Moreover, there is no need to define an epoch of reference, because (presumably) these directions will never change in inertial space (at least in the foreseeable future of mankind).

The IERS officially created the *International Celestial Reference System* (ICRS) starting in 1998 based on 212 defining sources, which then also constitute the realization of the system, the *International Celestial Reference Frame* (ICRF). An additional 396 *candidate* or other less well observed sources were used as additional ties to the reference frame. The origin of the ICRS is defined to be the center of mass of the solar system (*barycentric* system) and is realized by observations of planets and other bodies in the solar system (such as the Jet Propulsion Laboratory (JPL) development ephemerides) in the framework of the theory of general relativity. These dynamical planetary ephemerides are aligned with the ICRF to high accuracy [2.6, Chap. 3].

By Recommendation VII of the 1991 IAU General Assembly, the NCP and equinox of the ICRS are supposed to be close to the mean dynamical pole and equinox of J2000.0. Furthermore, the adopted pole and equinox for ICRS should be consistent with the directions realized for FK5. Specifically, the origin of right ascension for FK5 was originally defined on the basis of the mean right ascension of 23 radio sources from various catalogs, with the right ascension of one particular source fixed to its FK4 value, transformed to J2000.0. Similarly, the FK5 pole was based on its J2000.0 direction defined using the 1976 precession and 1980 nutation series (Sect. 2.5). The FK5 directions are estimated to be accurate to $\pm 50$ mas (milli-arcsec) for the pole and $\pm 80$ mas for the equinox; and, it is now known, from improved observations and dynamical models, that the ICRS pole

and equinox are close to the mean dynamical equinox and pole of J2000.0, well within these tolerances. The precise transformation to a dynamical system is a *frame bias* that is included in the modern formulations of the transformations between the celestial and terrestrial reference frames (Sect. 2.5). This bias is well determined and of the order of 10 mas [2.6, 74].

As the VLBI measurements of the quasars improve, the orientation of the ICRF will be adjusted with the constraint that it has no net rotation with respect to previous realizations (analogous to the ITRF). The original realization is designated ICRF1; and, it was extended in 1999 and again in 2002 with additional objects observed by VLBI, totaling 667 and 717, respectively. The next significant realization, designated ICRF2, was constructed in 2009, where now 295 quasars define the system (being more stable and better distributed in the sky than for ICRF1), and which also includes 3119 secondary extragalactic sources.

Aside from VLBI, the principal realization of the ICRS is through the Hipparcos catalog, based on recent observations of some 120 000 well-defined stars using the Hipparcos (High Precision Parallax Collecting Satellite), optical, orbiting telescope. This catalog is tied to the ICRF with an accuracy of about 0.6 mas in each axis. Additional catalogs for up to 100 million stars are described by [2.6].

## 2.5 Transformations Between ICRF and ITRF

The transformation from the CRF to the terrestrial reference frame requires an understanding of the dynamics of Earth rotation and its orbital motion, as well as the effects of observing celestial objects on a moving and rotating body such as the Earth. Even though the new definition of the celestial reference system (Sect. 2.4) no longer relies on models for the dynamics of the Earth's pole and the vernal equinox, but because the terrestrial system is fixed to the Earth, any transformation between celestial and terrestrial frames still does depend explicitly on these dynamics.

The description of the transformation, comprising *Earth orientation parameters*, has also changed with the adoption of the new system definition. Here, both the traditional description and the modern transformation are treated, where the traditional one is perhaps a bit more accessible in terms of physical intuition, whereas, the latter tends to hide these concepts. Furthermore, the new approach implements certain nuances necessary for an unambiguous definition of Earth rotation. Thus, the following starts with the traditional approach and evolves into the modern transformation formulas.

The theoretical description of Earth's *dynamics* in inertial space requires a system of time, and dynamic time, being theoretically the most uniform in scale (Sect. 2.1) is the natural choice. Because many of the dynamics vary on scales of years or longer, the time variable, $\tau$, is expressed typically as a (unit-less) fraction of a Julian century relative to a fixed epoch

$$\tau = \frac{t - t_0}{36\,525}\,, \tag{2.46}$$

where $t_0 = 2451545.0$ is the Julian day number for J2000.0 and $t$ is the Julian day number of the epoch of date.

### 2.5.1 Orientation of the Earth in Space

The gravitational interaction of the Earth with the other bodies of the solar system, including primarily the Moon and the Sun, but also the planets, cause Earth's orbital motion to deviate from the simple Keplerian motion of two point masses in space. Also, because the Earth is not a perfect homogeneous sphere, its rotation is affected likewise by the gravitational action of the bodies in the solar system. If there were no other planets (only the Earth/Moon system) then the orbit of the Earth/Moon system around the Sun would be essentially a plane fixed in space. This plane defines the ecliptic (Sect. 2.4). But the gravitational forces of the planets cause this ecliptic plane to behave in a dynamic way, called *planetary precession*.

If the obliquity of the ecliptic were zero (or the Earth were not flattened at its poles), then there would be no gravitational torques due to the Sun, Moon, and planets acting on the Earth's bulging equator. But since $\varepsilon \neq 0$ and $f \neq 0$, these celestial bodies (primarily, the Sun and Moon) do cause a precession of the equator and, hence, the pole, that is known as *luni-solar precession* and *nutation*, depending on the period of the motion [2.75]. That is, the equatorial bulge of the Earth and its tilt with respect to the ecliptic allow the Earth to be torqued by the gravitational forces of the Sun, Moon, and planets, since they all lie approximately on the ecliptic plane. Planetary precession together with luni-solar precession is known as *general precession*.

The complex dynamics of the precession and nutation is a superposition of many periodic motions originating from the myriad of periods associated with the orbital dynamics of the corresponding bodies. Conventionally, the period of 18.6 years associated with

the longest lunar cycle separates nutation from precession, where the latter can be described virtually as a secular motion of the pole and equinox owing to their fundamental respective periods of about 25 800 and 28 100 years. The periods of nutation depend primarily on the orbital motion of the Moon relative to the orbital motion of the Earth. The most recent models for nutation also contain short-periodic effects due to the relative motions of the planets. In terms of transformations, precession has been viewed as an accumulation of *mean* motion over a time interval, whereas, nutation is thought of as the correction, or residual, that transforms from the mean to the true location of the pole and equinox at a particular instant in time.

The theory for determining the motions of the coordinate reference directions was developed by Simon Newcomb at the turn of the twentieth century. Its basis lies in celestial mechanics and involves the *n*-body problem for planetary motion, for which no analytical solution exists. Instead, iterative, numerical procedures have been developed and formulated [2.76].

### Precession

*Planetary precession* may be described by two angles, $\pi_A$ and $\Pi_A$, where the subscript, $A$, refers to the *accumulated* angle from some fixed epoch, $t_0$, to some other epoch, $t$. Figure 2.17 shows the geometry of the motion of the ecliptic due to planetary precession from $t_0$ to $t$. The pictured ecliptics and equator are fictitious in the sense that they are affected only by precession, but not nutation, and as such are called *mean ecliptic* and *mean equator*. The angle, $\pi_A$, is the angle between the mean ecliptics at $t_0$ to $t$; while, $\Pi_A$ is the ecliptic longitude of the point, M, on the celestial sphere, which identifies the axis of rotation of the ecliptic due to planetary precession. The vernal equinox at $t_0$ is denoted by $\Upsilon_0$. Expressions for $\pi_A$ and $\Pi_A$ are truncated time series based on the celestial dynamics of the planets.

The *luni-solar precession*, on the other hand, also depends on the geophysical parameters of the Earth. Due to the more complicated nature of the Earth's shape and internal constitution, no analytic formula based on theory has been used for this part of the precession. Instead, Newcomb gave an empirical parameter, (now) called *Newcomb's precessional constant*, based on observed rates of precession. In fact, this *constant* rate is not strictly constant, as it depends slightly on time through a general relativistic term called the *geodesic precession* [2.77]. Newcomb's precessional constant depends on Earth's moments of inertia and enters in the dynamical equations of motion for the celestial equator due to the gravitational torques of the Sun and Moon.

Figure 2.18 shows the accumulated angles of planetary and luni-solar precession near the vernal equinox. The precession angles, $\psi_A$ and $\chi_A$, respectively, describe the motion of the mean vernal equinox along the mean ecliptic (luni-solar precession) and along the mean equator (planetary precession).

Due to their virtually secular variation over the near term (few thousands of years), the planetary and luni-solar precessional angles are expressed as polynomials in time, formulated with a certain set of adopted constants and a dynamical theory. The developments of Newcomb and his contemporaries was reformulated and extended in precision by [2.77] based on constants adopted by the IAU. This was further extended in precision and updated in 2000 and again in 2006 by the IAU based on the works of [2.58, 78]. The resulting model, designated the IAU 2006 precession, includes, for example, expressions

$$\begin{aligned}\psi_A &= 5038.481507''\tau - 1.0790069''\tau^2 \\ &\quad - 0.00114045''\tau^3 + \cdots \\ \chi_A &= 10.556403''\tau - 2.3814292''\tau^2 \\ &\quad - 0.00121197''\tau^3 + \cdots ,\end{aligned} \tag{2.47}$$

for the angles $\psi_A$ and $\chi_A$, where $\tau$ is given by (2.46) and where fourth- and fifth-order terms are omitted here for brevity. The linear parts then give the instantaneous rates of precession at $t_0$. The rate of luni-solar precession of the vernal equinox along the mean ecliptic is

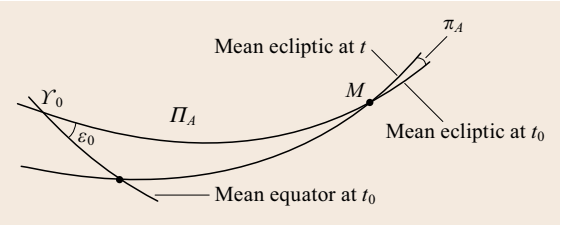

**Fig. 2.17** Planetary precession

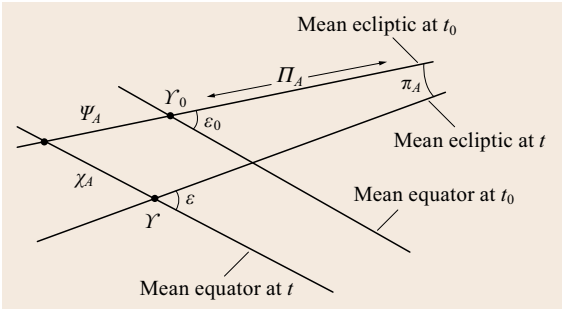

**Fig. 2.18** General precession of the vernal equinox. Planetary precession along the mean equator is indicated by the angle, $\chi_A$, and $\psi_A$ denotes the luni-solar precession along the mean ecliptic (not to scale)

approximately

$$\left.\frac{\mathrm{d}}{\mathrm{d}\tau}\psi_A\right|_{\tau=0} \approx 50.4\,''/\mathrm{y}\,, \tag{2.48}$$

and the planetary precession of $\Upsilon$ along the mean equator is approximately

$$\left.\frac{\mathrm{d}}{\mathrm{d}\tau}\chi_A\right|_{\tau=0} \approx 0.106\,''/\mathrm{y}\,. \tag{2.49}$$

Combined the vernal equinox has a rate on the mean equator of about $(50.4\,''/\mathrm{y}\cdot\cos\varepsilon_0) - 0.106\,''/\mathrm{y} = 46.1\,''/\mathrm{y}$, which prompted the recently revised definition of Earth rotation angle that removes this from the defined origin for right ascension in the instantaneous celestial coordinate system and thus indicates pure Earth rotation rate (Sect. 2.1.3).

Luni-solar precession is by far the largest component of general precession and causes the Earth's spin axis to precess with respect to the celestial sphere and around the ecliptic pole with a period of about 25 800 years. Expressions similar to (2.47) for other angles (e.g., the obliquity of the ecliptic, $\varepsilon$) are given by [2.78].

One way to determine the changes in celestial coordinates due to the effect of general precession of the coordinate frame is with the use of the precessional elements, $\zeta_A$, $z_A$, $\theta_A$, defined in Fig. 2.19. Let the coordinates of a point on the celestial sphere be $\alpha_0, \delta_0$ at $t_0$, and due to precession of the frame, they become $\alpha_m, \delta_m$ at epoch, $t$. In terms of unit vectors, define these points

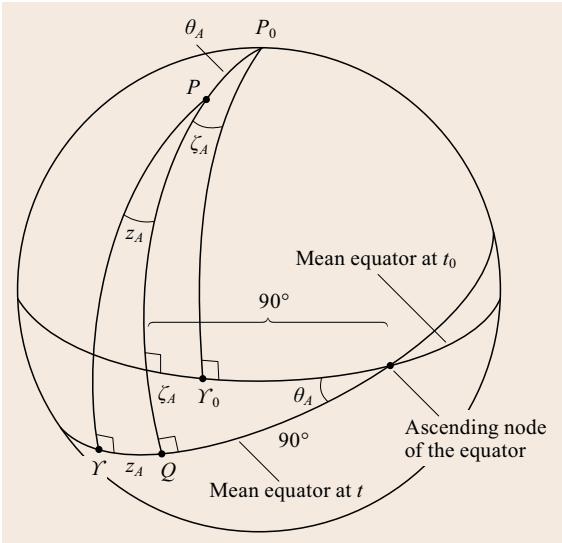

**Fig. 2.19** Traditional precessional elements, $\zeta_A$, $z_A$, $\theta_A$, for the coordinate frame at epoch, $t$, relative to the frame at $t_0$

as

$$\boldsymbol{r}_0 = \begin{pmatrix} \cos\alpha_0\cos\delta_0 \\ \sin\alpha_0\cos\delta_0 \\ \sin\delta_0 \end{pmatrix} \tag{2.50}$$

and $\boldsymbol{r}_m$, analogously. Then, the transformation between the two frames is achieved by the rotations

$$\begin{aligned} \boldsymbol{r}_m &= \mathbf{R}_3(-z_A)\mathbf{R}_2(+\theta_A)\mathbf{R}_3(-\zeta_A)\,\boldsymbol{r}_0 \\ &= \mathbf{P}\boldsymbol{r}_0 \end{aligned} \tag{2.51}$$

where it is noted that the great circle arc, $\widehat{\mathrm{P_0PQ}}$, intersects both mean equators of $t_0$ and of $t$ at right angles because it is an hour circle with respect to both poles, $\mathrm{P_0}$ and P. $\mathbf{R}_j\left(\alpha_j\right)$ denotes the usual orthogonal rotation matrix for a rotation by the angle, $\alpha_j$, about the $j$-th axis of a right-handed Cartesian coordinate system (Table 2.4). $\mathbf{P}$ is called the *precession transformation matrix*.

The precessional elements for the IAU 2006 model [2.78, 81] are given by

$$\begin{aligned} \zeta_A &= 2.650545'' + 2306.083227''\tau \\ &\quad + 0.2988499''\tau^2 + 0.01801828''\tau^3 \\ &\quad - 0.5971''\cdot 10^{-6}\tau^4 - 3.173''\cdot 10^{-7}\tau^5 \\ z_A &= -2.6505453'' + 2306.0771813''\tau \\ &\quad + 1.09273483''\tau^2 + 0.018268373''\tau^3 \\ &\quad - 28.596''\cdot 10^{-6}\tau^4 - 2.904''\cdot 10^{-7}\tau^5 \\ \theta_A &= 2004.191903''\tau - 0.4294934''\tau^2 \\ &\quad - 0.041822''\tau^3 - 7.089''\cdot 10^{-6}\tau^4 \\ &\quad - 1.274''\cdot 10^{-7}\tau^5\,, \end{aligned} \tag{2.52}$$

where, however, these expressions do not include the frame bias introduced with the change in celestial reference system definition (Sect. 2.4).

### Nutation

The nutations, also called *astronomic nutations*, describe the dynamics over the shorter periods, and, indeed, they are modeled as a series of sines and cosines. As a correction to the mean frame at the epoch of date, $t$, the transformation for nutation yields coordinates in the *true* or *instantaneous* frame. This true frame is called the intermediate frame in transformations between the celestial and terrestrial frames and is discussed in more detail in Sect. 2.5.4.

Since the nutations are primarily due to the luni-solar attractions, they are modeled firstly in terms of the ecliptic coordinates of the Sun and Moon. Traditionally, the nutations are expressed by two angles, $\Delta\varepsilon$ and $\Delta\psi$, that, respectively, describe the change (from mean to

**Table 2.4** Elementary rotation matrices. Multiplication of a coordinate vector referred to a frame $\mathcal{R}_{\text{from}}$ by matrix $\mathbf{R}_i$ provides the coordinates of the same vector in a frame $\mathcal{R}_{\text{to}}$, which is obtained from $\mathcal{R}_{\text{from}}$ by a right-handed rotation by angle $\alpha$ about the $i$-th axis (after [2.79, 80])

| Rotation about $x$-axis: | Rotation about $y$-axis: | Rotation about $z$-axis: |
|---|---|---|
| $\mathbf{R}_1(\alpha) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & +\cos\alpha & +\sin\alpha \\ 0 & -\sin\alpha & +\cos\alpha \end{pmatrix}$ | $\mathbf{R}_2(\alpha) = \begin{pmatrix} +\cos\alpha & 0 & -\sin\alpha \\ 0 & 1 & 0 \\ +\sin\alpha & 0 & +\cos\alpha \end{pmatrix}$ | $\mathbf{R}_3(\alpha) = \begin{pmatrix} +\cos\alpha & +\sin\alpha & 0 \\ -\sin\alpha & +\cos\alpha & 0 \\ 0 & 0 & 1 \end{pmatrix}$ |

true) in the tilt of the equator with respect to the mean ecliptic, and the change (again, from mean to true) of the equinox along the mean ecliptic (Fig. 2.20). There is no need to transform from the mean to the true ecliptic since only the dynamics of the true equator are of interest. The true vernal equinox, $\Upsilon_T$, is always defined to be on the mean ecliptic.

The *nutation in longitude*, $\Delta\psi$, is primarily caused by the ellipticities of the Earth's and Moon's orbits. The *nutation in obliquity*, $\Delta\varepsilon$, is mainly due to the Moon's orbital plane being out of the ecliptic (by about 5.145°). Models for the nutation angles are given in the form

$$\Delta\psi = \sum_{i=1}^{n} \left(a_i \sin A_i + a'_i \cos A_i\right)$$
$$\Delta\varepsilon = \sum_{i=1}^{n} \left(b_i \cos A_i + b'_i \sin A_i\right), \qquad (2.53)$$

where each amplitude, $a_i, a'_i, b_i, b'_i$, is a linear function of $\tau$ and the angle

$$A_i = n_{\ell,i}\ell + n_{\ell',i}\ell' + n_{F,i}F + n_{D,i}D + n_{\Omega,i}\Omega\ , \qquad (2.54)$$

represents a linear combination of fundamental arguments (*Delaunay variables*, [2.82]) of the solar and lunar orbits:

- $\ell$ Mean anomaly of the Moon,
- $\ell'$ Mean anomaly of the Sun,
- $F$ Mean longitude of the Moon minus the mean longitude of the Moon's ascending node,
- $D$ Mean elongation of the Moon from the Sun,
- $\Omega$ Mean longitude of the ascending node of the Moon.

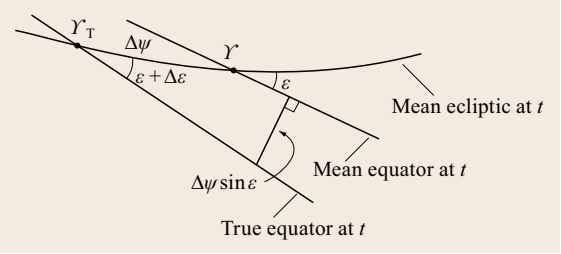

**Fig. 2.20** Nutation elements, $\Delta\varepsilon$ and $\Delta\psi$

The corresponding arguments are introduced for the planetary orbits in an expanded theory. The integer multipliers, $n_{\ell,i}, \ldots, n_{\Omega,i}$, specify how these variables are combined in the argument, $A_i$.

The theory and series developed by [2.76] included $n = 69$ terms for $\Delta\psi$ and $n = 40$ terms for $\Delta\varepsilon$. The subsequent theory and series [2.83] adopted by the IAU in 1980, which included modifications for a nonrigid Earth model [2.71] had $n = 106$ terms. The IAU1980 nutation model was replaced in 2003 by the new nutation model of [2.58], designated IAU2000A (2000B is an abbreviated, less precise version). This model accounts for the mantle anelasticity, the effects of ocean tides, electromagnetic couplings between the mantle, the fluid outer core, and the solid inner core, as well as various nonlinear terms not previously considered.

A slight revision of the model due to the new IAU 2006 precession model is designated the IAU2000A$_{\text{R06}}$ nutation model, which has 1320 terms for $\Delta\psi$ and 1037 terms for $\Delta\varepsilon$ ([2.6] and [2.84, Tables 5.3a,b]). Table 2.5 summarizes the largest of the nutation amplitudes and associated variables and parameters according to this model. The corresponding expressions for the Delaunay variables as low-order polynomials in $\tau$ are also given in [2.6, p. 67]. The periods of the nutations may be computed from the linear coefficients of the resulting polynomial expressions for the angle, $A_i$. The high-index angles, $A_i$, also include the longitudes of the planets. The frame bias (Sect. 2.4) is already incorporated in Table 2.5.

Figure 2.21 depicts the motion of the pole due to the dominant luni-solar precession combined with the largest of the nutation terms. This diagram also defines the *nutational ellipse* that describes the extent of the true motion with respect to the mean motion. The semi-axis of this ellipse that is orthogonal to the mean motion is the principal term in the nutation in obliquity and is also known as the *constant of nutation*. The values for it and for the other semi-axis, given by $\Delta\psi\sin\varepsilon$ (Fig. 2.20), can be inferred from Table 2.5. The total motion of the pole on the celestial sphere is due to the superposition of the general precession and all the nutations.

The transformation at the epoch of date, $t$, from the mean frame to the true frame, referring to Fig. 2.20, is

**Table 2.5** The dominant terms of the IAU2000A$_{R06}$ series for nutation in longitude and obliquity, referred to the mean ecliptic of date. $\tau$, as defined in (2.46) denotes the number of Julian centuries since 1.5 Jan 2000. Note that the index $i$ does not correspond to the order of the IAU $\Delta\varepsilon$ components.

| $i$ | Period (d) | $a_i$ ($10^{-6}$ ″) | | $b_i$ ($10^{-6}$ ″) | | $n_{\ell,i}$ | $n_{\ell',i}$ | $n_{F,i}$ | $n_{D,i}$ | $n_{\Omega,i}$ |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 6798.4 | −17 206 424.18 | −17 418.82$\tau$ | +9 205 233.10 | +883.03$\tau$ | 0 | 0 | 0 | 0 | +1 |

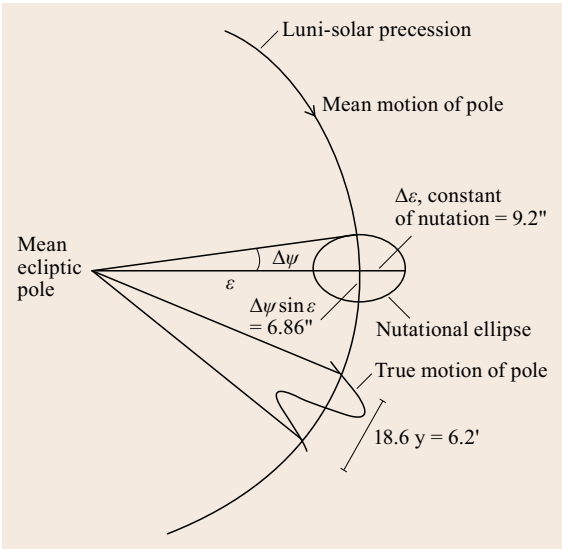

**Fig. 2.21** Dominant components of the combined general precession and nutation of the pole on the celestial sphere

accomplished with the following rotations,

$$\begin{aligned} \boldsymbol{r} &= \mathbf{R}_1(-\varepsilon - \Delta\varepsilon)\mathbf{R}_3(-\Delta\psi)\mathbf{R}_1(\varepsilon)\,\boldsymbol{r}_m \\ &= \mathbf{N}\,\boldsymbol{r}_m \end{aligned} \tag{2.55}$$

where $\varepsilon$ is the mean obliquity at epoch, $t$, and the true right ascension and declination are related to $\boldsymbol{r}$ as in (2.50).

The combined transformation due to precession and nutation from the epoch, $t_0$, to the current epoch, $t$, is given by the combination of equations (2.51) and (2.55),

$$\boldsymbol{r} = \mathbf{NP}\,\boldsymbol{r}_0\,. \tag{2.56}$$

The IAU 2006/2000A precession–nutation model is accurate to about 0.3 mas. For those seeking the highest accuracy and temporal resolution, small corrections (called *celestial pole offsets*) obtained from continuing VLBI observations, may be applied to the nutation series. For example, the most recent model does not contain the diurnal motion due to the free-core nutation (FCN) caused by the interaction of the mantle and the rotating fluid outer core ([2.75]; see also Sect. 2.5.3). The IERS publishes differential elements in longitude, $\delta\psi$, and obliquity, $\delta\varepsilon$, that can be added to the elements implied by the nutation series

$$\begin{aligned} \Delta\psi &= \Delta\psi\ (\text{model}) + \delta\psi \\ \Delta\varepsilon &= \Delta\varepsilon\ (\text{model}) + \delta\varepsilon\,. \end{aligned} \tag{2.57}$$

## 2.5.2 New Conventions

The new definition of the celestial reference system (CRS, Sect. 2.4) was prompted not only by the ability to realize the system geometrically with accurate VLBI observations, but also by a critical analysis of the system conventions for the origin of right ascension [2.85, 86]. Specifically, by avoiding a dynamical definition of the CRS axes, there is no particular reason to use the vernal equinox on the mean ecliptic as an origin of right ascensions, especially because even in the mean it is a dynamical point on the celestial sphere. That is, as an origin point it rotates about the NCP due to the precessional rotation of the ecliptic. This must then be corrected when considering the rotation of the Earth with respect to inertial space (Greenwich sidereal time, or the hour angle at Greenwich of the vernal equinox; Sect. 2.1.3).

In 2000, the IAU adopted a set of resolutions that precisely adhered to a new, more accurate, and simplified way of dealing with the transformation between the celestial and terrestrial reference systems. The IERS, in 2003, similarly adopted the new methods based on these resolutions [2.87]. These were reinforced with IAU resolutions in 2006 and adopted as part of the IERS Conventions 2010. The true NCP, previously also called the celestial ephemeris pole (CEP) with a resolution of

the IAU in 1979, now is called the celestial intermediate pole (CIP), thus identifying it as a transition between celestial and terrestrial reference frames. The new conventions also revised the origin for right ascension in this intermediate frame so as to eliminate residual rotations not associated with Earth rotation, while also ensuring continuity with the previously defined origin. These profoundly new definitions solidify the paradigm of *kinematics* (rather than dynamics) upon which the celestial reference system is based. In addition, the description of precession and nutation is now combined in a single transformation from $t_0$ to $t$.

Suppose that the instantaneous pole, P, on the celestial sphere coincides with the reference pole, $P_0$, at some fundamental epoch, $t_0$. At the epoch of date, $t$, the position of P then has celestial coordinates as shown in Fig. 2.22. These coordinates are the co-declination, $d$, and the right ascension, $E$, with respect to the reference origin, $\Sigma_0$. The true or instantaneous equator (the plane perpendicular to the axis through P) at time, $t$, intersects the reference equator (associated with $P_0$) at two nodes that are 180° apart. The hour circle of the node, $N$, is orthogonal to the great circle arc $\widehat{P_0P}$. Therefore, the right ascension of the ascending node of the equator is 90° plus the right ascension of the instantaneous pole, P. The origin for right ascension at the epoch of date, $t$, is defined kinematically under the condition that there is no rotation *rate* of the *instantaneous coordinate frame* about the pole due to precession and nutation. This is the concept of the *nonrotating origin* (NRO), which, as origin for right ascensions on the instantaneous equator, is now called the CIO; denoted as σ in Fig. 2.22).

Rather than successive transformations involving precessional elements and nutation angles, the transformation is more direct in terms of the coordinates, $d$ and $E$. The additional parameter $s$ defines the instantaneous origin of right ascension as an NRO (see below). Analogous to (2.51) and (2.55),

$$\begin{aligned} \boldsymbol{r} &= \mathbf{R}_3(-s)\mathbf{R}_3(-E)\mathbf{R}_2(d)\mathbf{R}_3(E)\,\boldsymbol{r}_0 \\ &= \mathbf{Q}^{\top}\boldsymbol{r}_0\,, \end{aligned} \tag{2.58}$$

which is easily derived by considering the successive rotations as the origin point transforms from the reference origin, $\Sigma_0$, to the instantaneous origin, σ (Fig. 2.22). Equation (2.58) not only replaces (2.56), but also incorporates the new conventions for defining the intermediate origin in right ascension (it is no longer the true vernal equinox). The IERS Conventions 2003 (and later) define the transformation matrix, $\mathbf{Q}$, as a rotation *from* the system of the instantaneous pole and origin *to* the reference system.

The total rotation rate of the pole, P, in inertial space is due to the rates in the coordinates, $d, E$, and in the

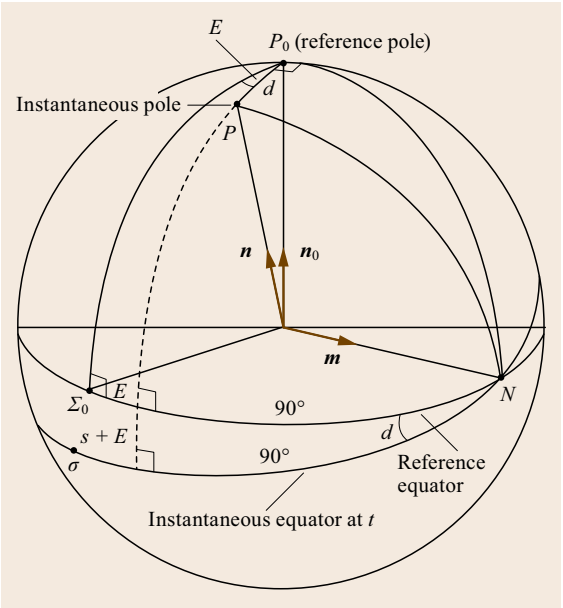

**Fig. 2.22** Coordinates of the instantaneous pole in the celestial reference system

parameter, $s$. Defining three noncolinear unit vectors, $\boldsymbol{n}_0$, $\boldsymbol{m}$, $\boldsymbol{n}$, as shown in Fig. 2.22, the total rotation rate may be expressed as

$$\boldsymbol{\Theta} = \boldsymbol{n}_0\dot{E} + \boldsymbol{m}\dot{d} - \boldsymbol{n}\left(\dot{E}+\dot{s}\right), \tag{2.59}$$

where the dots denote time derivatives. Now, $s$ is chosen so that the total rotation rate, $\boldsymbol{\Theta}$, has no component along $\boldsymbol{n}$. That is, $s$ defines the origin point, σ, on the instantaneous equator that has no rotation rate about the corresponding polar axis (it is thus a nonrotating origin). This condition is formulated as $\boldsymbol{\Theta}\cdot\boldsymbol{n} = 0$, meaning that there is no component of the total rotation rate along the instantaneous polar axis. Since $\boldsymbol{n}\cdot\boldsymbol{m} = 0$ and $\boldsymbol{n}\cdot\boldsymbol{n}_0 = \cos d$, (2.59) implies that

$$\dot{s} = (\cos d - 1)\,\dot{E}\,. \tag{2.60}$$

Defining coordinates

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \begin{pmatrix} \sin d\cos E \\ \sin d\sin E \\ \cos d \end{pmatrix}, \tag{2.61}$$

it is easily shown that

$$\mathbf{Q} = \begin{pmatrix} 1-aX^2 & -aXY & X \\ -aXY & 1-aY^2 & Y \\ -X & -Y & 1-a(X^2+Y^2) \end{pmatrix} \mathbf{R}_3(s) \tag{2.62}$$

where $a = 1/(1+\cos d)$. Furthermore, since

$$X\dot{Y} - Y\dot{X} = -\dot{E}\left(Z^2 - 1\right), \tag{2.63}$$

(2.60) integrates to

$$s = s_0 - \int_{t_0}^{t} \frac{X\dot{Y} - Y\dot{X}}{1+Z}\mathrm{d}t\,, \tag{2.64}$$

where $s_0 = s(t_0)$ is chosen so as to ensure continuity with the previous definition of the origin point at the epoch January 1, 2003.

Expressions for $X$ and $Y$ can be obtained directly from the precession and nutation equations [2.86]. For the latest IAU 2006/2000A precession–nutation models [2.6],

$$\begin{aligned} X = {} & -0.016617'' + 2004.191898''\tau \\ & - 0.4297829''\,\tau^2 - 0.19861834''\tau^3 \\ & - 0.000007578''\,\tau^4 - 0.0000059285''\tau^5 \\ & + \sum_{i=1}^{n}\left(e_i \sin A_i + e_i' \cos A_i\right) \\ Y = {} & -0.006951'' - 0.025896''\,\tau \\ & - 22.4072747''\,\tau^2 + 0.00190059''\,\tau^3 \\ & + 0.001112526''\,\tau^4 - 0.0000001358''\,\tau^5 \\ & + \sum_{i=1}^{n}\left(f_i \sin A_i + f_i' \cos A_i\right), \end{aligned} \tag{2.65}$$

where $\tau$ is given by (2.46), the coefficients, $e_i$, $e_i'$, $f_i$, $f_i'$ are polynomials in $\tau$, and the angles, $A_i$, are given by (2.54) including, for the higher indices, $i$, expressions for the longitudes of the planets (see Tables 5.2a,b in the electronic supplement [2.84] to the IERS Conventions 2010 [2.6]).

The corresponding series expression for the parameter $s$ includes all terms larger than 0.5 μas (microarcsec), as well as the constant $s_0$

$$\begin{aligned} s = {} & -\frac{1}{2}XY + 94 + 3808.65\,\tau \\ & - 122.68\,\tau^2 - 72574.11\,\tau^3 \\ & + \sum_k C_k \sin\alpha_k + \sum_k D_k \sin\beta_k \\ & + \sum_k E_k \tau \cos\gamma_k + \sum_k F_k \tau^2 \sin\theta_k \ (\mu\mathrm{as})\,. \end{aligned} \tag{2.66}$$

The coefficients $C_k$, $D_k$, $E_k$, $F_k$ and the arguments, $\alpha_k$, $\beta_k$, $\gamma_k$, $\theta_k$, are elaborated by [2.6, p. 59]. Values of $s$ are less than 0.01″ (until the early 2030s) and can be ignored for transformations at that level of accuracy.

The transformation formulas (2.65) and (2.66) yield an accuracy of about $0.3 \cdot 10^{-3}$″ in the position of the pole and incorporate the frame bias described in Sect. 2.4.

### 2.5.3 Polar Motion

The previous sections describe Earth's orientation from the celestial perspective – how the direction of an axis, such as the spin axis, progresses in time on the celestial sphere due to precession and nutation. From the terrestrial view, however, the spin axis and various other axes associated with Earth's rotation and geometry also exhibit motion with respect to the Earth's crust due to the natural dynamics of the rotation. Euler's equations describe the motion of the principal (geometric) axes for a rigid body, but because the Earth is partially fluid and elastic, the motion of these axes is not accurately predictable.

The details of the theoretical and mathematical developments of the dynamics equations for elastic rotating bodies may be found in [2.37]. These dynamics are influenced both by the internal composition and fluid characteristics of the Earth (nonforced, or free motion) and external gravitational torques that deform the Earth (forced motion). For example, the free motion of the principal axis (also called *figure axis*) corresponding to Earth's polar axis of symmetry has a circular diurnal motion relative a mean fixed location (*mean Tisserand axis*) with radius of about 60 m. The spin and angular momentum axes, on the other hand, have an order of magnitude smaller motion due to their greater stability, or relative insensitivity to Earth's deformation.

The change in direction of an axis, such as the instantaneous spin axis, of the Earth with respect to the surface of the Earth is called *polar motion* (also *wobble*). The motion is described by local coordinates, $x_p$,$y_p$, with respect to the reference pole of the terrestrial reference system. Figure 2.23 shows the polar motion coordinates for the CIP; note the defined direction of $y$, which is opposite to the $y$-axis of the right-handed system of Fig. 2.7. Viewed as horizontal Cartesian coordinates, their values change by only a few meters over several years; typically they are given by the subtended central angle, where 1″ corresponds approximately to 30 m on the Earth's surface.

The principal component of polar motion is the *Chandler wobble*. This is basically the free Eulerian motion which would have a period of about 304 days, based on the moments of inertia of the Earth, if the Earth were a rigid body. Due to the elastic yielding of the Earth, resulting in displacements of the maximum

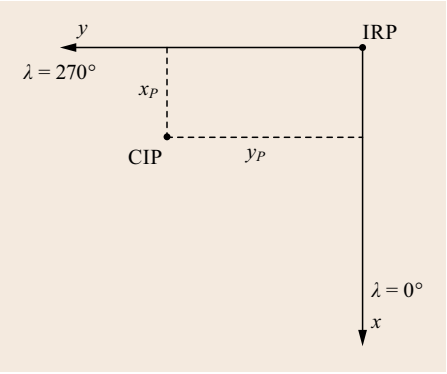

**Fig. 2.23** Polar motion coordinates

moment of inertia, this motion has a longer period of about 430 days. S. C. Chandler observed and analyzed this discrepancy in the period in 1891; and, Newcomb gave the dynamical explanation [2.79, p. 80], thus also proving that the Earth is, in fact, not a rigid body. The period of this main component of polar motion is called the *Chandler* period; its amplitude is about 0.2 arcsec. Other components of polar motion include the approximately annual signal due to the redistribution of masses by way of meteorological and geophysical processes, with an amplitude of about 0.05–0.1″, and the *nearly diurnal free wobble*, due to the slight misalignments of the rotation axes of the mantle and liquid outer core (also known as the *free core nutation*, with magnitude of about $0.1–0.3 \cdot 10^{-3}$″ and period of about 430 days with respect to the celestial sphere). Finally, there is the so-called *polar wander*, which is the secular motion of the pole. During 1900–2000, Earth's spin axis wandered about 0.004″ per year in the direction of the 280° meridian. Figure 2.24 shows the polar motion for the period 2000–2010, and also the general drift for the last 110 years.

If $\boldsymbol{r}_e$ is a unit vector that defines a geocentric direction of a point in the terrestrial reference system in terms of spherical coordinates

$$\boldsymbol{r}_e = \begin{pmatrix} \cos\lambda\cos\phi \\ \sin\lambda\cos\phi \\ \sin\phi \end{pmatrix}, \tag{2.67}$$

then the transformation from the terrestrial reference pole to the instantaneous, or intermediate pole (CIP), is given with appropriate rotations by

$$\begin{aligned} \boldsymbol{r}_i &= \mathbf{R}_1(y_\mathrm{p})\mathbf{R}_2(x_\mathrm{p})\,\boldsymbol{r}_e \\ &= \mathbf{W}\,\boldsymbol{r}_e \end{aligned} \tag{2.68}$$

Just as the instantaneous celestial system has a nonrotating origin for right ascension, one may define an

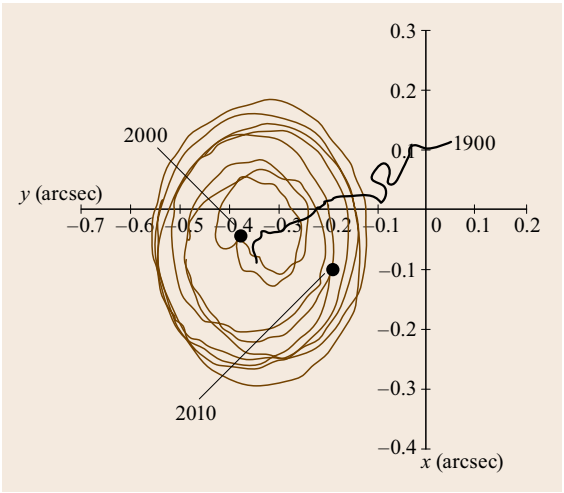

**Fig. 2.24** Polar motion from 2000 to 2010, and polar wander since 1900. Polar motion coordinates are obtained from IERS and are smoothed to obtain the trend

instantaneous terrestrial system that has a nonrotating origin for longitudes, called the *Terrestrial Intermediate Origin* (TIO). In this way, the only difference between the instantaneous celestial and terrestrial systems is Earth's rotation; the polar axes are the same.

With a derivation completely analogous to that for the precession–nutation matrix, $\mathbf{Q}$, the polar motion matrix is

$$\begin{aligned} \mathbf{W} &= \mathbf{R}_3(-s') \\ &\quad \times \begin{pmatrix} 1-a'x_\mathrm{p}^2 & a'x_\mathrm{p}y_\mathrm{p} & -x_\mathrm{p} \\ a'x_\mathrm{p}y_\mathrm{p} & 1-a'y_\mathrm{p}^2 & y_\mathrm{p} \\ x_\mathrm{p} & -y_\mathrm{p} & 1-a'(x_\mathrm{p}^2+y_\mathrm{p}^2) \end{pmatrix}, \end{aligned} \tag{2.69}$$

where $a' = 1/2 + \left(x_\mathrm{p}^2 + y_\mathrm{p}^2\right)/8$. The parameter $s'$ defines the location of the TIO on the instantaneous equator through an expression that is analogous to (2.66). By neglecting terms of second and higher orders, the exact equation (2.69) is approximately equal to

$$\mathbf{W} = \mathbf{R}_3(-s')\mathbf{R}_1(y_\mathrm{p})\mathbf{R}_2(x_\mathrm{p})\,. \tag{2.70}$$

Furthermore, $s'$ is significant only because of the largest components of polar motion and an approximate model is given by

$$s' = -0.0015'' \left(\frac{a_c^2}{1.2} + a_a^2\right)\tau\,, \tag{2.71}$$

where $a_c$ and $a_a$ are the amplitudes, in arcsec, of the Chandler wobble ($\mathcal{O}(0.2'')$) and the annual wobble

($\mathcal{O}(0.05'')$). Hence, the magnitude of $s'$ is of the order of $0.1 \cdot 10^{-3}$ arcsec.

The polar motion coordinates are tabulated by the IERS as part of the Earth Orientation Parameters (EOP) and predicted on the basis of observations, such as from VLBI and satellite ranging. Thus, **W** is a function of time, but there are no analytic models for polar motion as there are for precession and nutation. For the highest precision, the polar motion coordinates should be amended to include motions corresponding to nutations and tidal effects [2.6, Chaps. 5 and 8] with periods less than 2 days in the GCRS in order to comply with the definition of the intermediate pole.

### 2.5.4 Transformations

It is the current convention to formulate the transformation between celestial and terrestrial reference systems via an intermediate system. This intermediate, or true, or epoch-of-date system describes either precession and nutation when transformed from the celestial reference system, or polar motion and Earth rotation when transformed from the terrestrial reference system. As a dynamical system it is not a reference system since coordinates in this system vary significantly in time. For this reason, the intermediate system has also been called an *ephemeris* system. The newer *intermediate* nomenclature, more descriptive of the system's function, was adopted through a number of resolutions by the IAU during 2000–2006.

The ideal choice of the intermediate system largely falls on the choice of polar axis since the choice for the origin of the intermediate right ascension is now fixed by the nonrotating origin. In 1979 this pole was defined as having no motions with periods less than 2 days either with respect to the celestial or the terrestrial reference systems. The 2-day restriction on periods was consistent with the observational capability at the time to resolve such motions. The *Celestial Ephemeris Pole* (CEP), thus defined, divided the observable polar motion and predictable precession/nutations.

With improved VLBI observational techniques and data processing, shorter periods of motion could be discerned and in 2000 the IAU resolved to refine the definition of the intermediate pole. The newly named *celestial intermediate pole* (CIP) by definition, like the CEP, moves on the celestial sphere with periods greater than 2 days (frequencies less than $\pm 0.5$ cycles per sidereal day, cpsd). This includes all the conventional predictable precessions and nutations produced by external gravitational torques on the Earth. Also included are the observed polar motions within $\pm$ 0.5 cpsd of Earth's diurnal rotation frequency (the *diurnal retrograde band*) since it can be shown that they are equivalent to nutations with periods larger than 2 days. The terrestrial motions of the CIP, on the other hand, are defined to be those with frequencies outside the diurnal retrograde band. They not only include the conventional polar motions, such as the Chandler wobble, but also the high-frequency nutations, which are equivalent to polar motions outside this band. For additional details on these conventions, see [2.78, 88] and [2.75, p. 86].

It has been argued [2.89] that the intermediate pole is not essential in the transformation between the terrestrial and the celestial frame and that a combination of model and observations in a single transformation avoids much confusion and debate about the definition of the CIP. However, with current conventions the practical transformation between celestial and terrestrial reference frames combines the transformations (2.58) and (2.68) with Earth rotation,

$$\boldsymbol{r}_{\mathrm{TRS}} = \mathbf{W}^{\top}\mathbf{R}_3(\theta)\mathbf{Q}^{\top}\boldsymbol{r}_{\mathrm{CRS}}\,, \tag{2.72}$$

where $\theta$ is the Earth rotation angle (Sect. 2.1.3). This is called the *CIO method* of transformation, referring to the new convention of defining the origin for right ascension in the intermediate celestial system by the nonrotating origin. Alternatively, the so-called *equinox method*, uses the Greenwich sidereal time for the angle of Earth's rotation and the traditional precession and nutation series, given by (2.56)

$$\boldsymbol{r}_{\mathrm{TRS}} = \mathbf{W}^{\top}\mathbf{R}_3(\mathrm{GAST})\mathbf{NPB}\,\boldsymbol{r}_{\mathrm{CRS}}\,. \tag{2.73}$$

where a small rotation, **B**, is included to account for the frame bias.

Equations (2.72) and (2.73), of course, can be reversed to obtain coordinates in the CRF from coordinates in the terrestrial reference frame by noting that each rotation matrix is orthogonal – its inverse is its transpose

$$\boldsymbol{r}_{\mathrm{CRS}} = \mathbf{Q}\mathbf{R}_3^{\top}(\theta)\mathbf{W}\boldsymbol{r}_{\mathrm{TRS}} \tag{2.74}$$

and

$$\boldsymbol{r}_{\mathrm{CRS}} = \mathbf{B}^{\top}\mathbf{P}^{\top}\mathbf{N}^{\top}\mathbf{R}_3^{\top}(\mathrm{GAST})\mathbf{W}\boldsymbol{r}_{\mathrm{TRS}}\,. \tag{2.75}$$

In applying the transformation (2.72), or (2.73), to observed points on the celestial sphere, it is important to consider any observational effects on the celestial coordinates of objects, such as actual, or proper motion (e.g., of stars), parallax due to the observer's changing position relative to the barycenter, and aberration due to the velocity of the observer relative to the barycenter. These effects are of primary interest for directional (e.g., optical or VLBI) observations of celestial bodies

but of limited relevance for GNSS data processing. For a detailed description, interested readers are referred to [2.5].

No matter whether the *equinox method* or the *CIO method* is adopted, the CRF-to-TRF transformation is characterized by extremely lengthy series expansions of the respective rotation angles. In order to facilitate the correct and consistent application of the conventional transformation, all relevant coefficients are made available in electronic form [2.84] by the IERS. Furthermore, various computer implementations of the transformations (or selected aspects thereof) are offered by the IAU, the IERS, and individual authors. Such software may be applied directly, as a reference for validating independent implementations, or simply for better understanding of the underlying transformation concepts. Common examples include, for example, the IAU Standards of Fundamental Astronomy (SOFA, [2.90]) and the AstroRef package of [2.74]. Computational and implementation issues of the transformations are addressed in [2.91, 92]. Among others, the authors highlight the benefit of interpolating from a grid of precomputed values, when evaluating the transformation for a dense set of nearby epoch values.

## 2.6 Perspectives

This chapter has introduced the basic concepts of modern space–time reference systems and frames that have jointly been developed by astronomers and geodesists as a basis of their work. They enable a concise description of the Earth's motion in space and the location of objects on or near the Earth. Users of global navigation satellite systems are inevitably confronted with the issue of coordinates and reference systems, when it comes to the exchange and proper understanding of measured positions. Since GNSS provides essentially four-dimensional observations, with time as the fourth component of the navigation solution, the underlying concepts and conventions of time measurements are therefore equally important in all aspects of GNSS navigation.

Different GNSSs such as GPS, GLONASS, BeiDou, and Galileo have historically employed different time frames (realized by independent atomic clocks) and spatial reference frames (realized by different fundamental reference stations and partly different techniques). This affects the satellite orbit and clock information provided to the users and impacts a consistent navigation solution based on observations of multiple GNSS constellations. Fortunately, much progress has been achieved over the past decade. Individual frame realizations as used by the various GNSSs today exhibit centimeter-level differences that are well below the typical meter level accuracy of broadcast navigation information. Still, however, systematic time offsets (at the 10–100 ns level) between GNSS-specific time scales need to be carefully considered in the positioning and taken into account in the employed algorithms (Chap. 21).

Considering the high-level of accuracy that can today be achieved through carrier-phase-based GNSS positioning techniques, users are confronted with the fact that the Earth's crust is far from solid and itself subject to permanent changes. This includes both long-term changes such as tectonic plate motion (Sect. 2.3.2) but also periodic site shifts due to solid Earth and ocean tides (Sect. 2.3.5). Even though differential GNSS positioning techniques (Chap. 26) can offer (relative) accuracies down to the millimeter level, their use is largely unaffected by such intricate details. Undifferenced, precise point positioning (PPP) techniques, in contrast, aim at providing absolute positions in a global reference frame. Here, a proper understanding of the underlying frame definitions and the consistent application of conventional corrections (e.g., for frame motion or tides) in the PPP software becomes an essential aspect of the GNSS data processing (Chap. 25). Similarity transformations between different regional and global frames (Sect. 2.3.4) or the transition between ellipsoidal and geoid heights (Sect. 2.3.1) are likewise important aspects of GNSS surveying (Chap. 35) and geodesy (Chap. 36).

While most precise GNSS users can confine themselves to a proper understanding of terrestrial reference systems and frames, the relation betwen celestial and terrestrial frames as discussed in Sect. 2.5 is likewise of relevance for various specific aspects of GNSS data processing. This includes, for example, the generation of GNSS precise orbit products (Chap. 34) and the GNSS-based precise orbit determination of satellites in low Earth orbit (Chap. 32). Satellite orbits and their equations of motion are most naturally expressed in a celestial frame, while the locations of GNSS monitoring stations are best described in a terrestrial frame. Conventional relations for the CRF-to-TRF transformation are essential for consistency of products obtained by individual analysis centers. On the other hand, the joint adjustment of satellite orbits, site locations, and Earth orientation parameters has become a vital part of space geodesy (Chap. 36) and contributes to a continued improvement of references frames and the understanding of Earth rotation.

# 3. Satellite Orbits and Attitude

Urs Hugentobler, Oliver Montenbruck

This chapter discusses fundamentals of orbital dynamics and provides a description of key perturbations affecting global navigation satellite system (GNSS) satellites along with their impact on the orbits. Models for perturbing accelerations including Earth gravity, third body perturbations, surface forces, and relativistic corrections are described with emphasis on empirical and semiempirical solar radiation pressure models. Long-term evolution of GNSS orbits and orbit keeping maneuvers are discussed. The concepts of broadcast orbit models such as almanac models, analytical ephemeris models and numerical ephemeris models used by current GNSS systems are presented along with cook book algorithms and a summary of their performance. Complementary to the discussion of GNSS satellite orbits, the chapter introduces the basic concepts of GNSS satellite attitude, which are, for example, required to describe the antenna location relative to the center-of-mass.

## 3.1 Keplerian Motion

Long before the launch of the first man-made satellite, the motion of planets and moons in the solar system has been a subject of extensive research. Celestial mechanics [3.1, 2] has helped us to understand the properties of orbital motion around a central body under the action of gravitational forces from first principles. It allowed to accurately predict planetary and lunar motion for the benefit of science but likewise for timekeeping and navigation.

### 3.1.1 Basic Properties

The fundamental properties of planetary orbits were originally identified by Johannes Kepler based on his careful analysis of Tycho Brahe's observations of planet Mars. Applied to the case of an Earth-orbiting satellite, Kepler's three laws of planetary motion describe the following properties:

1. The orbit of a satellite is an ellipse with the Earth located in one of its foci.
2. The radius vector covers a constant area per unit time interval (law of areas).
3. The square of the orbital period increases with the third power of the mean distance from the center of the Earth.

In the most general sense, satellite orbits are described by conic sections, which also allows for parabolic and hyperbolic trajectories. Such orbits may be attained by spacecraft on their way to or from the solar system. However, ellipses represent the only type of closed and periodic orbits around the central body (Fig. 3.1).

The shape of an ellipse is determined by the two radii $a$ (semimajor axis) and $b$ (semiminor axis) along

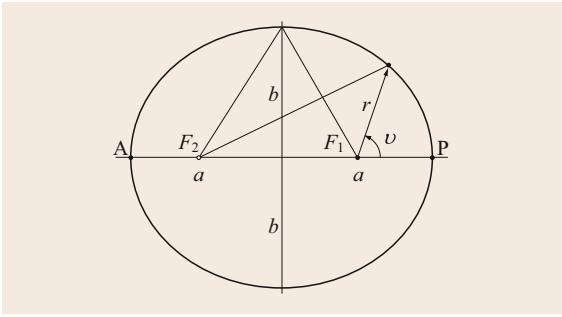

**Fig. 3.1** An *ellipse* describes the set of all points for which the sum of the distances from the two given foci ($F_1$, $F_2$) has a constant value. In the case of a planetary satellite orbit, the central body is located in one of these focal points. The line of apsides passes through both foci and connects the apocenter (A) and the pericenter (P) of the orbit

the principal axes, or, equivalently the eccentricity

$$e = \frac{\sqrt{a^2 - b^2}}{a} \,. \tag{3.1}$$

The distance from the focus varies between a minimum of $r_{\min} = a\,(1-e)$ at pericenter (P) and a maximum of $r_{\max} = a\,(1+e)$ at apocenter (A). Denoting by $\upsilon$ the angle between the radius vector and the pericenter direction, the radius is described by the conic section equation

$$r = \frac{a\,(1-e^2)}{1+e\cos\upsilon} \,, \tag{3.2}$$

which likewise holds for ellipses, parabolas, and hyperbolas [3.3].

Kepler's laws are rigorously valid for the so-called two-body problem, which addresses the motion of two point-masses under the action of their mutual gravitational attraction. Additional forces such as the gravitational attraction of third bodies, the gravitational field of nonspherical, extended bodies, or diverse types of nongravitational forces may induce perturbations, which are further addressed in Sect. 3.2 and discussed in full detail in common textbooks of astrodynamics [3.4, 5]. Still, Keplerian motion remains an important concept for understanding and describing the trajectories of Earth orbiting satellites.

As can be shown, Kepler's laws can be fully explained from Newton's law of gravity [3.2, 5]. They are a direct consequence of the fact that the gravitational attraction is always direct along the line joining the two bodies and decreases with the second power of the distance.

Denoting the position vector and distance of a satellite with respect to the center of the Earth by $\boldsymbol{r}$ and $r = ||\boldsymbol{r}||$, respectively, the corresponding acceleration is given by

$$\ddot{\boldsymbol{r}} = -\frac{GM_\oplus}{r^2}\,\frac{\boldsymbol{r}}{r} \,. \tag{3.3}$$

Here, $G \approx 6.674 \cdot 10^{-11}\,\mathrm{m^3\,kg^{-1}s^{-2}}$ [3.6] is the universal constant of gravity and $M_\oplus \approx 5.973 \cdot 10^{24}\,\mathrm{kg}$ denotes the mass of the Earth. The latter is about 20 orders of magnitude larger than the satellite's mass $m$, which has therefore been neglected in Eq. 3.3. It may be noted that the gravitational acceleration (3.3) depends only on the product of the gravitational constant and the Earth mass. While the individual values are only known to roughly four digits, the product

$$GM_\oplus = 3.986004415 \cdot 10^{14}\,\mathrm{m^3 s^{-2}} \tag{3.4}$$

can in fact be determined with very high precision from the analysis of satellite orbits [3.7]. Note that the number given in (3.4) is consistent with the terrestrial scale defined by the rate of clocks at the rotating geoid.

As can be recognized from the unit vector $\boldsymbol{r}/r$ in (3.3), the gravitational acceleration is always directed radially inward. Changes of the velocity are thus confined to a plane spanned by the instantaneous position and velocity vectors. In the absence of perturbing accelerations directed perpendicular to $\boldsymbol{r}$ and $\dot{\boldsymbol{r}}$, the satellite will thus move in a constant orbital plane at all times.

Physically speaking, the angular momentum vector $\boldsymbol{h} = \boldsymbol{r} \times \dot{\boldsymbol{r}}$ does not change over time, since

$$\dot{\boldsymbol{h}} = \boldsymbol{r} \times \ddot{\boldsymbol{r}} + \dot{\boldsymbol{r}} \times \dot{\boldsymbol{r}} = \boldsymbol{0} \tag{3.5}$$

whenever the acceleration is directed along the radius vector. As illustrated in Fig. 3.2, the modulus of the angular momentum vector matches twice the area $\Delta A$ swept by the satellite's radius vector within a time interval $\Delta t$

$$h = ||\boldsymbol{r} \times \dot{\boldsymbol{r}}|| = 2\frac{\Delta S}{\Delta t} \,. \tag{3.6}$$

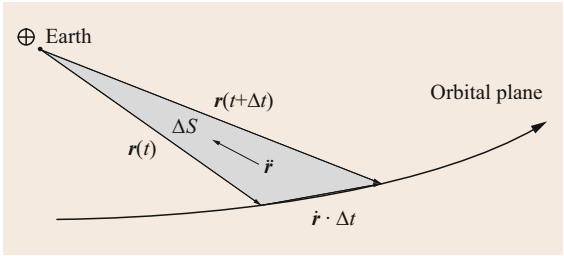

**Fig. 3.2** A central acceleration $\ddot{\boldsymbol{r}}$ does not alter the plane of the satellite's orbit and results in a constant areal velocity $\Delta S/\Delta t$ of the radius vector

The areal velocity is thus constant, which proves the validity of Kepler's second law.

While the law of areas is equally valid for all types of central forces, the property of an elliptic motion is specific to an attractive force varying with the inverse square of the distance. In this case, the so-called *Runge–Lenz* or *Laplace* vector

$$\boldsymbol{A} = -\boldsymbol{h} \times \dot{\boldsymbol{r}} - GM_{\oplus} \frac{\boldsymbol{r}}{r} \tag{3.7}$$

is found to be constant throughout the orbit [3.8]. By forming the scalar product with the radius vector, the conic section equation (3.2) with angle $\upsilon = \angle(\boldsymbol{A}, \boldsymbol{r})$, eccentricity $e = ||\boldsymbol{A}||/GM_{\oplus}$ and parameter $a\,(1-e^2) = h^2/GM_{\oplus}$ can finally be obtained.

Kepler's third law, while valid for all eccentricities, can most easily be justified for a circular orbit. Considering a satellite orbit of radius $r = a$ with orbital period $T$ and angular velocity $n = 2\pi/T$, the equality of centrifugal and gravitational acceleration yields the relation

$$a^3 n^2 = GM_{\oplus} \,. \tag{3.8}$$

Among others, this representation of Kepler's third law is useful to find the semimajor axis at which a given orbital period is achieved. For navigation satellites, a certain repeat rate of the orbit relative to the Earth is typically desired and the orbital period is therefore chosen to match a rationale multiple of the Earth's sidereal rotation period of 23 h 56 min (Table 3.1).

### 3.1.2 Keplerian Orbit Model

The time dependence of the orbital motion is fully determined by the law of areas and may be derived from the geometric properties of the ellipse. Both the angular velocity and the orbital velocity are highest at perigee (the point nearest to the Earth) and lowest at apogee (the most distant point of the orbit). For a mathematical description, it is common to introduce an auxiliary quantity termed the eccentric anomaly $E$ (Fig. 3.3).

Making use of this value, the perifocal coordinates, that is, the position of the satellite relative to the central body and a Cartesian coordinate system oriented in the pericenter direction, may be expressed as

$$\begin{aligned} x_{\mathrm{p}} &= r\,\cos\upsilon = a\,(\cos E - e)\,, \\ y_{\mathrm{p}} &= r\,\sin\upsilon = a\,\sqrt{1-e^2}\,\sin E\,. \end{aligned} \tag{3.9}$$

Furthermore, the shaded area encompassed by the radius vector, the orbit arc and the line of apsides (Fig. 3.3) is given by

$$S(E) = \frac{1}{2} a^2 \sqrt{1-e^2}\,(E - e\,\sin E)\,. \tag{3.10}$$

Using (3.6) for computing the area swept by the radius vector between time $t_0$ when the satellite passes the pericenter and the satellite position at time $t$, we finally get

$$E - e\,\sin E = M = n\,(t - t_0)\,. \tag{3.11}$$

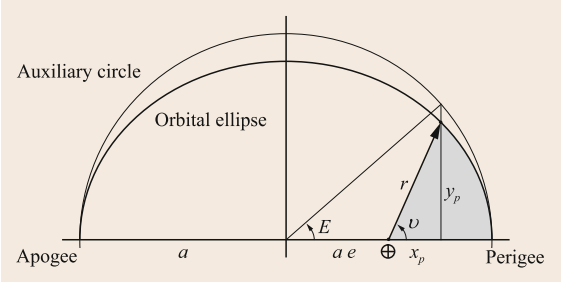

**Fig. 3.3** Geometric relation of the eccentric anomaly $E$ and the true anomaly $\upsilon$ in an elliptic orbit

**Table 3.1** Representative orbital parameters (period, semimajor axis $a$, height $h$, eccentricity $e$, and inclination $i$) of global and regional navigation satellite systems satellites

| System | Period ($\mathrm{rev/d_{sid}}$) | Period (h) | $a$ (km) | $h$ (km) | $e$ | $i$ (°) |
|---|---|---|---|---|---|---|
| GLONASS | 17/8 | 11 h 16 min | 25 510 | 19 130 | 0.0 | 64.8 |
| GPS | 2/1 | 11 h 58 min | 26 560 | 20 180 | 0.0 | 55 |
| BeiDou (MEO) | 13/7 | 12 h 53 min | 27 910 | 21 530 | 0.0 | 55 |
| Galileo | 17/10 | 14 h 05 min | 29 600 | 23 220 | 0.0 | 56 |
| QZSS | 1/1 | 23 h 56 min | 42 160 | 35 790 | 0.1 | 43 |
| BeiDou IGSO | 1/1 | 23 h 56 min | 42 160 | 35 790 | 0.0 | 55 |
| NavIC (IGSO) | 1/1 | 23 h 56 min | 42 160 | 35 790 | 0.0 | 27 |
| BeiDou/NavIC/QZSS GEO; SBAS | 1/1 | 23 h 56 min | 42 160 | 35 790 | 0.0 | $\leq 2$ |

GLONASS: Globalnaja Nawigazionnaja Sputnikowaja Sistema (Russian Global Navigation Satellite System); GPS: Global Positioning System; MEO: medium altitude Earth orbit; QZSS: Quasi-Zenith Satellite System; IGSO: inclined geo-synchronous orbit; NavIC: Navigation with Indian Constellation; GEO: geostationary Earth orbit; SBAS: satellite-based augmentation system

Here, $M$ denotes the mean anomaly which grows linearly with time at the mean motion. Equation (3.11) links geometric quantities with time and is commonly known as Kepler's equation. Unfortunately, it cannot be used directly to compute the eccentric anomaly $E(t)$ at a given time $t$, but must be solved in an iterative manner. A first approximation $E_0 = M$ is typically given by the mean anomaly itself. Refined values can then be obtained using Newton's method

$$E_{i+1} = E_i - \frac{E_i - e\sin E_i - M}{1 - e\cos E_i} \,. \tag{3.12}$$

Except for QZSS, which adopts an intentional eccentricity of $e \approx 0.1$, the orbits of most navigation satellites are almost circular with eccentricities $e = 0.01$ or less. Given the quadratic convergence of Newton's method, a few iterations are therefore sufficient to compute the eccentric anomaly $E$ with an accuracy of 10 digits, which provides a subcentimeter-level accuracy in the resulting positions.

The spacecraft velocity in the perifocal system is obtained from differentiation of (3.9) and (3.11), which results in

$$\begin{aligned} \dot{x}_\mathrm{p} &= -\frac{\sqrt{GM_\oplus a}}{r}\,\sin E \,, \\ \dot{y}_\mathrm{p} &= +\frac{\sqrt{GM_\oplus a}}{r}\,\sqrt{1-e^2}\cos E \,. \end{aligned} \tag{3.13}$$

The description of the satellite orbit has so far been confined to the orbital plane and the line of apsides. In order to express the motion in a global reference frame, such as the International Celestial Reference Frame (ICRF; Chap. 2), the orientation of the orbit is commonly described by a set of three angles (Fig. 3.4):

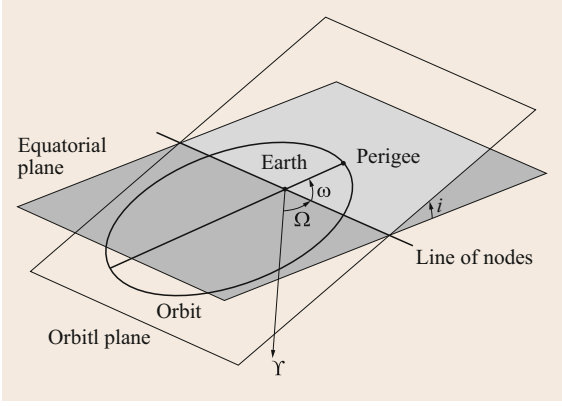

**Fig. 3.4** Orbital elements defining the orientation of the orbital plane and the line of apsides

- The *right ascension of the ascending node* (RAAN, $\Omega$) measures the angle between the $x$-direction of the celestial coordinate system (roughly aligned with the vernal equinox) and the ascending node. The latter describes the point of the orbit, in which the satellite crosses the equatorial plane from South to North (i. e., in *ascending* direction).
- The *inclination* $i$ specifies the angle between the orbital plane and the reference plane (i. e., the celestial equator). More specifically, the inclination is defined as the angle between the North direction and the angular momentum vector of the orbit. Satellites orbiting the Earth in the direction of the Earth rotation (i. e., anticlockwise as seen from North) exhibit inclinations of $0° \le i < 90°$. Those orbiting the Earth in the opposite (retrograde) direction are described by inclinations of $90° < i \le 180°$.
- Finally, the *argument of perigee* $\omega$ measures the angle between the ascending node and the pericenter of the orbit, measured in the direction of satellite motion.

For global navigation satellite system (GNSS) satellites in medium altitude Earth orbits (MEOs), inclination values near 55° are most commonly adopted in an effort to achieve good visibility, moderate orbital perturbations, and acceptable launch cost. However, different values have been adopted for GLONASS as well as the various regional systems (Table 3.1). Geostationary satellites, such as those of the various space-based augmentation systems (SBAS; Chap. 12) apply a near-zero inclination (along with an orbital period of about 24 h) to maintain an almost constant position in the sky for terrestrial users.

Altogether, the three angles $(\Omega, i, \omega)$ uniquely define the spatial orientation of the orbit and allow a transformation from the perifocal coordinates $(x_\mathrm{p}, y_\mathrm{p})$ to celestial coordinates $\boldsymbol{r}_\mathrm{ICRF} = (x, y, z)_\mathrm{ICRF}$ through a series of three consecutive rotations

$$\boldsymbol{r}_\mathrm{ICRF} = \mathbf{R}_3(-\Omega)\mathbf{R}_1(-i)\mathbf{R}_3(-\omega)\begin{pmatrix} x_p \\ y_p \\ 0 \end{pmatrix} \,. \tag{3.14}$$

A corresponding transformation

$$\dot{\boldsymbol{r}}_\mathrm{ICRF} = \mathbf{R}_3(-\Omega)\mathbf{R}_1(-i)\mathbf{R}_3(-\omega)\cdot\begin{pmatrix} \dot{x}_p \\ \dot{y}_p \\ 0 \end{pmatrix} \tag{3.15}$$

applies for the velocity, since the orientation of the orbital plane remains constant in the Keplerian orbit model. The matrices $\mathbf{R}_1(\phi)$ and $\mathbf{R}_3(\phi)$ used in the above

expression used in (3.14) and (3.15) describe elementary rotations about the *x*- and *z-axis*, respectively, and are defined as

$$\mathbf{R}_1(\phi) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & +\cos\phi & +\sin\phi \\ 0 & -\sin\phi & +\cos\phi \end{pmatrix} \tag{3.16}$$

and

$$\mathbf{R}_3(\phi) = \begin{pmatrix} +\cos\phi & +\sin\phi & 0 \\ -\sin\phi & +\cos\phi & 0 \\ 0 & 0 & 1 \end{pmatrix} . \tag{3.17}$$

Combining (3.9) with (3.14) and evaluating the individual transformations, the satellite position may finally be expressed as

$$\boldsymbol{r}_{\mathrm{ICRF}} = r \begin{pmatrix} \cos u \cos\Omega - \sin u \cos i \sin\Omega \\ \cos u \sin\Omega + \sin u \cos i \cos\Omega \\ \sin u \sin i \end{pmatrix} . \tag{3.18}$$

Here,

$$u = \omega + \upsilon \tag{3.19}$$

denotes the instantaneous angle between the radius vector and the ascending node, which is also known as *argument of latitude*.

Alltogether, six quantities $(a, e, i, \Omega, \omega, M)$ are used to uniquely define the position and velocity in the Keplerian orbit model at a given time. They are commonly termed the Keplerian orbital elements.

### 3.1.3 Ground Track and Visibility

While the satellite is moving around the Earth in its orbital plane, the Earth continuously rotates beneath the satellite. Neglecting, for simplicity, variations in the orientation of the Earth rotation axis (such as precession, nutation, and polar motion; Chap. 2), the transformation between the celestial reference frame (such as the ICRF) and the terrestrial reference frame (such as the International Terrestrial Reference Frame (ITRF)) is described by a uniform rotation about the common *z-axis* with angular velocity

$$\omega_\oplus \approx 7.292 \cdot 10^{-5}\ \mathrm{rad/s} . \tag{3.20}$$

The Earth rotation angle (or *mean sidereal time*) $\Theta$ is approximately given by

$$\Theta \approx 280.46^\circ + (360.985653^\circ/\mathrm{d})\, d , \tag{3.21}$$

where $d$ denotes the number of days elapsed since 1 January 2000 Universal Time.

In the case of a nonrotating Earth, the satellite's footprint would describe a great circle on the surface of the Earth that covers a latitude range of $-i \le \varphi \le +i$ (Fig. 3.5) and repeats itself after each revolution. Due to the Earth's rotation, however, repeated equator crossings will no longer take place at the same geographic longitude but are shifted West by an angle $\Delta\lambda = \omega_\oplus T$ that matches the Earth rotation during the orbital period.

The resulting ground tracks are illustrated in Fig. 3.6 for representative satellites of the various GNSS systems. For MEO satellites of the GPS, GLONASS, BeiDou, and Galileo systems a periodic variation of latitude versus longitude is obtained. Depending on their orbital periods, consecutive ascending node crossings are offset in Eastern direction by angles between 148° (Galileo) and 191° (GLONASS). As a special case, a 180° offset is obtained for GPS, which results in a repetition of the ground track after just two revolutions. As discussed earlier, the orbital periods of GLONASS, BeiDou (MEO), and Galileo satellites are also rational fractions of the Earth rotation period (see second column in Table 3.1). Accordingly, their ground tracks likewise repeat after several revolutions. However, the repeat cycles are substantially longer than for GPS and last a total of eight, seven, and 10 days, respectively.

For inclined geosynchronous orbits (IGSOs), which are employed in QZSS, BeiDou, and NavIC, the ground track attains a distinct figure-of-eight. Since the orbital period of IGSO satellites matches that of the

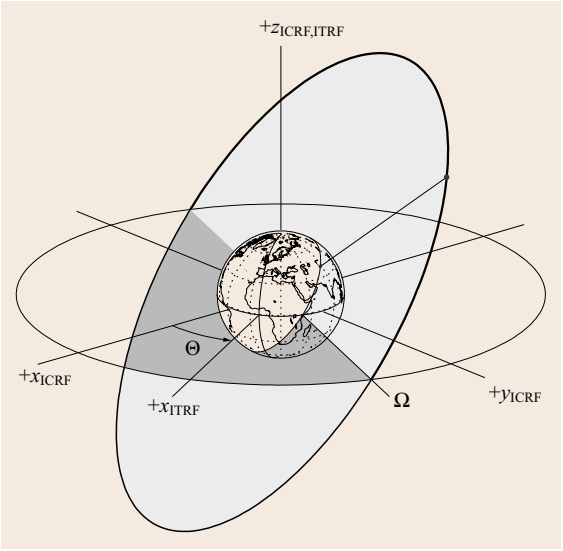

**Fig. 3.5** GPS satellite orbit relative to the Earth

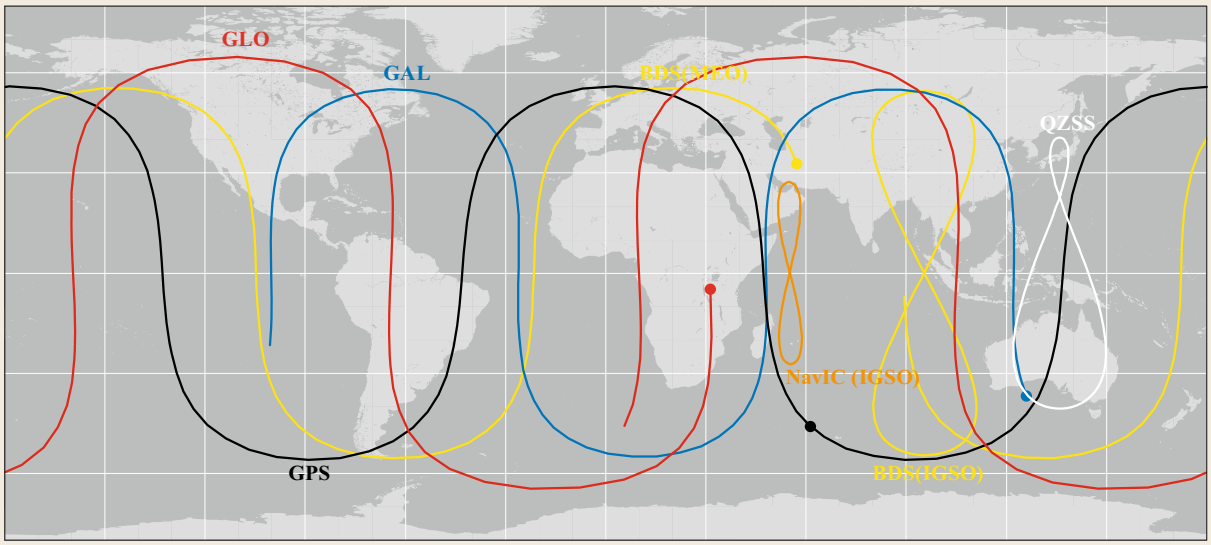

**Fig. 3.6** Representative ground tracks of GNSS satellites in medium altitude Earth orbit (MEO) and IGSO over a 24 h period. The footprint of MEO satellites proceeds from West (*left*) to East (*right*). End points are marked by filled circles. The IGSO ground track describes a figure of eight, which is traversed in clockwise direction in the Northern Hemisphere and in counter-clockwise direction in the Southern Hemisphere

Earth rotation, all equator crossings take place at the same longitude. However, the projected angular velocity varies with the satellite's latitude and is less than that of the Earth at the ascending and descending nodes. As such, the ground track crosses the equator from East to West and the Northern part is traversed in a clockwise sense, while the Southern loop is traversed in a counter-clockwise direction.

Satellites in geostationary orbit (GEO), finally, employ both a near-zero inclination as well as an orbital period closely matching a sidereal day. As a result, they exhibit an essentially stationary footprint throughout a day at a selected point on the equator. In practice, small variations arise due to nonperfect conditions and orbital perturbations but these are typically confined to the order of 1° in longitude and latitude.

In accord with the orbital properties discussed earlier, GEO and IGSO satellites are only ever visible from certain regions of the Earth, while MEO satellite can be viewed from any location on Earth for at least part of their orbit.

To describe the motion of a GNSS satellite relative to a station on the surface of the Earth, a local tangential coordinate system originating in the station and aligned with the East (E), North (N), and Up (U) direction is most commonly employed. Considering a station at geographic longitude $\lambda$ and latitude $\varphi$, the transformation from the terrestrial reference frame to the ENU frame is described by the rotation matrix

$$\mathbf{E} = \begin{pmatrix} -\sin\lambda & +\cos\lambda & 0 \\ -\sin\varphi\cos\lambda & -\sin\varphi\sin\lambda & +\cos\varphi \\ +\cos\varphi\cos\lambda & +\cos\varphi\sin\lambda & +\sin\varphi \end{pmatrix}. \tag{3.22}$$

For a given station at position $\boldsymbol{r}_{\mathrm{sta}}$ to a GNSS satellite at position $\boldsymbol{r}_{\mathrm{sat}}$ (both expressed in the terrestrial frame) the line-of-sight (LOS) unit vector in the ENU frame is

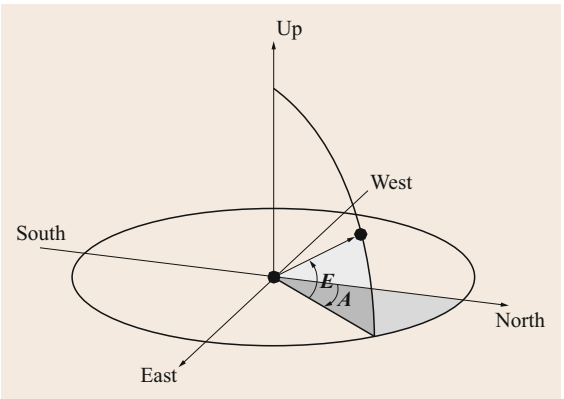

**Fig. 3.7** Azimuth and elevation of a GNSS satellite in the local topocentric coordinate system of the observer

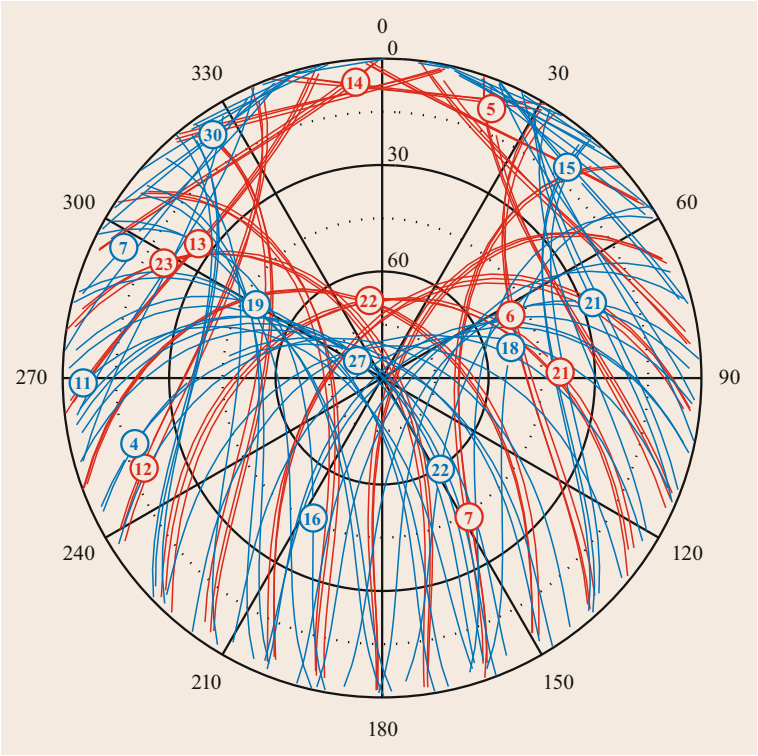

**Fig. 3.8** Azimuth and elevation of GPS and GLONASS satellites for an observer in Munich ($\varphi = 48.8°$N) over a 24 h period on 1st April 2015. At the midnight epoch a total of 11 GPS satellites and 9 GLONASS satellites were visible above a 5° elevation threshold

thus given by

$$\boldsymbol{e} = \mathbf{E} \cdot \frac{\boldsymbol{r}_{\text{sat}} - \boldsymbol{r}_{\text{sta}}}{||\boldsymbol{r}_{\text{sat}} - \boldsymbol{r}_{\text{sta}}||} \,. \tag{3.23}$$

The satellite's *azimuth* describes the angle between North direction and the projection of the line-of-sight vector on the local horizontal plane, while the *elevation* gives the angle between the LOS and the horizon (Fig. 3.7).

A skyplot illustrating the motion of GPS and GLONASS satellites for a station in the Northern Hemisphere over a 1-day period is shown in Fig. 3.8. Satellites remain above the horizon for periods of up to about six hours. While the satellites are roughly symmetrically distributed in the Eastern and Western Hemispheres, a pronounced asymmetry in the North-South distribution may be recognized. In particular, no GPS satellites are ever visible in a cone of about 40° semidiameter around the celestial pole. In view of their higher inclination, the GLONASS satellites offer a better sky coverage with an exclusion zone of about 30° semidiameter.

For polar stations, GNSS satellites of the GPS, Galileo and BeiDou MEO constellations achieve peak elevations of about 45°, which results in an unfavorable vertical dilution of precision (VDOP; Chap. 1) and thus a degraded vertical positioning performance. Again the situation is somewhat improved for GLONASS satellites, which attain a maximum elevation of about 57°. A largely symmetric distribution of visible satellites and a good overall sky coverage, in contrast, are obtained for stations near the equator. Here, the exclusion zone is made up of two semicircles centered around the North and South points on the horizon.

## 3.2 Orbit Perturbations

Section 3.1 describes the Keplerian motion of a satellite about a massive parent body under the sole influence of the gravitational force originating from a central body. Kepler's laws and the equations describing the satellite motion are strictly valid under the assumption that the central body can be considered as a point mass or has a spherically symmetrical mass distribution. In real situations the central body (the Earth) has a complex mass distribution which is varying under the influence of tidal deformation, additional bodies like Sun and Moon exert their gravitational influence, radiation pressure impacts the satellite, and atmospheric drag dissipates orbit energy. These perturbing forces affect the motion of the satellite in a complex way.

To describe the motion of a satellite in this more realistic situation, the two-body equation of motion given in (3.3) has to be extended to include the additional perturbing accelerations and may read

$$\ddot{\boldsymbol{r}} = -\frac{GM_{\oplus}}{r^2}\frac{\boldsymbol{r}}{r} + \boldsymbol{a}(\boldsymbol{r}, \dot{\boldsymbol{r}}, t) \; . \tag{3.24}$$

The perturbing acceleration $\boldsymbol{a}$ is, in general, a function of the satellite's position, of the satellite's velocity (e.g., in case of drag), and of time. As the largest perturbation is about 1000 times smaller than the central force we may indeed consider the additional acceleration $\boldsymbol{a}$ as a perturbation, allowing for approximative analytical solutions of (3.24) (e.g., [3.9–11]). In order to reach the highest accuracy the perturbed equation of motion is however solved using methods of numerical integration.

### 3.2.1 Orbit Representation

In the presence of perturbations, the orbit of a satellite is no longer an ellipse (or more generally, a conic sections) as described in the previous section. However, because the perturbations are small compared to the central term, the orbit of a satellite can still be considered as an ellipse with constantly varying parameters. Due to perturbations, the orientation of the orbital plane in space is in general no longer stable (i. e., the orbital angular momentum $\boldsymbol{h}$ is no longer conserved) but varying.

In each point $\boldsymbol{r}(t)$ along the perturbed trajectory of the satellite a best fitting ellipse can be defined. This so-called *osculating ellipse* is tangent to the satellite trajectory at position $\boldsymbol{r}(t)$ and both orbit representations have in this point the identical vectorial velocity $\dot{\boldsymbol{r}}$. The perturbed orbit of the satellite can be considered as the envelope of the osculating ellipses associated with each orbit position $\boldsymbol{r}(t)$ (Fig. 3.9). The perturbed orbit can thus be represented by the orbital elements of these osculating ellipses. This bijective relation between position and velocity on one side and time dependent so-called *osculating elements* on the other side

$$\{\boldsymbol{r}(t), \dot{\boldsymbol{r}}(t)\} \leftrightarrow \{a(t), e(t), i(t), \Omega(t), \omega(t), t(t_0)\}$$

thus allows us to uniquely describe the perturbed trajectory by its osculating elements.

In order to assess the impact of perturbing forces the time variations of the osculating elements may be studied. Perturbations induce typical variations in osculating elements. These can be classified into short-periodic, long-periodic, and secular variations. Short-periodic perturbations in the osculating elements have typical periods that are equal to the satellite's revolution period or integer fractions thereof while long-periodic perturbations have periods of weeks to many years. Secular perturbations show no periodic patterns but a continuous increase or decrease of an osculating element. They are typically observed in the right ascension of ascending node $\Omega$ and in the argument of perigee $\omega$. As short- and long-periodic perturbations are bounded by their amplitudes, secular perturbations in the osculating elements will after sufficiently long time always dominate all other perturbations. They are thus of par-

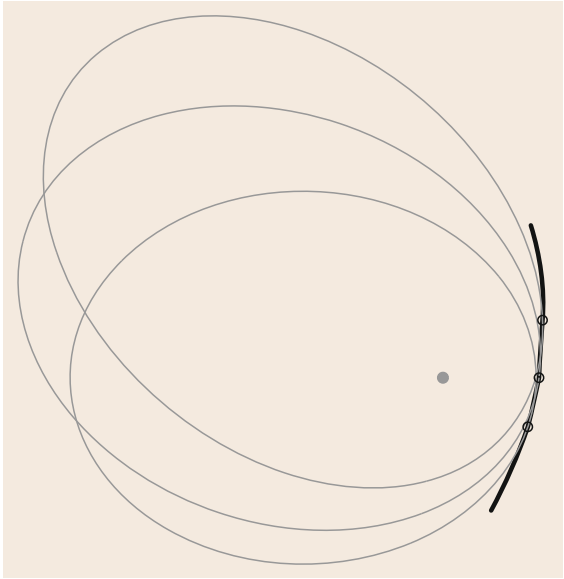

**Fig. 3.9** True orbit (*bold*) approximated at successive positions by osculating ellipses (*thin lines*)

ticular interest when assessing the impact of perturbing accelerations on satellite orbits.

Figure 3.10 shows variations of four osculating elements of a Galileo satellite for a time period of 10 days. These perturbations in the orbital elements are induced by the strongest perturbing acceleration at GNSS altitude caused by the oblateness of the Earth. The osculating semimajor axis (Fig. 3.10a) shows short-periodic oscillations with a period of twice-per-revolution (7 h) and an amplitude of about 1.5 km. The eccentricity (Fig. 3.10b) shows short-periodic variations consisting of a superposition of once-per-revolution and three-times-per-revolution oscillations as well as a long-periodic perturbation caused by Sun and Moon. In the inclination (Fig. 3.10c) a long-periodic variation is superimposed to a short-periodic perturbations. The RAAN (Fig. 3.10d) finally shows a secular perturbation, a retrograde precession of $-1.7$ arcmin/day, superimposed by a short-periodic perturbation. Similar perturbations can be observed for the remaining orbital elements. They are also very similar for other GNSS satellites at MEO altitudes.

### 3.2.2 Perturbing Accelerations

For typical satellite orbits, the accelerations caused by the inhomogeneous mass distribution inside the Earth represent the strongest perturbations. The gravitational acceleration of the Earth may be described by the gradient $\nabla V$ of the gravitational potential $V(\boldsymbol{r})$ which may be represented in the space surrounding the Earth in terms of a spherical harmonic series in the form

$$V(\boldsymbol{r}) = \frac{GM_\oplus}{r} \sum_{n=0}^{\infty} \sum_{m=0}^{n} \left(\frac{R_\oplus}{r}\right)^n \times P_{nm}(\sin\varphi)(C_{nm}\cos m\lambda + S_{nm}\sin m\lambda) \,, \quad (3.25)$$

where $r$, $\lambda$, and $\varphi$ represent the spherical coordinates (radius, geocentric longitude, and latitude) of the position $\boldsymbol{r}$ given in the Earth-fixed reference frame, $R_\oplus$ represents the equatorial radius of the Earth, $P_{nm}$ stands for the associated Legendre polynomials of degree $n$ and order $m$, and $C_{nm}$ and $S_{nm}$ are the so-called Stokes coefficients [3.12]. Modern gravity fields obtained from

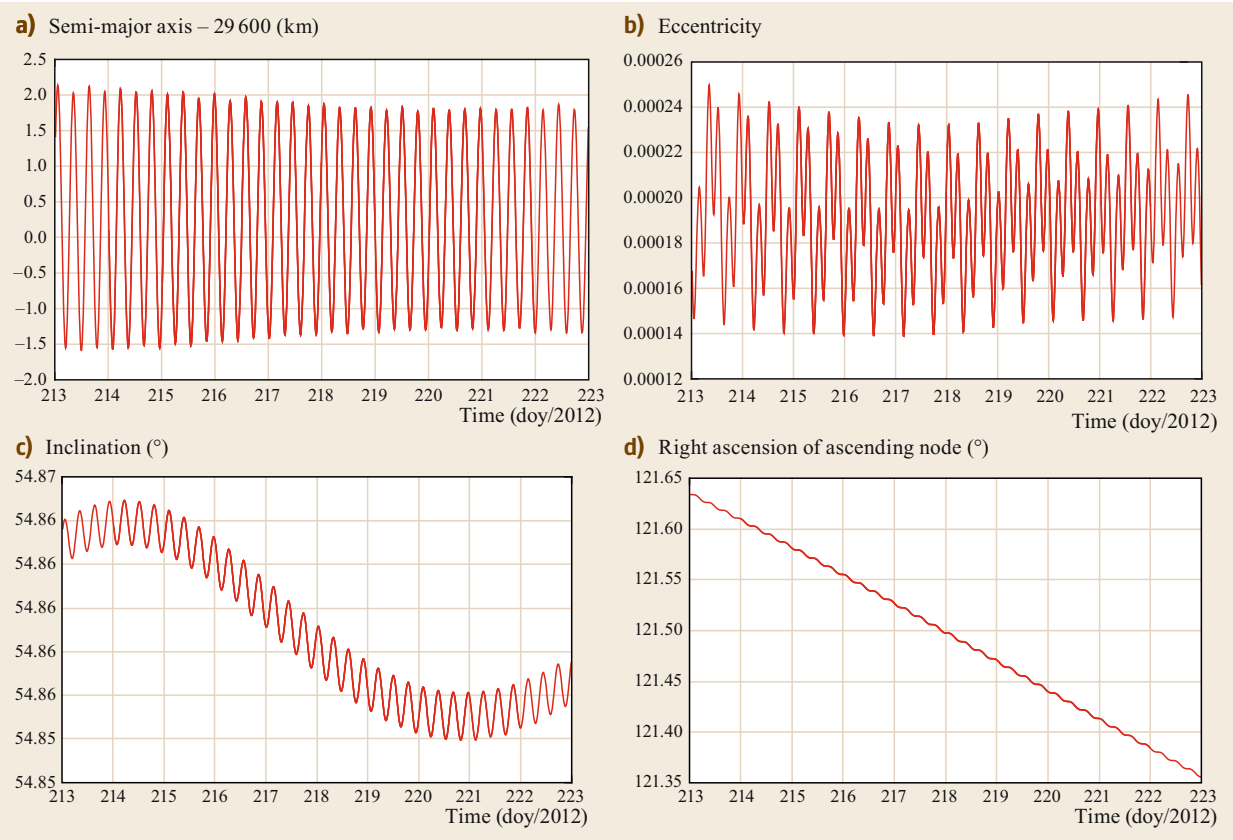

**Fig. 3.10a–d** Osculating elements for the Galileo IOV-1 satellite over 10 days from July 7 to August 10, 2012. Semimajor axis **(a)**, offset by 29 600 km, eccentricity **(b)**, inclination **(c)**, right ascension of ascending node **(d)**

gravity field recovery missions are expanded up to high degree and order, for example, $280 \times 280$ for the static gravity field determined by the gravity field and steady state ocean circulation explorer (GOCE) [3.13], up to $2190 \times 2190$ for EGM2008 [3.14] which combines satellite information with terrestrial gravity measurements. Note that the perturbing acceleration exerted by gravity field terms of degree $n$ decreases with a power of $n+2$ with the distance from the Earth's center. While for low orbiting satellites the gravity field may have to be considered up to degree and order 100, potential terms with degree above 8 cause perturbations below $10^{-11}\,\mathrm{m/s^2}$ at GNSS altitudes causing orbit errors at the sub-millimeter level and can be neglected with respect to other perturbations.

The first term $n = 0$ in the harmonic expansion (3.25) corresponds to the gravitational potential of a spherically symmetric mass distribution which leads to the two-body acceleration, that is, the first term on the right-hand side of (3.24). As the gravity field is represented in the geocentric frame, the terms of degree $n = 1$ vanish. The zonal term of degree 2, $C_{20} = -J_2 = -1.082 \cdot 10^{-3}$ reflects the flattening of the Earth. The net torque exerted by the perturbing acceleration resulting from the oblate mass distribution of the Earth causes a precession of the orbital planes in space as well as a rotation of the osculating ellipses within their planes. The secular part of this precession in the RAAN $\Omega$ and in the argument of perigee $\omega$ may be written in the following form

$$\dot{\Omega}|_{\mathrm{secular}} \simeq -\frac{10.0\,^\circ/\mathrm{d}\cos i}{\left(\frac{a}{R_\oplus}\right)^{7/2}(1-e^2)^2}\,, \tag{3.26}$$

$$\dot{\omega}|_{\mathrm{secular}} \simeq +\frac{5.0^\circ\mathrm{day}(5\cos^2 i - 1)}{\left(\frac{a}{R_\oplus}\right)^{7/2}(1-e^2)^2}\,. \tag{3.27}$$

We recognize that for orbital inclinations $i$ smaller than 90° the precession of the node is retrograde (opposite to the direction of the Earth's rotation) while for inclinations larger than 90° (retrograde motion of the satellite) the precession of the node is prograde. A proper selection of the inclination $i > 90°$ allows the exploitation of the oblateness perturbation for the establishment of sun-synchronous orbits that precess at the same rate as the mean motion of the Sun. Sun-synchronous orbits are particularly popular for Earth observation satellites at low Earth orbits but of no interest for GNSS satellites.

The equation for the secular precession of the perigee (3.27) shows that there is a critical inclination of $i_{\mathrm{crit}} = 63.4°$. The precession of the perigee is prograde resp. retrograde for inclinations smaller resp. larger than the critical value while the perigee shows no secular drift caused by oblateness if the inclination is equal to the critical value. It is interesting to note that the value of the critical inclination can be computed from the mathematical relation $5\cos(i_{\mathrm{crit}}) = 1$ and does not depend on the value of the zonal coefficient $J_2$. Critical inclination is, e.g., exploited for Russian telecommunication satellites of the Molnyia class. As GNSS orbits have typically low eccentricities the orbit inclinations are defined by other requirements than by perturbations in the location of the perigee.

Besides the Earth also other celestial bodies, in particular Sun and Moon, perturb the motion of Earth orbiting satellites. To model these third-body perturbations the Newtonian gravitational attraction is computed assuming point masses for the perturbing bodies. As the perturbing accelerations need to be represented in the geocentric frame, an additional term appears in the equation for the perturbing acceleration of third bodies

$$\boldsymbol{a}_i = -GM_i\left(\frac{\boldsymbol{r}-\boldsymbol{r}_i}{||\boldsymbol{r}-\boldsymbol{r}_i||^3} + \frac{\boldsymbol{r}_i}{||\boldsymbol{r}_i||^3}\right). \tag{3.28}$$

Here $M_i$ represents the mass of the perturbing celestial body $i$, $\boldsymbol{r}_i$ is the geocentric position vector of this body, and $\boldsymbol{r}$ is the geocentric position vector of the perturbed satellite.

The second term on the right-hand side of (3.28) represents the (negative) perturbing acceleration of the celestial body acting on the Earth and accounts for the fact that the geocentric reference frame is not inertial but accelerated under the action of the perturbing celestial body. The gravitational third-body acceleration is represented in the geocentric frame by a so-called tidal acceleration which decreases with the third power of the distance of the perturbing body but increases linearly with the distance of the satellite from the center of the Earth. The third-body perturbations are also called direct tides.

In order to precisely model the motion of Earth satellites also the so-called indirect tides have to be considered. In fact, the gravitational forces from Sun and Moon cause a tidal deformation of the Earth's body. These solid Earth tides result in a time variable mass distribution of the Earth which results in its turn in a perturbation of the satellite orbits. Similarly the impact on satellite orbits from tidal mass variations in the oceans are considered. For the computation of the temporal variations of the Stokes coefficients in (3.25) due to solid Earth tides closed-form models are available from conventional models [3.7] while the temporal variations of the gravity field from ocean tides are computed from sophisticated ocean tide models that are based on hydrodynamic finite element models, (e.g., FES2004, [3.15]) or altimetry observations (e.g., EOT11a [3.16]).

As the equation of motion (3.24) is formulated in Euclidian space relativistic corrections are added as perturbing accelerations in order to account for the curvature of space–time. The main correction is the so-called Schwarzschild term which describes the space curvature caused by the mass of the Earth [3.7, 17]. The Schwarzschild perturbation is proportional to the mass of the Earth and decreases with the third power of the distance of the satellite from the center of the Earth. For low Earth satellites it is of the order of $2 \cdot 10^{-8}\,\mathrm{m/s^2}$ while it reaches $7 \cdot 10^{-11}\,\mathrm{m/s^2}$ for geosynchronous orbits. The Schwarzschild correction results in a negligible perigee precession of the order of 1 mas/d for GNSS satellites. As the Schwarzschild correction is an in-plane correction it does not affect the orientation of the orbital plane.

The Lense–Thirring effect – also called gravitomagnetic or frame dragging effect – is a general relativistic correction caused by the spinning mass of the Earth. It results in a precession of the reference frame which is modeled by Coriolis accelerations. The perturbing acceleration is proportional to the angular momentum of the Earth and decreases with the power 7/2 of the distance of the satellite from the center of the Earth. The effect is of the order of $2 \cdot 10^{-10}\,\mathrm{m/s^2}$ for low Earth satellites and $4 \cdot 10^{-13}\,\mathrm{m/s^2}$ for geosynchronous orbits. The corresponding orbit precession varies between 500 μas/d and 2 μas/d from low to high satellites.

The de-Sitter or geodetic precession is caused by the space–time curvature induced by the mass of the Sun along the orbit of the Earth around the Sun. It causes a precession of the geocentric reference frame with respect to the fixed stars of 19.2 mas/yr or 53 μas/d. The corresponding Coriolis acceleration is proportional to the mass of the Sun and decreases from $5 \cdot 10^{-11}\,\mathrm{m/s^2}$ to $2 \cdot 10^{-11}\,\mathrm{m/s^2}$ from low to high satellites.

In addition to the gravitational accelerations discussed earlier the motion of satellites is also affected by nongravitational forces, also called surface forces. Contrary to gravitational forces, surface forces do not act on the mass of the satellite but on the surface of the satellite body. They are caused by interaction of particles or radiation with the outer satellite surfaces, for example, by atoms and ions in the high atmosphere causing drag forces, or by photons from the Sun reflected and absorbed by the illuminated surfaces and transferring momentum to the satellite thus causing a perturbing force. Characteristic for surface accelerations is their direct dependency on the satellite cross-section $A$ and inverse dependency on the satellite mass $m$. A discussion may be found, for example, in [3.5, 18].

Atmospheric drag acceleration is caused by atmospheric particles at satellite orbit height and is proportional to the air mass density. As air density decreases exponentially with height above the Earth's surface, air drag is relevant for satellites below an altitude of about 2000 km. For GNSS satellites air drag is irrelevant. The simplest model of drag acceleration reads

$$\boldsymbol{a}_{\mathrm{drag}} = -\frac{1}{2} C_{\mathrm{D}} \frac{A}{m} \rho(\boldsymbol{r})\, v_{\mathrm{rel}}^2 \frac{\boldsymbol{v}_{\mathrm{rel}}}{v_{\mathrm{rel}}} \,. \tag{3.29}$$

The acceleration acts in the opposite direction to the velocity vector $\boldsymbol{v}_{\mathrm{rel}}$ relative to the atmosphere and is proportional to the square of the velocity for the laminar flow of air at satellite altitudes. The drag coefficient $C_D$ depends on the aerodynamic properties of the satellite body and on the details of the interaction of the satellite surfaces and the air particles. Typical values are between 2 and 3. The air density $\rho(\boldsymbol{r})$ is very difficult to model. It depends on the thermospheric temperature which in its turn depends on the solar and geomagnetic activity. The drag acceleration at an altitude of 450 km is of the order of $1\,\mu\mathrm{m/s^2}$ and increases to some $100\,\mu\mathrm{m/s^2}$ at an altitude of 250 km. Depending on solar activity, the drag acceleration at given altitude may vary by more than one order of magnitude.

Radiation pressure is caused by the interaction of light with the surface of the satellite which results in a momentum transfer. For a satellite at position $\boldsymbol{r}$ the simplest *cannon-ball* form for the acceleration from radiation pressure due to direct sunlight reads

$$\boldsymbol{a}_{\mathrm{rpr}} = -\gamma C_{\mathrm{R}} \frac{A}{m} \frac{S_0}{c} \left( \frac{1\,\mathrm{AU}}{r_\odot} \right)^2 \frac{\boldsymbol{r}_\odot - \boldsymbol{r}}{||\boldsymbol{r}_\odot - \boldsymbol{r}||} \,. \tag{3.30}$$

where $\boldsymbol{r}_\odot$ is the geocentric position vector of the Sun. $S_0$ represents the solar radiation flux of $1361\,\mathrm{Wm^{-2}}$ [3.19] at a distance of one astronomical unit which gives, divided by the speed of light $c$ the radiation pressure of $4.539 \cdot 10^{-6}\,\mathrm{Nm^{-2}}$. The factor $(1\,\mathrm{AU}/r_\odot)^2$ scales this flux to the current distance of the Earth from the Sun on its slightly eccentric orbit. $C_{\mathrm{R}}$ is the radiation pressure coefficient which depends on the shape and surface properties such as reflectivity and absorption, and $\gamma$ represents the eclipse factor which is 1 in full sunlight and 0 in the shadow of the Earth or the Moon. More complex models consider the satellite structure decomposed into individual surfaces with specified size, orientation, and optical properties (*box-wing model*). The force caused by radiation pressure is then computed for each illuminated surface and added up to the total force. The accuracy of the model depends on the information provided by the manufacturer and on the known attitude of the satellite with respect to the Sun. Typical accelerations due to solar radiation are of the order of $1 \cdot 10^{-7}\,\mathrm{ms^{-2}}$.

**Table 3.2** Average acceleration and orbit error after two revolutions for different orbit types and perturbations

| Perturbation | GPS | | | Galileo | | | IGSO | | |
|---|---|---|---|---|---|---|---|---|---|
| | Average acceleration | Orbit error after 2 rev. Initial conditions | | Average acceleration | Orbit error after 2 rev. Initial conditions | | Average acceleration | Orbit error after 2 rev. Initial conditions | |

Apart from direct solar radiation also indirect radiation reflected from the Earth surface (albedo radiation) as well as infrared radiation emitted by the Earth represents an important fraction of the total radiation-induced perturbing acceleration for low orbiting satellites. Albedo models decompose the surface of the Earth into segments and compute for each of them the radiation impact on the satellite [3.20, 21]. Radiation absorbed by the satellite is re-radiated as thermal radiation causing an acceleration opposite to the direction of emission. For a thorough modeling of the effect a thermal model of the satellite has to be considered.

If the satellite is spinning delayed re-radiated thermal emission causes additional effects such as the Yarkovsky–Rubincam effect [3.22] caused by thermal radiation from the Earth and the Yarkovsky–Schach effect [3.23] caused by heating of the satellite by direct solar radiation. For a satellite like the geodetic laser geodynamic satellite (LAGEOS) these effects cause an alongtrack acceleration of the order of a few $10^{-12}\,\mathrm{ms}^{-2}$ [3.24]. Finally, also the radio emission broadcast by a satellite causes a recoil force of the order of $L/c$ where $L$ is the emitted radio power and $c$ is the speed of light. For an emission power of 100 W, the resulting force is about $3 \cdot 10^{-7}$ N.

The impact of solar wind can be computed from flux, velocity, and mass of the high-energetic particles ejected by the Sun and captured by the Earth's magnetosphere. For typical strong Solar events the resulting perturbing acceleration is some 4 orders of magnitude below that caused by solar radiation and can thus be neglected.

### 3.2.3 Perturbations at GNSS Satellite Altitude

After the general introduction to perturbations in Sect. 3.2.2, let us discuss the orbit perturbations for GNSS satellites. Table 3.2 summarizes the magnitude of perturbations and their impact on GPS and Galileo satellites as well as on IGSO satellites. For the latter, a near circular orbit with a semimajor axis of 42 164 km and an inclination of 55° from the BeiDou constellation is taken as an example. The table gives the mean accelerations of selected perturbations as well as their impact on the orbits. The values listed in the table are average values, computed as the root mean square of the values obtained for individual satellites.

The impact of the perturbing acceleration on the orbits is obtained by numerically integrating the orbits of an ensemble of satellites with and without the respective perturbation switched on. The orbit differences after two satellite revolutions (i. e., 1 d for GPS and 2 d for IGSO) were then determined and averaged. The numerical integration was performed in two different ways. The values in the first column give the differences obtained if the orbit is propagated with the same initial conditions. The orbit differences thus show the plain effect of the perturbations on the orbits.

The values in the second columns of the table were obtained by adjusting the initial conditions in order to allow an optimum fit of the orbit to the case with and without the perturbation enabled. The orbit differences after two revolutions are then significantly smaller than with fixed initial conditions. Because initial conditions always have to be estimated as part of an orbit determination process, these values more realistically represent the observable impact of the perturbations on the orbits. Since, in general, additional parameters such as empirical parameters of a radiation pressure model (Sect. 3.2.4) are adjusted, even these values are in fact pessimistic estimates.

We observe that the Earth's oblateness has by far the largest impact on GNSS satellites, resulting in orbit fit errors at the kilometer level. Accelerations by Sun and Moon are the second-largest effect causing orbit deformations at the order of several hundred meters. Although the gravitational attraction of the Sun at the position of the satellites is larger than that of the Moon due to the much higher mass of the Sun, the tidal acceleration, that is, the gravitational acceleration represented in the geocentric frame is larger for the Moon due to the much lower distance. Terms in the geopotential with higher degree and order than the oblateness have an impact on GNSS orbits at a similar level as radiation pressure. As terms with a degree above 8 have a negligible impact, a very modest harmonic expansion of the geopotential to $8 \times 8$ is sufficient for modeling GNSS satellite orbits.

While variations of the geopotential due to deformations of the solid Earth by tides from Sun and Moon have an impact on GNSS orbits at the several centimeter level, the effect of ocean tides is nearly an order of magnitude smaller. Third body perturbations from other planets have effects on the orbit at the centimeter or subcentimeter level. Perturbations for Venus, Mars, and Jupiter are given for their closest distance to the Earth, that is, for the inferior conjunction for Venus, that is, for the inner planet between Sun and Earth, and the opposition, that is, closest approach for the outer planets.

Contrary to gravitational accelerations, the effects related to interaction of the satellites with radiation from the Sun and the Earth are difficult to model. As they cause large orbit perturbations at the several ten meter level their modeling is a challenge for reaching an orbit accuracy at the few centimeter level.

### 3.2.4 Radiation Pressure

Solar radiation pressure is the largest nongravitational perturbation acting on GNSS satellites. It is significantly more difficult to model than gravitational perturbations, because it depends on the details of the satellite structure, dimensions, optical surface properties, and attitude, that is, information which is often not publicly available for GNSS satellites. Different types of radiation pressure models were thus developed to cope with this perturbation that causes orbit errors at the few hundred meter level within a day.

Nominal orientation of GNSS satellites requests that the navigation antenna points to the center of the Earth while the solar panels are oriented perpendicularly to the direction of the Sun (Sect. 3.4). As a consequence, the Sun moves in the body-fixed $xz$-plane and may illuminate only three surfaces of the body while the satellite orbits around the Earth. These are the front panel, where the navigation antenna is mounted ($+z$-panel), the panel on the backside of the satellite ($-z$-panel), and the top panel ($+x$- or $-x$-panel depending on the definition of the body-fixed coordinate frame), while the panels where the solar arrays are mounted ($+y$- and $-y$-panel) as well as the bottom panel are not illuminated. The satellite body orientation with respect to the Sun can thus solely be parameterized by the Sun-elongation angle $\varepsilon$ (the angle between Sun and center of the Earth as seen by the satellite). While the acceleration caused by radiation pressure exerted on the solar arrays remains constant and points away from the Sun for nominal attitude, the magnitude and direction of the acceleration caused by the satellite body vary with the Sun elongation angle or, equivalently, with argument of latitude $u$, that is, with the position angle of the satellite along its orbit.

As the average satellite cross-section exposed to the Sun as well as the amplitude of the required yawing motion depends on the elevation $\beta$ of the Sun above or below the orbital plane, perturbations will repeat with the period the Sun takes from successive crossings through the same orbital plane in the northward direction. This so-called draconitic period is several days shorter than 1 year because the orbital planes perform a retrograde rotation due to gravitational perturbations caused by the Earth's oblateness. Neglecting the fact that the Sun is not moving along the celestial equator but along the ecliptic and using the precession rates from (3.26) we obtain the mean draconitic periods for different GNSS constellations displayed in Table 3.3. They correspond to the repeat periods of the Sun with respect to the respective GNSS orbit constellation. If we consider that the Sun is moving along the ecliptic, we realize that the draconitic period also depends on the RAAN $\Omega$ of the orbital plane. The draconitic periods for individual orbital planes may thus differ from the values given in Table 3.3 by up to $\pm 30$ days.

Two broad classes of GNSS radiation pressure models may be distinguished, physical models derived from satellite surface properties and empirical models derived from orbit analysis. Models of the first class typically provide the perturbing acceleration vector for given satellite orientation using mathematical functions, which approximate the accelerations derived from detailed physical space vehicle models. The first available models derived from physical characteristics of GPS satellites were the ROCK4 and ROCK42 models for the Block I and Block II/IIA vehicles developed by the spacecraft manufacturer Rockwell International and IBM. While the ROCK-S models consider the solar radiation, the ROCK-T models include in addition the thermal reradiation of the satellites. These models were approximated by Fourier series in the Sun elongation angle $\varepsilon$ by [3.25] and called T10 and T20, respectively, [3.26] used the same approach to develop the T30 model for the Block IIR satellites based on a detailed spacecraft model from the manufacturer Martin Marietta while [3.27] developed an improved radiation pressure model for the same satellite type which includes satellite shadowing effects, Earth albedo radiation, thermal reradiation, and antenna radiation thrust.

Detailed physical models for GNSS satellites are developed at University College London. *Ziebart* and *Dare* [3.28] describe a radiation pressure model for the old GLONASS II $v$ satellites based on ray tracing of a detailed model of the complexly shaped satellites. The model takes into account also shadowing effects and reflected radiation striking another part of the satellite [3.29]. More recently, similar models have been developed for Block IIR satellites [3.30, 31].

Empirical radiation pressure models include parameters that are adjusted in the orbit determination process. One of the most popular empirical models used within the International GNSS Service (IGS [3.32]; Chap. 33) is the empirical CODE (Center for Orbit Determination in Europe) orbit model (ECOM) developed

**Table 3.3** Precession rate and mean draconitic period for the different GNSS constellations

| System | Orbit precession (°/year) | Draconitic period (days) |
|---|---|---|
| GPS | −15.16 | 351.4 |
| GLONASS | −12.10 | 353.4 |
| BeiDou (MEO) | −11.90 | 353.6 |
| Galileo | −9.69 | 355.7 |
| QZSS | −3.65 | 361.6 |
| BeiDou (IGSO) | −2.81 | 362.4 |
| NavIC (IGSO) | −4.36 | 360.9 |

at University of Bern [3.33]. The model represents the components of the solar radiation acceleration in a Sun-oriented reference frame with the unit vector of the first axis $\boldsymbol{e}_\mathrm{D}$ pointing from the satellite to the Sun, the second axis $\boldsymbol{e}_\mathrm{Y}$ pointing along the solar panel axis, and the third axis $\boldsymbol{e}_\mathrm{B}$ completing a right-handed triad, or more specifically

$$\begin{aligned}\boldsymbol{e}_\mathrm{D} &= \frac{\boldsymbol{r}_\odot - \boldsymbol{r}}{||\boldsymbol{r}_\odot - \boldsymbol{r}||}\,,\\ \boldsymbol{e}_\mathrm{Y} &= \frac{\boldsymbol{e}_\mathrm{D}\times\boldsymbol{r}}{||\boldsymbol{e}_\mathrm{D}\times\boldsymbol{r}||}\,,\\ \boldsymbol{e}_\mathrm{B} &= \boldsymbol{e}_\mathrm{D}\times\boldsymbol{e}_\mathrm{Y}\,,\end{aligned} \tag{3.31}$$

where $\boldsymbol{r}$ and $\boldsymbol{r}_\odot$ represent the geocentric position vectors of the satellite and the Sun, respectively. This so-called DYB-reference frame thus rotates around the direction pointing to the Sun as the satellite performs its yaw-steering motion while orbiting the Earth. All three components of the radiation pressure acceleration vector with respect to the axes of this frame are represented by a constant term and a harmonic sine–cosine-term parameterized by the argument of latitude $u$ of the satellite

$$\begin{aligned}D(u) &= D_0 + D_\mathrm{c}\cos u + D_\mathrm{s}\sin u\,,\\ Y(u) &= Y_0 + Y_\mathrm{c}\cos u + Y_\mathrm{s}\sin u\,,\\ B(u) &= B_0 + B_\mathrm{c}\cos u + B_\mathrm{s}\sin u\,.\end{aligned} \tag{3.32}$$

This first-order Fourier decomposition of the radiation pressure acceleration thus contains nine empirical parameters that are estimated in course of the orbit determination procedure. Due to the fact that once-per-revolution terms in the $D$ and $Y$ direction particularly strongly correlate with the orientation of the orbital plane [3.34], thus leading to an instability of the orbit orientation, in general only five of the nine parameters are estimated in the orbit determination process. This reduces the ECOM model to

$$\begin{aligned}D(u) &= D_0\,,\\ Y(u) &= Y_0\,,\\ B(u) &= B_0 + B_\mathrm{c}\cos u + B_\mathrm{s}\sin u\,.\end{aligned} \tag{3.33}$$

In addition to these five empirical parameters small and constrained velocity changes (stochastic pulses) are introduced for each GNSS satellite orbit at noon and at midnight in order to cope with residual orbit modeling deficiencies.

An a priori model that includes additional acceleration terms in the satellite body-fixed $x$- and $z$-directions is described in [3.35]

$$\begin{aligned}D &= D_0\,,\\ Y &= Y_0\,,\\ B &= B_0\,,\\ Z(\Delta u) &= Z_1\sin\Delta u\,,\\ X(\Delta u) &= X_1\sin\Delta u + X_3\sin 3\Delta u\,.\end{aligned} \tag{3.34}$$

Here $\Delta u = u - u_\mathrm{s}$ represents the argument of latitude with respect to the Sun. This angle is related to the satellite position angle $\mu$ from the midnight point as defined in Fig. 3.19 through $\Delta u = \mu + \pi$. The six parameters of the model are in their turn parameterized as functions of the Sun elevation angle $\beta$ above the orbital plane. The model thus includes a total of 18 parameters which were adjusted using several years of CODE final orbits. Similar models were later developed for the newer GPS block types as well as for GLONASS satellites. These models are used by several International GNSS Service (IGS) Analysis Centers as a priori models together with the five-parameter ECOM model (3.32).

Using a similar approach, empirical GPS solar pressure models (GSPM) were also developed at Jet Propulsion Laboratory (JPL). The GSPM.97 model by [3.36] was available for GPS Block IIA satellites. It was improved and extended to GPS Block IIR satellites by [3.37] based on more than 4 years of JPL orbits. The GSPM.04 model represents the acceleration components in the body-fixed frame as a truncated harmonic series with the Sun-elongation $\varepsilon$ as argument

$$\begin{aligned}X(\varepsilon) &= X_1\sin\varepsilon + X_2\sin 2\varepsilon + X_3\sin 3\varepsilon\\ &\quad + X_5\sin 5\varepsilon + X_7\sin 7\varepsilon\,,\\ Y(\varepsilon) &= Y_1\cos\varepsilon + Y_2\cos 2\varepsilon\,,\\ Z(\varepsilon) &= Z_1\cos\varepsilon + Z_3\cos 3\varepsilon + Z_5\cos 5\varepsilon\,.\end{aligned} \tag{3.35}$$

Some of the 10 coefficients ($Y_1$ and $X_2$) are functions of the Sun-elevation angle $\beta$. Separate sets of model parameters are provided for GPS Blocks IIA and IIR. The model is used as a priori model while in addition a constant acceleration bias in the $Y$-direction and a constant scale parameter in the Sun direction as well as stochastic scale variations in the body-fixed coordinate axes are adjusted during orbit determination [3.38].

An alternative approach was developed by [3.39]. This adjustable box-wing model is based on a simple satellite box and solar panel array with defined geometrical dimensions. Optical properties of the illuminated surfaces are estimated during the orbit determination process, specifically the combined optical properties for the solar panels as well as the sum of absorption and diffusion coefficients and the reflection coefficients for

the $+x$-, $+z$- and $-z$-surfaces of the satellite. To cope with correlations between the parameters the reflection coefficients are tightly constrained to a priori values. In addition to these parameters, an acceleration bias along the solar panel axis and a solar panel rotation lag angle are estimated during orbit determination. This model with a total of nine solve-for parameters can thus be considered as an empirical radiation pressure model with physical interpretation of the estimated parameters in terms of surface properties. Together with an improved satellite attitude model, the adjustable box-wing model results in a significant reduction of the impact of orbit modeling deficiencies at draconitic frequencies on geodetic time series such as station coordinates or apparent geocenter motion [3.40, 41].

Motivated by the finding that the classical empirical CODE orbit model (3.32) indicates deficiencies for GLONASS satellites [3.42], an enhanced version of the ECOM model was developed in [3.43].

$$\begin{aligned} D(u) &= D_0 + D_{2c}\cos 2\Delta u + D_{2s}\sin 2\Delta u \\ &\quad D_{4c}\cos 4\Delta u + D_{4s}\sin 4\Delta u \,, \\ Y(u) &= Y_0 \,, \\ B(u) &= B_0 + B_c\cos\Delta u + B_s\sin\Delta u \,. \end{aligned} \tag{3.36}$$

The model includes additional empirical coefficients parameterizing higher frequency variation of the direct solar radiation acceleration in order to cope for the fact that the GLONASS satellites have an elongated shape causing more prominent variation of the satellite body's cross-section exposed to the Sun while orbiting the Earth. The argument $\Delta u$ has the same interpretation as in (3.34).

For Galileo satellites orbit modeling deficiencies could also be identified when using the classical ECOM radiation pressure model (3.32). In fact, satellite laser ranging (SLR) residuals show prominent once-per-revolution variations with an amplitude depending on the Sun elevation angle $\beta$ and reaching up to 20 cm [3.44]. Realizing that these variations originate from the notably rectangular shape of the Galileo in-orbit validation (IOV) satellites with a ratio of about 2 : 1 for the main body axes, an enhanced radiation pressure model was developed in [3.45]. This model complements the empirical CODE 5-parameter model (3.32) by a simple box-wing a priori model whose optical surface parameters were estimated based on Galileo tracking data spanning half a year.

Early Earth radiation models were developed by [3.20]. These models consider the perturbing impact of solar radiation reflected in the visible light on the surface of the Earth (albedo) and infrared radiation emitted by the Earth. The inclusion of these perturbations significantly reduces the orbit prediction errors for GPS satellites [3.30]. Inclusion of Earth radiation and antenna thrust reduces the GPS orbit radius by 2 cm, resulting in a corresponding reduction of the observed bias of SLR residuals [3.21, 46].

Also, thermal imbalance in the satellite body and solar panels causes orbit perturbations through thermal re-radiation. Models for GPS satellites were developed by [3.47–49]. It was already shown by [3.47] that the impact of thermal re-radiation on orbit prediction reaches 10 m after 1 week for eclipsing GPS satellites. [3.48] demonstrates a reduction of the error for a 12 h orbit prediction of GPS Block IIR satellites from 2.7–3.0 m to 0.6 m in the alongtrack direction.

### 3.2.5 Long-Term Evolution

For operational reasons, the ground tracks of all GNSS constellations repeat after a time period, which is specific for each system (Table 3.1). While, for example, the GPS satellites perform two revolutions in one sidereal day, the Galileo satellites perform 17 revolutions in 10 d. For an Earth-fixed observer the GPS constellation thus repeats after one sideral day and the Galileo constellation after 10 d. In general, the ground track of a satellite repeats, if its revolution period is commensurable with the rotation of the Earth. This means that the ratio of the revolution period $U$ and the length of the sidereal day $T$, or, equivalently, the ratio of the Earth rotation rate $\omega_\oplus$ and the satellite's mean motion is an irreducible fraction

$$\frac{U}{T} = \frac{\omega_\oplus}{n} = \frac{K}{N} \tag{3.37}$$

of two integer numbers $N$ and $K$. The satellite then performs $N$ revolutions in $K$ sidereal days. $K$ is also called the orbit repeat cycle.

As a satellite on a ground track repeatable orbit appears again at the same location above the surface of the Earth after $N$ revolutions, it encounters the same acceleration from the inhomogeneous gravity field of the Earth ever again. This periodic perturbation may result in a resonance effect. The most important resonant perturbation appears in the osculating semimaior axis, which results in a changed mean motion of the satellite. As a consequence, the satellite drifts away from its nominal position along the orbit.

These resonant perturbations are caused by specific terms in the Earth's gravity potential (3.26) with characteristic degree $n$ and order $m$ that depend on the integer numbers $N$ and $K$ of the repeat orbit [3.11]. For larger $N$ potential terms of higher degree $n$ are responsible for the perturbations. As the perturbing accelerations are decreasing with a power of $n+2$ of the satellite's distance, the resonant perturbations are much smaller for

satellites with larger number of revolutions $N$ per cycle $K$.

For geostationary satellites, the resonance is particularly strong, since they are apparently fixed above a given location along the Earth's equator and thus experience a constant perturbation by the Earth's gravity field. Theory shows that the geopotential term $(n, m) = (2, 2)$, that is, the ellipticity of the Earth's equator, is responsible for the largest perturbation in this case. Indeed, GEO satellites require frequent station keeping maneuvers in order to keep them in the required longitude box of 0.1°, since the semimajor axis may drift up to 150 m/d, which causes a corresponding acceleration in longitude [3.50].

GEO satellites are, for example, used within the BeiDou constellation. To compensate the semimajor axis drift and the associated change in longitude, these satellites perform an orbit correction maneuver about once every three weeks. Figure 3.11 shows the geographic longitude for the satellite C01. Overlayed by shortperiodic perturbations, the satellite experiences a constant acceleration in the westward direction, which is periodically corrected by a maneuver changing the mean drift from westward to eastward. In a time interval of 200 d, a total of eight maneuvers can be observed. Also, IGSO satellites perform regular maneuvers, although only about two per year.

For satellites at a geostationary distance, the perturbing accelerations from Sun and Moon are of similar magnitude as the accelerations caused by the oblateness of the Earth. The combined perturbation results in a precession of the orbital planes around the so-called Laplace plane, a plane tilted around the line of equinoxes by about 7.5° from the equatorial toward the ecliptic plane. The consequence for geostationary satellites is an increase of the orbit inclination from 0° to 15° and back in a period of about 50 years [3.51]. To compensate the drift in inclination, geostationary satellites typically perform inclination maneuvers. For BeiDou GEO and IGSO satellites, however, no such maneuvers are observed. As a result, the BeiDou GEO satellite have a small and increasing inclination of a few degrees.

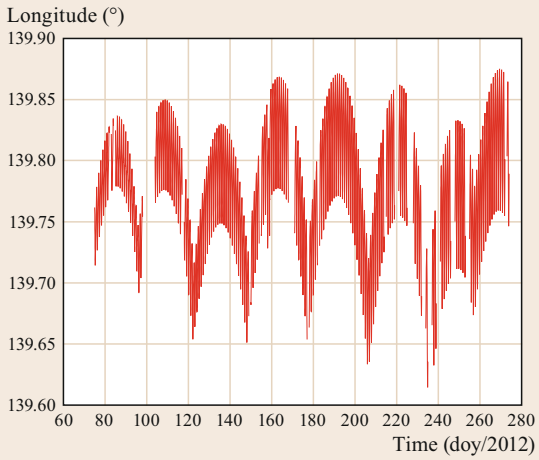

**Fig. 3.11** Longitude of the geostationary BeiDou satellite C01 showing, apart from short-periodic variations, a resonant acceleration in the westward direction. The resulting mean longitude drift is periodically corrected by a station keeping maneuver

Orbits of GPS satellites are in a 2 : 1-commensurability with Earth rotation. Figure 3.12 shows the ground track of a selected GPS satellite together with the geopotential term with degree and order $(n, m) = (3, 2)$. This term causes the largest resonant perturbation as can be recognized from the perturbing accelerations excerted by this term, which repeat after every half revolution of the satellite. As an example, this geopotential term causes an acceleration in the positive alongtrack direction (red arrows) at the peak Northern and Southern latitudes. Drift rates in semimajor axis caused by this potential term may reach 6 m/d. The drift in semimajor axis caused by all resonant geopotential terms may reach 10 m/d for GPS satellites depending on the orbit eccentricity. Figure 3.13 shows the total resonant drift in semimajor axis for all GPS satellites together with the respective maximum possible value.

As a consequence, GPS satellites require regular station keeping maneuvers to cope with this resonant perturbation. Figure 3.14 displays the continuous growth of the mean semimajor axis for GPS satellite G04 due to resonant perturbations, which is interrupted by sudden decreases induced by maneuvers at about yearly intervals. GPS satellites in fact perform station-keeping maneuvers at an average rate of about 0.6 maneuvers per year (Fig. 3.15).

If no maneuvers were performed, the osculating elements would exhibit long-periodic variations with periods of 8 years or longer. The mean semimajor axis may show variations of up to 10 km while the deviation from the nominal slot position may reach ±180°. Figure 3.16 shows the development of the mean semimajor axis and the deviation from the nominal slot position for PRN G04 from a numerical integration without applying any maneuver. In this example, the mean semimajor axis varies between about ±4 km and the deviation of the nominal slot position reaches 210°. Not applying maneuvers would thus significantly affect the regular distribution of the GPS satellites in the constellation.

While GPS satellites require regular maneuvers, MEO satellites from other constellations do not need maneuvers as resonant perturbations can be neglected due to the much higher number $N$ of revolutions per cy-

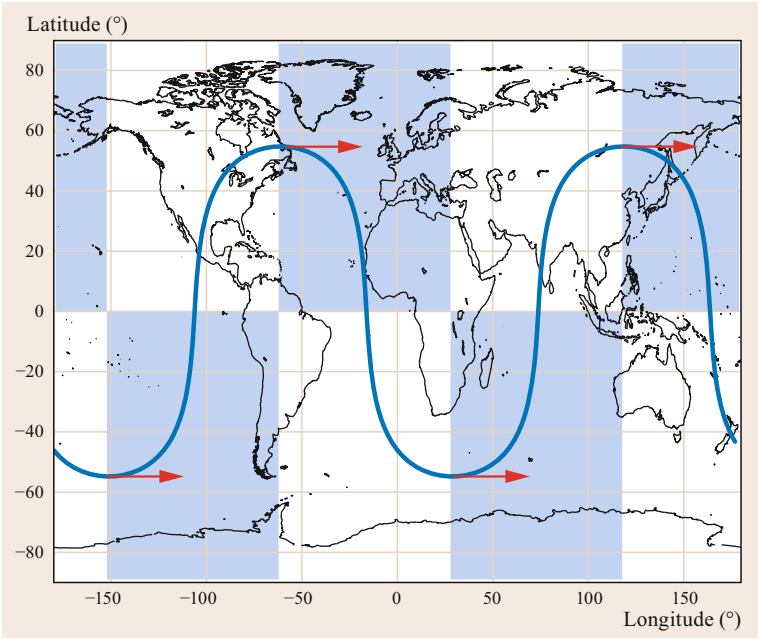

**Fig. 3.12** Ground track of a GPS satellite together with the geopotential term with degree and order (3, 2). *Arrows* indicate the direction of acceleration at the orbit positions of minimum and maximum latitude

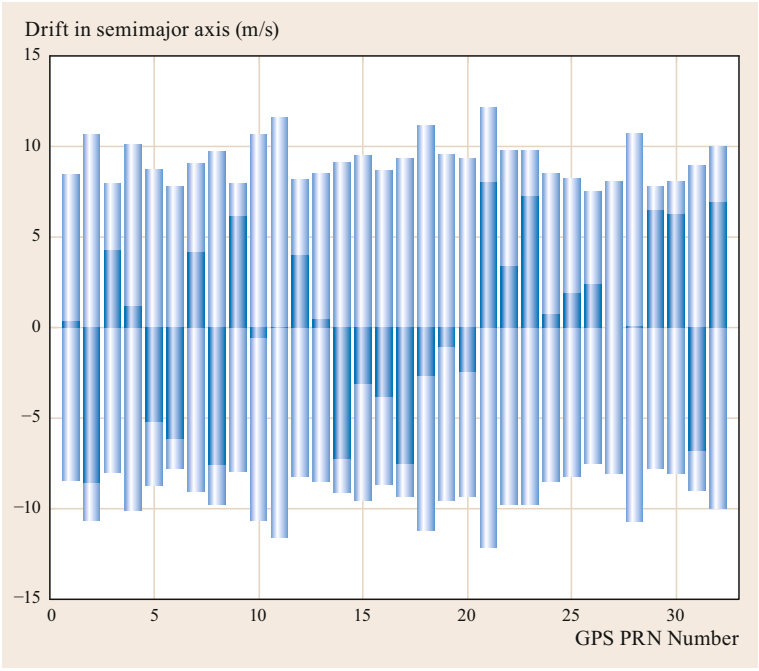

**Fig. 3.13** Drift in semimajor axis for all GPS satellites (PRN numbers for July 2015). *Light*: maximum possible drift. *Dark*: actual total drift

cle for all of them. In fact, the gravity potential terms responsible for resonant perturbations have a minimum degree of 17 for GLONASS and Galileo and of 13 for BeiDou MEO satellites.

On the longer term, resonant perturbations of the eccentricity caused by accelerations from Sun and Moon and zonal terms of the geopotential have to be considered for MEO satellites as well [3.52–54]. These resonances occur when the secular motion of the lines of nodes and apsides becomes commensurable with the motion of Sun and Moon. Depending on the initial orbit orientation, these inclination-dependent resonances may lead to a quasi secular grow of the eccentricity, raising the orbit apogee and lowering the perigee, as

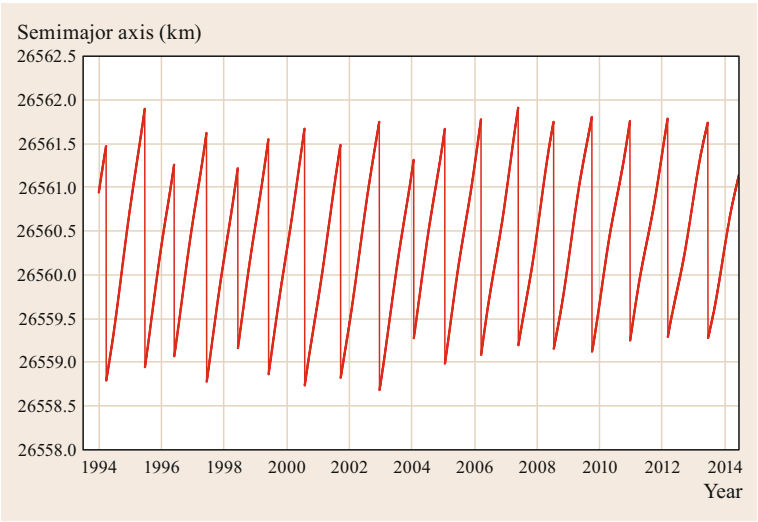

**Fig. 3.14** Semimajor axis for GPS satellite PRN04 (space vehicle number SVN 34) showing a maneuver about once per year

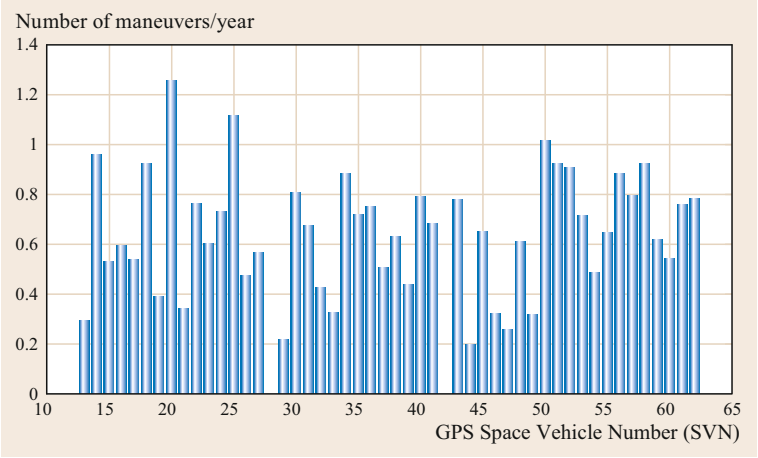

**Fig. 3.15** Number of maneuvers per year performed by GPS satellites in the time period from January 1994 to July 2015. Repositioning maneuvers are not included

soon as, after end of life, orbit correction maneuvers are no longer performed.

Decommissioned GNSS satellites remain in orbit. They are reorbited into a *graveyard* orbit above or below the operational orbits in order to minimize the collision risk with operational satellites of the constellation. The perigee of the orbit of decommissioned GPS satellites is raised by about 1000 km, for Galileo satellites reorbiting policy consists of raising the orbital latitude by 300 km at end-of-life [3.56].

Due to the resonant growth of eccentricity reorbited satellites of a GNSS constellation may penetrate the operational altitude of a neighboring GNSS constellation within only a few decades [3.57, 58]. It is even discussed to exploit the resonant eccentricity build-up to lower the perigee of decommissioned GNSS satellites so far that they re-enter the atmosphere [3.58–60].

### 3.2.6 Orbit Accuracy

Precision and accuracy of orbits may be assessed with different methods each with its individual advantages and weaknesses [3.44, 61].

Precise orbit products are typically made available as daily files (Chaps. 33 and 34). Internal consistency of an orbit product may then be assessed by the analysis of the orbit discontinuities at day boundaries. This measure of internal quality depends on the arc length originally used for computing the orbits. Smaller day boundary discontinuities are, e.g., expected if the daily orbits are generated as the middle day of a three-day-arc.

Similarly, the precision of an orbit product can be assessed by adjusting a long orbit arc through orbit positions of successive one-day-arcs. The root mean square (RMS) of the orbit residuals then serves as

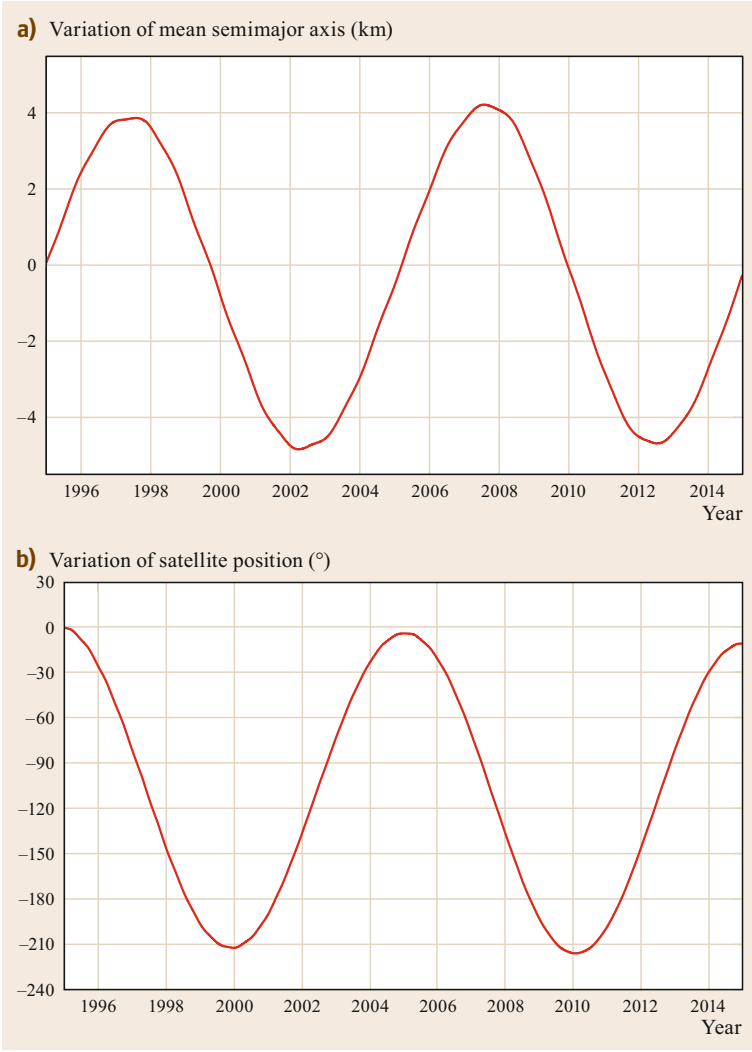

**Fig. 3.16a,b** Orbit of GPS satellite PRN04 (SVN 34) numerically integrated over 20 years without maneuver. **(a)** Mean semimajor axis. **(b)** Deviation of satellite position from nominal slot

a quality indicator. The indicator may however be biased toward the orbit model used as reference for the long-arc calculation. Also for this method optimistic values may be obtained for daily arcs extracted from longer arcs.

The comparison of orbits of the same satellites provided by different providers allows to assess the consistency of orbits computed using different software, analysis strategies, and subsets of the tracking network. The method allows the assessment of modeling differences between the providers while common biases remain undetected.

For satellites tracked by the SLR (satellite laser ranging) stations of the international laser ranging service [3.62]. Residuals of the ranges observed with this independent measurement technique versus. ranges computed from the orbits allow an assessment of the orbit accuracy. Due to the hight altitude of the GNSS satellites mainly the radial component of the orbit is validated. In addition, the GNSS satellites have to be equipped with laser retro-reflectors with known location with respect to the satellite's center of mass, and knowledge of the satellite attitude is required.

Only two (by now decommissioned), GPS Block IIA satellites, SVN 35 and 36, are equipped with laser retro-reflectors, while all satellites from all other GNSS constellations carry onboard retro-reflectors. New GPS satellites will again be equipped with retro-reflectors starting with GPS III SV-9 [3.63].

Orbits of GPS satellites provided by the IGS show a high degree of consistency and accuracy (Chaps. 33 and 34). The weighted RMS of the differences between the GPS orbits delivered by all IGS Analysis Centers and the final IGS orbit product is today be-

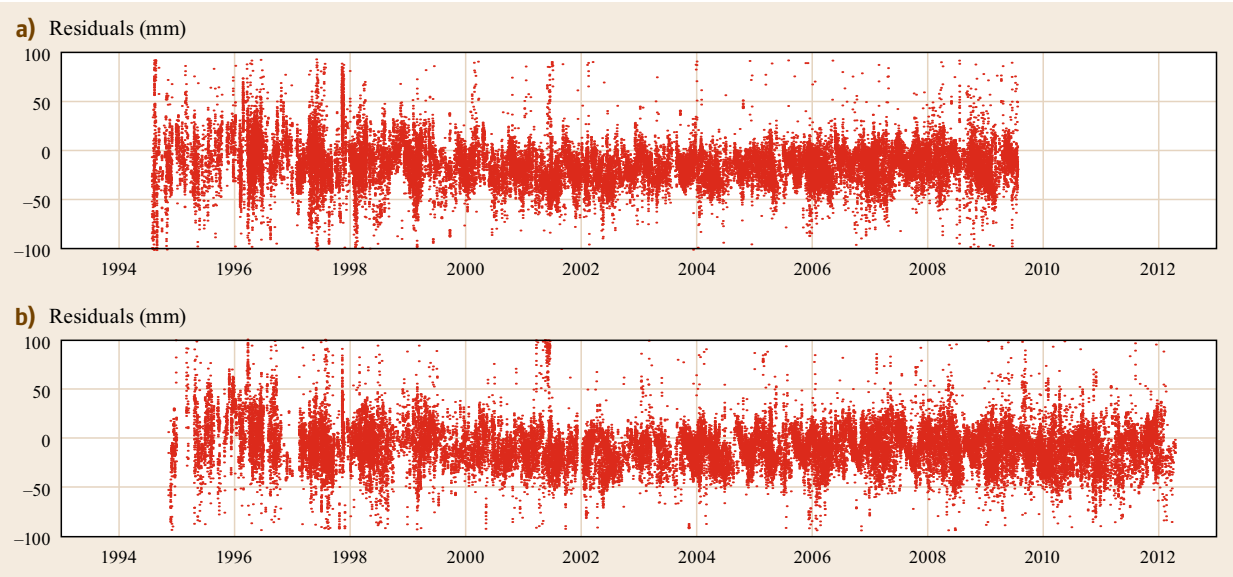

**Fig. 3.17a,b** Laser residuals based on reprocessed IGS orbits [3.55] for the two GPS satellites SVN 35 **(a)** and 36 **(b)** that are equipped with laser retro-reflectors

low 2 cm [3.61] despite the fact that the individual Analysis Center orbits are computed using different software packages, analysis strategies, and tracking station selections. This consistency corresponds with an average 1-dim day boundary orbit misfit for noneclipsing satellites of 21 mm [3.61]. Spectral analysis of daily orbit overlap time series of IGS orbits shows signals with amplitudes at the centimeter level with draconitic, fortnightly, and weekly periods that originate probably from orbit modeling issues and inaccuracies of the subdaily Earth rotation model [3.64].

SLR residuals to the two GPS satellites equipped with laser retro-reflectors (Fig. 3.17) show a standard deviation of 19 mm (SVN 35) and 25 mm (SVN 36) [3.65]. New results by [3.66] based on reprocessed CODE orbits show an SLR standard deviation of 19 mm for the two satellites. Systematic SLR biases which were originally at a level of −5 to −6 cm (negative bias indicating that the SLR measurements show shorter ranges) [3.34] could be reduced to −3 cm [3.65] and finally to 13 mm [3.65] using improved orbit models and more accurate retro-refletor offset values.

Precise orbits of the Russian GLONASS satellites delivered by the IGS have a slightly reduced quality compared to the GPS final orbits. This is due to a reduced tracking network compared to the IGS GPS network, ambiguity resolution for satellite-specific frequencies, and orbit modeling issues. SLR RMS values for GLONASS-M satellites are between 30 and 40 mm with an average value of 35 mm and a vanishing bias [3.66].

For the new GNSSs, no orbits at a comparable quality are yet available. For the Galileo IOV satellites SLR residuals of up to 20 cm with a standard deviation of about 8–9 cm and a mean bias of about 4–5 cm were obtained originally [3.44]. With an improved solar radiation pressure model, the standard deviation and bias of the SLR residuals could be reduced to some 5 cm and −3 cm, respectively [3.45], Sect. 3.2.4. BeiDou MEO and IGSO orbits accuracies are currently at a level of about 2 dm while BeiDou GEO orbits are about 1 order of magnitude worse [3.67, 68]. In particular, the along-track component of the GEO orbits is difficult to determine because geostationary satellites perform only a small motion with respect to the ground stations. This causes strong correlations of the satellite longitude with pseudorange biases and phase ambiguities.

## 3.3 Broadcast Orbit Models

A key element of each satellite navigation system consists in the provision of broadcast orbit information, which enables the receiver to compute the position and velocity of GNSS satellites in the constellation. Such information can be used to assess the visibility and tracking conditions when allocating the tracking chan-

nels and thus helps to speed up the initial acquisition. More importantly, however, accurate orbit information is required to compute modeled pseudoranges and pseudo-range rates as part of the navigation solution. In accord with these needs, two types of parameter sets are commonly distinguished:

- The *almanac* provides coarse orbit information with a typical accuracy at the 1 km level [3.69] to support the acquisition process. Each satellite transmits the orbit parameters of all satellites in the constellation along with auxiliary health and status information.
- The *ephemeris* provides (sub-)meter level orbit information for use in the position and velocity computation. Each satellite transmits only the ephemeris data for itself, thus allowing for a shorter total message length and a higher repeat rate.

Both almanac and ephemeris data are accompanied by satellite clock information (offset, drift, and, optionally, drift rate; Chap. 5), even though this information is solely required for the computation of the navigation solution. Detailed specifications are given in the interface control documents (ICDs) of the GPS [3.69], GLONASS [3.70], Galileo [3.71], BeiDou [3.72], and QZSS [3.73] systems, which provide a comprehensive description of the navigation message format and contents along with instructions for the use of all data.

Within this section, the almanac and ephemeris models employed in current GNSSs are discussed and basic algorithms are presented in a harmonized form. Despite large commonalities, care must be taken, though, that individual constellations employ different coordinate system realizations as well as different physical constants. Considering the latest reference frame realizations in use today, differences between constellations cause position offsets at the few centimeter level and can thus be neglected in comparison with the inherent precision of the broadcast ephemerides [3.74]. On the other hand, care should be taken to make proper use of the constellation-specific physical constants as defined within the respective ICDs (Table 3.4). This is particularly true for the Earth's gravitational coefficient, since even subtle $GM_\oplus$ difference would affect the computed mean motion and create position errors that grow linearly over time.

**Table 3.4** Physical parameters of GNSS almanac and ephemeris models

| System | $GM_\oplus$ ($m^3/s^2$) | $\omega_\oplus$ (rad/s) |
|---|---|---|
| BeiDou | $398\,600.4418 \cdot 10^9$ | $7.2921150 \cdot 10^{-5}$ |
| Galileo | $398\,600.4418 \cdot 10^9$ | $7.2921151467 \cdot 10^{-5}$ |
| GLONASS | $398\,600.4418 \cdot 10^9$ | $7.292115 \cdot 10^{-5}$ |
| GPS | $398\,600.5 \cdot 10^9$ | $7.2921151467 \cdot 10^{-5}$ |
| QZSS | $398\,600.5 \cdot 10^9$ | $7.2921151467 \cdot 10^{-5}$ |

### 3.3.1 Almanac Models

A Keplerian-style orbit model with six independent orbital elements is used to describe the constellation status in the navigation messages of GPS, Galileo, BeiDou, and QZSS. Aside from a secular orbital plane rotation caused by the Earth-oblateness, the corresponding almanac model does not consider orbital perturbations.

As summarized in Table 3.5, seven orbital parameters are provided to the user in addition to the almanac reference epoch $t_a$. These have originally been introduced in GPS, but were later inherited by most other GNSSs for improved communality. Instead of the semimajor axis $a$, its square-root is historically given to save the evaluation of a transcendental function in the computation of the mean motion

$$n_0 = \frac{\sqrt{GM_\oplus}}{\sqrt{a^3}} \tag{3.38}$$

and the mean anomaly

$$M = M_0 + n_0(t - t_a) \tag{3.39}$$

at the epoch of interest $t$. The inclination $i = i_{ref} + \delta_i$ is referred to a reference value $i_{ref}$ (which varies from constellation to constellation) and only the difference is provided to optimize the number of data bits required for transmitting the almanac.

A specific feature of the GPS/GNSS almanac model is the direct computation of orbital positions in an Earth-fixed reference frame. Instead of the right ascension $\Omega$ of the ascending node, its longitude $\Omega_0$ relative to the Greenwich meridian at the beginning $t_w$ of the calendar week is given in the almanac data set. Both quantities are related by

$$\Omega_0 = \Omega(t_a) - \Theta(t_w)\,, \tag{3.40}$$

**Table 3.5** GNSS almanac parameters

| Parameter | Description |
|---|---|
| $\sqrt{a}$ | Square root of semimajor axis |
| $e$ | Eccentricity |
| $\delta_i$ | Inclination offset from reference value<br>$i_{ref} = 54°$ (GPS),<br>63° (GLONASS),<br>56° (Galileo),<br>54° (BeiDou MEO/IGSO),<br>0° (BeiDou GEO),<br>45° (QZSS) |
| $\Omega_0$ | Longitude of the ascending node at the weekly epoch |
| $\dot{\Omega}$ | Rate-of-change of the right ascension of the ascending node |
| $\omega$ | Argument of perigee |
| $M_0$ | Mean anomaly at reference epoch |

where $\Theta$ denotes the Greenwich mean sidereal time. As a consequence of the Earth's oblateness, the inertial RAAN is not a constant, but exhibits a mean drift $\dot{\Omega}$ in the retrograde direction, which varies with inclination and orbital radius. It ranges from a minimum of roughly $-0.01\,^\circ/\mathrm{d}$ for high-altitude, geosynchronous orbits to a maximum of about $-0.04\,^\circ/\mathrm{d}$ for the GPS MEO constellation (Table 3.3).

Making use of the nodal rate provided in the almanac parameters, the Earth-fixed longitude $\lambda_\Omega$ of the ascending node at epoch $t$ can be expressed as

$$\begin{aligned}\lambda_\Omega(t) &= \Omega(t) - \Theta(t)\\ &\approx \Omega(t_\mathrm{a}) + \dot{\Omega}(t-t_\mathrm{a})\\ &\quad - \Theta(t_\mathrm{w}) - \omega_\oplus(t-t_\mathrm{w})\\ &= \Omega_0 + \dot{\Omega}\,(t-t_\mathrm{a}) - \omega_\oplus(t-t_\mathrm{w})\,. \end{aligned} \tag{3.41}$$

Following the solution of Kepler's equation (3.11) for the eccentric anomaly $E$ and the computation of the perifocal coordinates $(x_\mathrm{p}, y_\mathrm{p})$ from (3.9), the position of the GNSS satellite in the ITRF (or the respective constellation-specific, Earth-fixed frame) can thus be computed from the relation

$$\boldsymbol{r}_\mathrm{ITRF} = \mathbf{R}_3(-\lambda_\Omega)\mathbf{R}_1(-i)\mathbf{R}_3(-\omega)\cdot\begin{pmatrix} x_\mathrm{p}\\ y_\mathrm{p}\\ 0\end{pmatrix}. \tag{3.42}$$

Differentiation with respect to time $t$ yields the associated expression

$$\begin{aligned}\dot{\boldsymbol{r}}_\mathrm{ICRF} &= \mathbf{R}_3(-\lambda_\Omega)\mathbf{R}_1(-i)\mathbf{R}_3(-\omega)\begin{pmatrix}\dot{x}_\mathrm{p}\\ \dot{y}_\mathrm{p}\\ 0\end{pmatrix}\\ &\quad - \begin{pmatrix}0\\0\\ \omega_\oplus - \dot{\Omega}\end{pmatrix}\times \boldsymbol{r}_\mathrm{ICRF}\,. \end{aligned} \tag{3.43}$$

for the velocity relative to the rotating ITRF, where $(\dot{x}_\mathrm{p}, \dot{y}_\mathrm{p})$ is the perifocal velocity obtained in (3.13).

For completeness, we note that the generic formulation of the almanac model given above is mathematically equivalent to the algorithms specified in the GPS, Galileo, BeiDou, and QZSS ICDs, but employs a slightly different notation and arrangement of the individual equations. Among others, the ICD formulation refers all times to the start-of-week, makes use of the true anomaly and avoids explicit matrix rotations. Furthermore, the ICDs lack instructions for the computation of the spacecraft velocity.

Other than the aforementioned constellations, the GLONASS system specifies an analytical almanac model, which considers both secular and short periodic perturbations to compute position and velocity from a set of six mean orbital elements. While potentially more accurate than the GPS almanac model, the GLONASS model is substantially more complex and cannot be presented here in adequate detail. Interested readers are referred to the GLONASS ICD [3.70] for a comprehensive formulation, while a truncated version with adequate accuracy for practical purposes is described in [3.75].

### 3.3.2 Keplerian Ephemeris Models

A perturbed Keplerian orbit representation is used for the broadcast ephemeris model of the GPS, Galileo, BeiDou, and QZSS constellations. Other than GLONASS that builds on a numerical orbit propagation, the spacecraft position and velocity can directly be computed from the given orbital parameters at arbitrary epochs in the overall validity interval.

The most common ephemeris model has been established for use with the GPS LNAV and later inherited by most other constellations. It represents an extended version of the almanac model discussed earlier and introduces additional parameters for a refined orbit representation (Table 3.6). These account for differences in the mean motion relative to its Keplerian value,

**Table 3.6** Parameters of Keplerian broadcast ephemeris models

| Parameter | Description |
|---|---|
| $\sqrt{a}$, $\Delta a$ | Square root of semimajor axis legacy navigation message (LNAV) or semimajor axis offset from reference value $a_\mathrm{ref} = 26\,559\,710$ m (GPS civil navigation message (CNAV)), 42 164 200 m (QZSS CNAV) |
| $\dot{a}$ | Rate of change of the semimajor axis (CNAV) |
| $\Delta n$ | Correction to mean motion |
| $\dot{n}_0$ | Rate of change of mean motion (CNAV) |
| $e$ | Eccentricity |
| $i_0$ | Inclination at reference epoch |
| $di/dt$ | Rate-of-change of inclination |
| $\Omega_0$ | Longitude of the ascending node at the weekly epoch |
| $\dot{\Omega}$ | Rate-of-change of the right ascension of the ascending node (LNAV) |
| $\Delta\dot{\Omega}$ | Rate-of-change of the right ascension of the ascending node relative to a reference value $\dot{\Omega}_\mathrm{ref} = 4.68\cdot 10^{-7}\,^\circ/\mathrm{s}$ (GPS/QZSS CNAV) |
| $\omega$ | Argument of perigee |
| $M_0$ | Mean anomaly at reference epoch |
| $C_\mathrm{rc}$, $C_\mathrm{rs}$ | Amplitude of (co)sine harmonic correction term to the orbital radius |
| $C_\mathrm{uc}$, $C_\mathrm{us}$ | Amplitude of (co)sine harmonic correction term to the argument of latitude |
| $C_\mathrm{ic}$, $C_\mathrm{is}$ | Amplitude of (co)sine harmonic correction term to the inclination |

a drift of the orbital inclination and for perturbations in the radial, along-track, and cross-track direction with a twice-per-rev characteristics. To achieve even higher accuracy, the drifts of the semimajor axis and the mean motion are, furthermore, considered in the new CNAV transmitted with the GPS L2C and L5 signals [3.69, 76]. Also, the CNAV message provides the offset of the nodal drift from a reference value rather than the full value to achieve higher precision with a smaller number of data bits. All orbital elements and parameters refer within a broadcast navigation message refer to a common epoch $t_e$, but different epochs (and elements) apply for the LNAV ad CNAV message types.

The ephemeris algorithm starts with computing the mean anomaly

$$M = M_0 + n\,(t - t_e) \tag{3.44}$$

at the epoch of interest from the semimajor axis

$$a = \begin{cases} \left(\sqrt{a}\right)^2 & \text{(LNAV)}\,, \\ a_{\text{ref}} + \Delta a & \text{(CNAV)}\,, \end{cases} \tag{3.45}$$

and (perturbed) mean motion

$$n = \sqrt{\frac{GM_\oplus}{a^3}} + \begin{cases} \Delta n & \text{(LNAV)}\,, \\ \Delta n + \Delta\dot{n}(t - t_e) & \text{(CNAV)}\,. \end{cases} \tag{3.46}$$

Following the solution of Kepler's equation (3.11), the true anomaly

$$\upsilon = 2\tan^{-1}\left(\sqrt{\frac{1+e}{1-e}}\,\tan\frac{E}{2}\right) \tag{3.47}$$

and the unperturbed argument of latitude $\bar{u} = \omega + \upsilon$ are obtained. The latter serves to evaluate the periodic corrections

$$\begin{aligned} \delta r &= C_{\text{rs}}\sin(2\bar{u}) + C_{\text{rc}}\cos(2\bar{u})\,, \\ \delta u &= C_{\text{us}}\sin(2\bar{u}) + C_{\text{uc}}\cos(2\bar{u})\,, \\ \delta i &= C_{\text{is}}\sin(2\bar{u}) + C_{\text{ic}}\cos(2\bar{u})\,, \end{aligned} \tag{3.48}$$

and yields the perturbed values

$$\begin{aligned} r &= a(1 - e\cos E) + \delta r\,, \\ u &= \bar{u} + \delta u\,, \\ i &= i_0 + \frac{di}{dt}(t - t_e) + \delta i\,, \end{aligned} \tag{3.49}$$

of the radius, the argument of latitude, and the inclination. As in the almanac model, the Greenwich longitude of the ascending node is given by

$$\lambda_\Omega = \Omega_0 + \dot{\Omega}\,(t - t_e) - \omega_\oplus(t - t_w)\,, \tag{3.50}$$

where the nodal rate $\dot{\Omega}$ is either given directly in the ephemeris data (LNAV) or obtained from the reference value (CNAV)

$$\dot{\Omega} = \dot{\Omega}_{\text{ref}} + \Delta\dot{\Omega}\,. \tag{3.51}$$

Collecting the above results, the Earth-fixed position is finally given by

$$\boldsymbol{r}_{\text{ITRF}} = \mathbf{R}_3(-\lambda_\Omega)\mathbf{R}_1(-i)\begin{pmatrix} r\cos u \\ r\sin u \\ 0 \end{pmatrix}. \tag{3.52}$$

Complementary to the GNSS satellite position, its velocity is required as part of the navigation solution process, when determining the user velocity from observed range rate or Doppler values (Chap. 21). While undocumented in the ICDs, the velocity can again be found by differentiation of the above expressions for the position with respect to time $t$. The resulting expression are substantially more complex, though, and cannot be reproduced here in view of limited space. Interested readers are therefore referred to [3.77, 78], and [3.79], which provide consistent sets of equations for computing position, velocity, and, optionally, acceleration in the Earth-fixed reference frame based on the standard LNAV ephemeris model.

The basic GPS LNAV ephemeris model has likewise been adopted by Galileo and BeiDou. System-specific adaptations are limited to the use of individual time and reference systems and a slightly varying bit-field representation of the individual quantities [3.71, 72]. As a major addition, a special formulation has, however, been introduced for the specific case of geostationary BeiDou satellites in view of their moderate inclination with respect to the equator [3.72, 80]. The inclination $i$ provided in the broadcast ephemeris for GEO satellites is therefore referred to an auxiliary plane with a 5° tilt relative to the Earth equator. Also, a different convention and origin apply for the specification of the longitude of the ascending node $\Omega$. These result in the alternative expression

$$\begin{aligned} \boldsymbol{r} = {} & \mathbf{R}_3(\omega_\oplus\,(t - t_w))\,\mathbf{R}_1(-5^\circ) \\ & \times\,\mathbf{R}_3(-\Omega)\,\mathbf{R}_1(-i)\begin{pmatrix} r\cos u \\ r\sin u \\ 0 \end{pmatrix} \end{aligned} \tag{3.53}$$

with

$$\Omega(t) = \Omega_0 + \dot{\Omega}\,(t - t_e) - \omega_\oplus\,(t_e - t_w)\,. \tag{3.54}$$

Making use of the auxiliary plane, potential singularities can readily be avoided. Since the orbital plane of

the BeiDou GEO satellites is typically controlled to fall within less than about 2° from the equator, the inclination with respect to the auxiliary plane can never attain a zero value. It is emphasized, though, that the modified model is exclusively used for the geostationary satellites of the BeiDou constellation, whereas the standard model and parameterization are employed for the BeiDou MEO and IGSO satellites.

### 3.3.3 Cartesian Ephemeris Model

An alternative for distributing GNSS orbit information has been introduced by the Russian GLONASS system. Here, users are provided with a Cartesian state vector (i. e., position $\boldsymbol{r}$ and velocity $\boldsymbol{v}$) at the ephemeris reference epoch $t_e$. The trajectory in the vicinity of this epoch can then be obtained by numerical integration of first-order equation of motion

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\boldsymbol{r}\\ \boldsymbol{v}\end{pmatrix}=\begin{pmatrix}\boldsymbol{v}\\ \boldsymbol{a}\end{pmatrix}. \tag{3.55}$$

To avoid the need for explicit reference system transformations, the equation of motion is expressed in the rotating, Earth-fixed reference frame. Accordingly, centrifugal and Coriolis terms are considered in the modeled acceleration

$$\begin{aligned}\boldsymbol{a} = &-GM_\oplus\frac{\boldsymbol{r}}{r^3}\\ &-\frac{3}{2}J_2GM_\oplus\frac{R_\oplus^2}{r^5}\begin{pmatrix}\frac{x-5xz^2}{r^2}\\ \frac{y-5yz^2}{r^2}\\ \frac{3z-5z^3}{r^2}\end{pmatrix}\\ &+\omega_\oplus^2\begin{pmatrix}x\\ y\\ 0\end{pmatrix}+2\omega_\oplus\begin{pmatrix}+\dot{y}\\ -\dot{x}\\ 0\end{pmatrix}\\ &+a_{\odot\mathbb{C}}\end{aligned} \tag{3.56}$$

next to the central component of the Earth gravity field and the Earth oblateness [3.70, 81]. Within this expression, the spacecraft position $\boldsymbol{r}=(x,y,z)^\top$ and the acceleration $\boldsymbol{a}$ are consistently referred to an Earth-fixed reference frame aligned with the instantaneous equator and rotation axis. Third-body perturbations by the Sun and Moon are taken into account by the acceleration $a_{\odot\mathbb{C}}$, which is considered as constant over the ephemeris propagation interval (of typically ±15 min). To simplify the user algorithm, $a_{\odot\mathbb{C}}$ is provided as part of the navigation message next to position and velocity at the reference epoch.

Based on the equation of motion and the given initial conditions, the position and velocity can by obtained at any time within the validity interval through numerical integration. While no particular integration method is specified within the GLONASS ICD, a fourth-order Runge–Kutta method is commonly recommended. It provides an approximation

$$\boldsymbol{y}(t+h)\approx\boldsymbol{y}(t)+\frac{h}{6}(\boldsymbol{k}_1+2\boldsymbol{y}_2+2\boldsymbol{y}_3+\boldsymbol{y}_4) \tag{3.57}$$

with

$$\begin{aligned}\boldsymbol{k}_1&=\boldsymbol{f}\,(t,\boldsymbol{y}(t))\ ,\\ \boldsymbol{k}_2&=\boldsymbol{f}\left(t+\frac{h}{2},\boldsymbol{y}(t)+\frac{h\boldsymbol{k}_1}{2}\right)\ ,\\ \boldsymbol{k}_3&=\boldsymbol{f}\left(t+\frac{h}{2},\boldsymbol{y}(t)+\frac{h\boldsymbol{k}_2}{2}\right)\ ,\\ \boldsymbol{k}_4&=\boldsymbol{f}(t+h,\boldsymbol{y}(t)+h\boldsymbol{k}_3)\ .\end{aligned} \tag{3.58}$$

A simplified form of a Cartesian trajectory model has, furthermore, been adopted for the various SBAS systems. Here, a set of position, velocity and acceleration values is provided at the given reference epoch, which describes a Taylor series approximation

$$\boldsymbol{r}(t)=\boldsymbol{r}(t_e)+\boldsymbol{v}(t_e)(t-t_e)+\frac{1}{2}\boldsymbol{a}(t_e)(t-t_e)^2 \tag{3.59}$$

of the spacecraft position over short time intervals [3.82, 83]. As in the GLONASS model, all quantities refer directly to the Earth-fixed coordinate system. The simplicity of the SBAS ephemeris model in comparison to the more elaborate GLONASS model is mainly achieved through frequent ephemeris updates as well as a continuous upload capabilities. Compared to the 24 h period of the geostationary SBAS satellites, the common update interval of about 4 min covers less than 1/300th of an orbit. Accordingly, higher-order terms can be neglected and a second-order expansion is sufficient to meet the desired accuracy.

**Table 3.7** Typical update interval of broadcast ephemerides for individual GNSSs and navigation message types

| System | Type | Interval |
|---|---|---|
| GPS | LNAV | 2 h |
| | CNAV | 3 h |
| GLONASS | | 30 min |
| BeiDou | | 1 h |
| Galileo | INAV, FNAV | 10–180 min |
| QZSS | LNAV, CNAV | 15 min |

### 3.3.4 Broadcast Ephemeris Generation and Performance

Consecutive sets of ephemeris parameters with update intervals of 10 min to 3 h (Table 3.7) are generated from a common predicted trajectory and uploaded as a com-

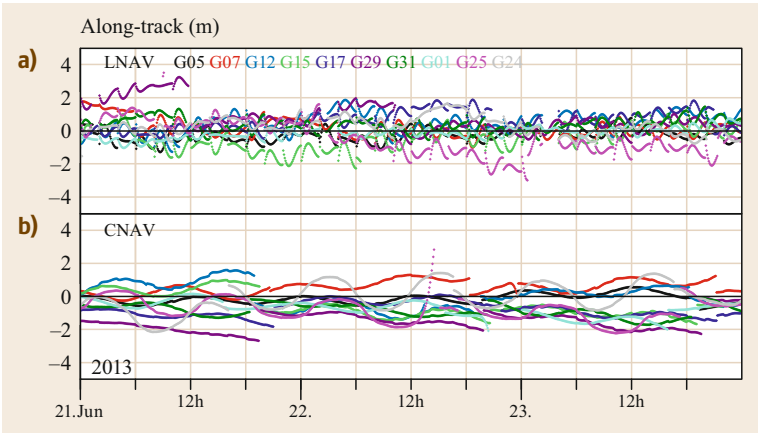

**Fig. 3.18a,b** Along-track position errors of GPS LNAV (a) and CNAV (b) navigation messages during the first CNAV transmisson in June 2013 (after [3.74])

mon batch to the GPS satellite during a ground contact. As a minimum, uploads are performed once per day during nominal operations in GPS [3.84]. Even though consecutive ephemeris sets refer to the same trajectory between such uploads, small discontinuities will still be encountered when transitioning from one set to another due to the inherent approximation error. For the GPS LNAV message, such errors may amount to 0.5 m but are reduced to centimeter level in the new CNAV message [3.84, 85]. The smooth nature of the CNAV ephemeris can also be recognized from the comparison of LNAV and CNAV ephemeris errors shown in Fig. 3.18. While both ephemeris types exhibited similar overall errors during the early CNAV test phase, no discontinuities can be recognized at the (three hourly) updates in between the daily uploads.

Discontinuities at the 1 m level are also present in the GLONASS ephemeris as a result of the limited resolution (1 mm/s) of the velocity field within the GLONASS navigation message. The resulting approximation errors are still smaller than the overall ephemeris error budget but may in fact limit future performance improvements.

The quality of broadcast ephemeris data of GPS and GLONASS has been assessed in various studies [3.86–88], which demonstrated a continuous improvement over time. The performance figures for the two legacy systems are compared in Table 3.8 with early results for the new constellations BeiDou, Galileo and QZSS based on a comparison of broadcast and precise ephemerides over a 1 year interval. While the along-track component is least well determined in all systems, it only contributes an average of 9–15% to the user range error (URE) depending on the orbit altitude. Radial errors, which directly map into the URE are typically confined to less than 0.5 m. For completeness, it is emphasized that the values given Table 3.8 do not include the contribution of clock offset uncertainties in the broadcast ephemerides. Depending on the clock type (cesium, rubidium, or hydrogen-maser; Chap. 5) and quality, the errors of the broadcast clock will typically exceed the orbit uncertainty and therefore dominate the overall error budget. The total signal-in-space range error (SISRE), which measures the contribution of broadcast orbit and clock errors to the modeled pseudorange, presently amounts to 0.7 m for GPS but up to 2 m for other constellations [3.74].

**Table 3.8** RMS position errors radial (R), along track (T) and the cross-track (N) direction of broadcast ephemerides in 2013/14 (after [3.74])

| System | Type | R (m) | T (m) | N (m) |
|---|---|---|---|---|
| GPS | LNAV | 0.18 | 1.05 | 0.44 |
| GLONASS | | 0.35 | 2.41 | 1.33 |
| BeiDou (MEO+IGSO) | | 0.50 | 2.42 | 1.31 |
| Galileo | INAV | 0.63 | 2.65 | 2.29 |
| QZSS | LNAV | 0.48 | 1.42 | 0.92 |

## 3.4 Attitude

The discussion of orbital dynamics in the previous sections aims at describing the motion of the spacecraft center-of-mass (CoM) under the action of various external forces. However, knowledge of the CoM location alone is not sufficient for a precise modeling of GNSS observations. All radio signals transmitted by a GNSS satellite originate from the phase center of the antenna, rather than the CoM. The offset of the antenna from the CoM is a constant vector in a body-fixed coordinate system, but varies in space depending on the instantaneous orientation, or *attitude*, of the satellite body. Aside from the antenna offset, the changing orientation of the spacecraft relative to the observer may also affect the observed carrier phase of the transmitted signal through the so-called *phase wind-up* effect. A comprehensive discussion of both aspects is provided as part of the observation modeling in Chap. 19. Last, but not the least, solar radiation pressure modeling (Sect. 3.2.4) relies on a proper understanding of the orientation of the spacecraft body and the solar panels relative with respect to the orbit and the Sun.

The nominal orientation of a GNSS satellite is driven by a small set of requirements, which is largely independent of the particular system or satellite manufacturer. First, the boresight of the antenna must always be directed to the center of the Earth to maintain an optimum coverage and proper strength of the navigation signals. Secondly, the solar panels shall be aligned perpendicular to the Sun direction to maximize the projected area and thus the received solar energy. The solar panel rotation axis must therefore be oriented perpendicular to the plane spanned by the Sun and Earth direction. Finally, one of the satellite faces perpendicular to the antenna boresight and solar panel rotation axis should permanently point into the hemisphere opposite the Sun to facilitate thermal stabilization of the atomic clocks (mounted close to this *cool* panel).

The resulting attitude control mode is commonly known as *yaw-steering mode* and jointly applied by GPS, GLONASS, Galileo, BeiDou, and QZSS satellites in MEO or IGSO orbits. It is illustrated in Fig. 3.19, where the principal spacecraft axes have been labeled in accord with established conventions [3.89] of the international GNSS service (IGS):

- The $+x$-, $y$-, and $z$-axis form a right-handed coordinate system attached to the satellite body.
- The $+z$-axis coincides with the antenna boresight direction.
- The $y$-axis is parallel to the rotation axis of the solar panels. Furthermore, the $+y$-direction is assigned such that the $+x$-panel is illuminated by the Sun during nominal yaw-steering, while the $-x$-panel is oriented toward deep space.

Maintaining the ideal GNSS attitude requires a permanent rotation of the spacecraft body about the Earth-pointing $+z$-axis as well as a rotation of the solar panels about the $+y$-axis.

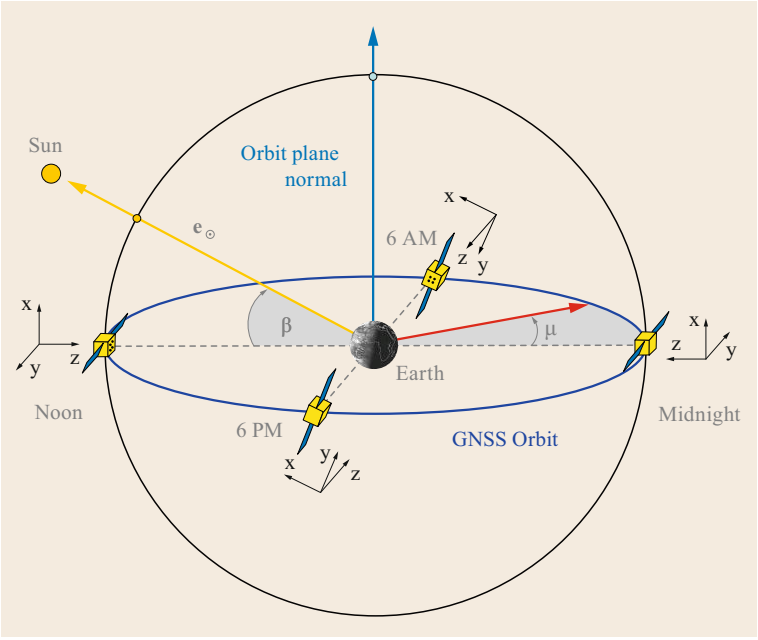

**Fig. 3.19** GNSS satellite orientation in yaw-steering mode (after [3.89])

The required orientation of the spacecraft body is most easily described in an orbital reference frame aligned with the unit vectors

$$\begin{aligned} \boldsymbol{e}_{\mathrm{R}} &= \frac{\boldsymbol{r}}{||\boldsymbol{r}||} \,, \\ \boldsymbol{e}_{\mathrm{T}} &= \boldsymbol{e}_{\mathrm{N}} \times \boldsymbol{e}_{\mathrm{R}} \,, \\ \boldsymbol{e}_{\mathrm{N}} &= \frac{\boldsymbol{r} \times \boldsymbol{v}}{||\boldsymbol{r} \times \boldsymbol{v}||} \,, \end{aligned} \tag{3.60}$$

in the radial, transverse, and normal direction (Fig. 3.20), which are defined by the instantaneous position $\boldsymbol{r}$ and velocity $\boldsymbol{v}$ of the GNSS satellite. The yaw-angle $\Psi$ specifies the angle between the $\boldsymbol{e}_{\mathrm{T}}$- and $\boldsymbol{e}_{\mathrm{x}}$-axes for a right-handed rotation around the $+z/-R$-axis. For $\Psi = 0°$, the spacecraft $+x$-axis is aligned with the transverse direction and $+y$ is oriented antiparallel

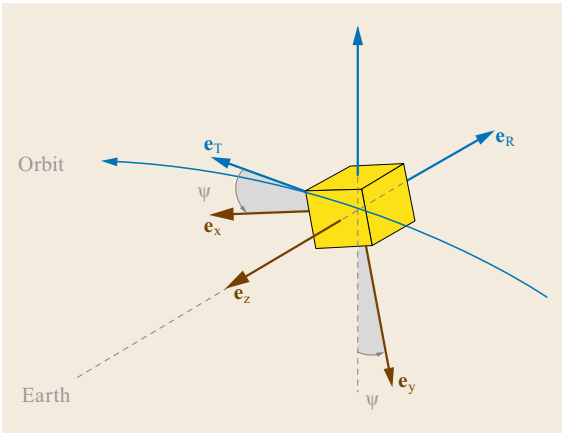

**Fig. 3.20** Definition of the yaw-angle (after [3.89])

to the orbital angular momentum. Following [3.36], the nominal yaw angle in yaw-steering mode can be expressed as

$$\Psi = \mathrm{atn2}(-\tan\beta, \sin\mu) \,, \tag{3.61}$$

where $\beta$ denotes the elevation of the Sun above the orbit plane and $\mu$ measures the orbit angle relative to the midnight point (Fig. 3.19). The nominal attitude of a GNSS satellite is thus fully determined by its orbital position and the direction of the Sun.

According to its definition, the yaw-angle is negative for positive Sun elevations and vice versa. Its variation with orbit angle is illustrated in Fig. 3.21 for various values of the Sun elevations. While $\Psi$ remains close to $\pm 90°$ for high $\beta$-angles, it varies between roughly $0°$ and $\pm 180°$ whenever the Sun is close to the orbit plane. During these periods, which coincide with the eclipse season, the GNSS satellites need to perform rapid yaw-slews near orbit angles of $\mu = 0°$ and $\mu = 180°$. Depending on the design of the attitude control system (ACS), the actual raw rate may be limited thus inhibiting a perfect yaw-steering during these *noon-* and *midnight-turns*. Furthermore, the lack of Sun-visibility during eclipses may result in nonnominal yaw angles during limited periods of time. Models describing the yaw-angle variation for the GPS Block IIA/IIR/IIF satellites as well as GLONASS-M satellites in low-$\beta$ regimes and during eclipse transits have been developed by various authors ([3.36, 90–92] and [3.93], respectively) and are further discussed in Chap. 19.

To avoid the need for rapid yaw slews, the orbit-normal (or yaw-fixed) mode is employed by QZSS [3.94] and the Beidou MEO/IGSO satellites [3.95] as an alternative to yaw-steering during periods of low $\beta$-angles.

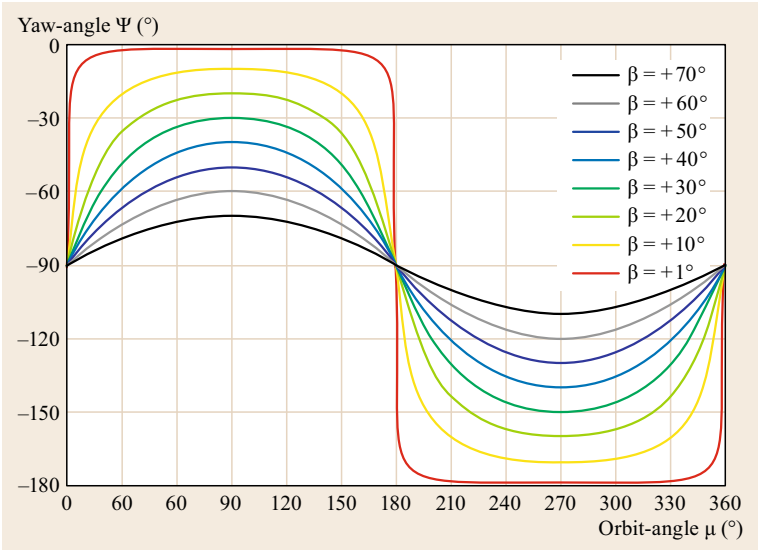

**Fig. 3.21** Yaw-angle variation for positive $\beta$-angles

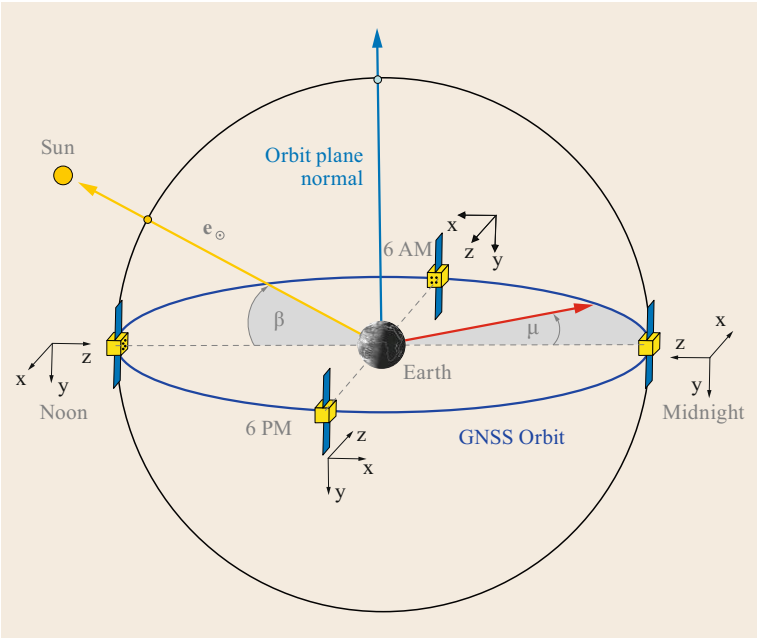

**Fig. 3.22** GNSS satellite orientation in orbit-normal mode with a fixed yaw-angle $\Psi = 0°$ (after [3.89])

In this mode, either the $+x$-axis ($\Psi = 0°$) or the $-x$-axis ($\Psi = 180°$) is permanently aligned with the transverse direction of the orbital frame (Fig. 3.22) and the solar panels rotation axis is kept perpendicular to the orbital plane. Accordingly, the effective cross-section of the solar panels is slightly decreased, which results in a small, but tolerable, reduction of the received power.

In the orbit-normal mode, the $-x$-panel is no longer kept away from the Sun, but illuminated in turn with the $+z$-, $+x$-, and $-z$-panels. Likewise, either the $+y$- or $-y$-panel is permanently illuminated. Both effects need to be properly considered in the radiation pressure modeling and may constitute a challenge for precise orbit determination [3.96].

The transition from yaw-steering to orbit-normal mode takes place when $||\beta||$ drops below a limiting value of about 20° for QZS-1 [3.94] and about 4° for BeiDou. However, the exact instant of the mode switch is determined by the control center and may deviate slightly from the idealized values [3.97–99].

# 4. Signals and Modulation

Michael Meurer, Felix Antreich

Satellite navigation relies on signals radiated by orbiting satellites and received by mobile satellite navigation receivers. This chapter addresses the fundamentals of such navigation signals and introduces the most important underlying concepts. It provides an introduction to radio frequency signals including the basics of electromagnetic waves, their carrier frequency, polarization, as well as group and phase velocity. The application of waves for carrying signals, their power and spectrum are addressed. It is shown how information-carrying signals can be modulated onto the wave using various modulation schemes such as binary phase shift keying, binary offset carrier, and alternating binary offset carrier. Setting out from international agreed allocations, the frequency bands used in GNSS are described. The concept of pseudo-random codes which is typically used for GNSS signals is introduced as well as their receiver side processing following a correlation principle.

## 4.1 Radiofrequency Signals

### 4.1.1 Maxwell's Theory of Electromagnetic Waves and Electromagnetic Foundation

The propagation of navigation signals through space relies on electromagnetic waves. In this section, a brief introduction to wave propagation is given as needed in the scope of this book. For a further detailed introduction to electromagnetic theory, the reader is referred to [4.1].

The physical foundation of all electromagnetic phenomena is Maxwell's theory and its corresponding equations [4.1–6]. Using $\boldsymbol{E}$ and $\boldsymbol{H}$ as three-dimensional vectors describing the electric and the magnetic field strength, respectively, Maxwell's equations take the following coordinate independent form

$$\nabla \times \boldsymbol{E} = -\mu \frac{\partial \boldsymbol{H}}{\partial t} \,, \tag{4.1}$$

$$\nabla \times \boldsymbol{H} = \varepsilon \frac{\partial \boldsymbol{E}}{\partial t} \,, \tag{4.2}$$

$$\nabla \cdot \boldsymbol{E} = 0 \,, \tag{4.3}$$

$$\nabla \cdot \boldsymbol{H} = 0 \,. \tag{4.4}$$

The variable $t$ denotes time, whereas the constants $\varepsilon$ and $\mu$ are the electrical permittivity and the magnetic permeability, respectively. The notations $\nabla\times$ and $\nabla\cdot$ denote the curl and divergence operators for vectorial fields [4.7]. By further applying the curl operation

on (4.1), we obtain

$$\nabla \times (\nabla \times \boldsymbol{E}) = \nabla(\nabla \cdot \boldsymbol{E}) - \nabla^2 \boldsymbol{E} \,,$$
$$= -\mu \frac{\partial}{\partial t} \nabla \times \boldsymbol{H} \,, \tag{4.5}$$

where $\nabla$ and $\nabla^2$ denote the gradient and vectorial Laplacean operators. Combining (4.2) with (4.3) and (4.5) yields the fundamental wave equations

$$\nabla^2 \boldsymbol{E} = \varepsilon\mu \frac{\partial^2}{\partial t^2} \boldsymbol{E} \,, \tag{4.6}$$

$$\nabla^2 \boldsymbol{H} = \varepsilon\mu \frac{\partial^2}{\partial t^2} \boldsymbol{H} \,. \tag{4.7}$$

The solutions of (4.6) and (4.7) describe electromagnetic waves which propagates through space.

For further discussion, let us consider a Cartesian coordinate system with coordinates $x$, $y$, $z$, the position vector $\boldsymbol{r} = (x, y, z)^\top$ and the corresponding components of the electric field vector $\boldsymbol{E} = (E_x, E_y, E_z)^\top$. Moreover, for a moment let us assume that the electrical field vector $\boldsymbol{E}$ is not a function of $x$ and $y$. In this case, all partial derivatives in (4.6) with respect to $x$ and $y$ vanish, that is,

$$\frac{\partial \boldsymbol{E}}{\partial x} = \frac{\partial \boldsymbol{E}}{\partial y} = 0 \,. \tag{4.8}$$

Solving (4.6) and using (4.8) it can be shown that

$$\boldsymbol{E}(z,t) = \boldsymbol{E}_0 \cos\left[2\pi f_\mathrm{c}\left(\frac{z}{v_\mathrm{p}} - t\right)\right] \tag{4.9}$$

is a solution of the fundamental wave equations of (4.6), where

$$v_\mathrm{p} = \frac{1}{\sqrt{\varepsilon\mu}} \,. \tag{4.10}$$

is the propagation speed or phase velocity of the wave and $f_\mathrm{c}$ its carrier frequency. In free space, $v_\mathrm{p}$ is identical to the speed of light c. Equation (4.9) describes a sinusoidal electromagnetic wave propagating in the direction of the positive $z$-axis. $\boldsymbol{E}(z,t)$ is a periodic function in $t$ and $z$, where the spatial period is quantified by the wavelength

$$\lambda = \frac{v_\mathrm{p}}{f_\mathrm{c}} \,. \tag{4.11}$$

The wavelength $\lambda$ is the distance traveled by the wave within one period $1/f_\mathrm{c}$ of the wave. Substituting (4.11) into (4.9) yields

$$\boldsymbol{E}(z,t) = \boldsymbol{E}_0 \cos\left[\underbrace{\frac{2\pi}{\lambda}}_{=k}(z - \mathrm{c}t)\right] , \tag{4.12}$$

where $k$ is termed wave number. The result of (4.12) can easily be generalized to waves propagating in any direction characterized by the wave vector

$$\boldsymbol{k} = \frac{2\pi}{\lambda} \boldsymbol{n}_0 \,, \tag{4.13}$$

where $\boldsymbol{n}_0$ is a unit vector pointing into the direction of propagation. Using (4.13) one obtains

$$\boldsymbol{E}(\boldsymbol{r},t) = \boldsymbol{E}_0 \cos\left(\boldsymbol{k}^\top \boldsymbol{r} - \frac{2\pi}{\lambda}\mathrm{c}\,t + \varphi_0\right) , \tag{4.14}$$

where $\varphi_0$ is an additional degree of freedom termed zero-phase offset. At each location within a plane which is perpendicular to $\boldsymbol{k}$, that is, in all locations in which $\boldsymbol{k}^\top \boldsymbol{r}$ is constant, the same electrical field strength can be observed. Therefore, the wave characterized by (4.14) is a planar wave. If further $\boldsymbol{E}_0$ is orthogonal to $\boldsymbol{k}$, the wave is a transversal planar wave. Usually electromagnetic waves which are relevant in satellite navigation can be considered to be of that kind.

So far, we only discussed the electrical field strength $\boldsymbol{E}$. However, similar considerations can be made for the magnetic field strength $\boldsymbol{H}$. Moreover, it can be shown that in a homogenous, isotropic, and stationary medium, the electrical field strength $\boldsymbol{E}$ and the magnetic field strength $\boldsymbol{H}$ are always orthogonal to each other, while both of them are orthogonal to the propagation direction described by the wave vector $\boldsymbol{k}$ (Fig. 4.1).

For the electromagnetic wave of (4.14) the ratio between the components of the electrical field strength $\boldsymbol{E}$ is constant and defined by $\boldsymbol{E}_0$. Such a wave is termed linearly polarized, see Fig. 4.1. If two linearly polarized waves with identical wave vector $\boldsymbol{k}$ but orthogonal $\boldsymbol{E}_{0,1}$ and $\boldsymbol{E}_{0,2}$ are superposed, the electrical field strength $\boldsymbol{E}(\boldsymbol{r},t)$ at a certain location $\boldsymbol{r}$ experiences in general over time an elliptical variation. If further the absolute magnitudes of $\boldsymbol{E}_{0,1}$ and $\boldsymbol{E}_{0,2}$ are identical and the zero-phase offsets $\varphi_{0,1}$ and $\varphi_{0,2}$ differ by $\pi/2$, the elliptical variation gets a circular one. Waves of that type are termed circularly polarized (see Fig. 4.1, right). If the electric field vector rotates clockwise, when looking into the direction of propagation, the electromagnetic wave is right-handed polarized, if not it is left handed.

Electromagnetic waves propagating through ionized gases or through the Earth magnetic field undergo changes in their polarization causing linearly polarized waves to become elliptically or circularly polarized [4.8]. All current satellite navigation systems circumvent this effect by using right-handed circularly polarized (RHCP) signals.

The Austrian physicist Christian Doppler postulated in 1842 that a relative motion between transmitter and

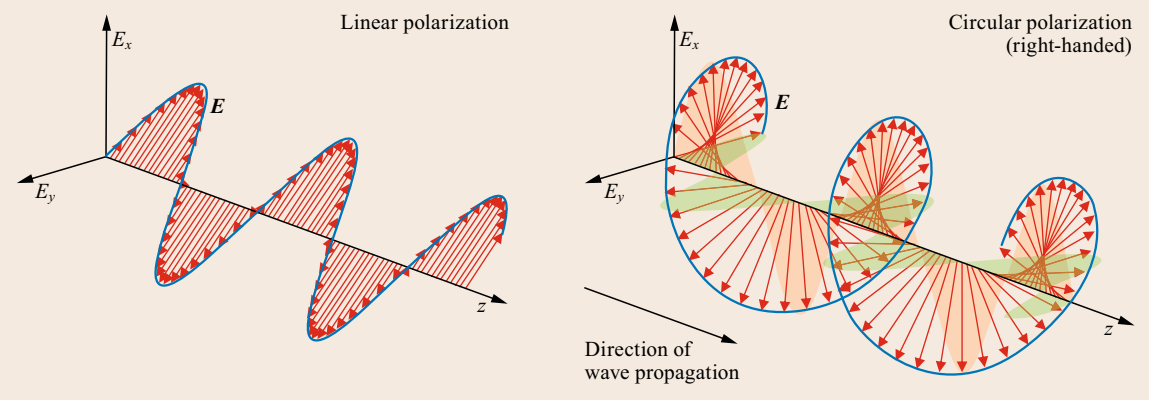

**Fig. 4.1** Linear and circular polarization of radio waves

receiver of a wave will cause a frequency shift, which is today known as Doppler shift of Doppler effect [4.8]. Let us shortly revisit our previous simplified example of (4.9) and assume that the transmitter of the radio wave is moving into the direction of the positive $z$-axis with velocity $v$. Moreover, the origin of the coordinate system is assumed to be at the (moving) location of the transmitter (Fig. 4.2). In this case, the (time dependent) position vector $\boldsymbol{r}_{\mathrm{rx}}(t)$ of a stationary receiver located on the $z$-axis gets

$$\boldsymbol{r}_{\mathrm{rx}}(t) = \begin{pmatrix} 0 \\ 0 \\ r_{\mathrm{rx},0} \end{pmatrix} - \begin{pmatrix} 0 \\ 0 \\ v \end{pmatrix} t \,. \tag{4.15}$$

Applying the position vector of (4.15) onto the wave equation (4.9) yields the oscillation of the electric field strength observed by the receiver

$$\begin{aligned} &\boldsymbol{E}(\underbrace{r_{\mathrm{rx},0} - v\,t}_{=z}, t) \\ &= \boldsymbol{E}_0 \cos\left[2\pi f_{\mathrm{c}} \left(\frac{r_{\mathrm{rx},0} - v\,t}{\mathrm{c}} - t\right)\right] \\ &= \boldsymbol{E}_0 \cos\left(2\pi \left[f_{\mathrm{c}} \frac{r_{\mathrm{rx},0}}{\mathrm{c}} - \underbrace{\left(1 + \frac{v}{\mathrm{c}}\right) f_{\mathrm{c}}}_{=f_{\mathrm{c}}+f_{\mathrm{D}}}\, t\right]\right). \end{aligned} \tag{4.16}$$

The quantity

$$f_{\mathrm{D}} = \frac{v}{c} f_{\mathrm{c}} \tag{4.17}$$

is termed Doppler shift or Doppler frequency and describes the frequency shift experienced by the receiver. Introducing the unit vector $\boldsymbol{n}$ pointing from the transmitter to the receiver and the velocity vector $\boldsymbol{v}$ of the transmitter relative to the receiver, the result of (4.17) can be generalized to

$$f_{\mathrm{D}} = \frac{\boldsymbol{v}^{\top}\boldsymbol{n}}{\mathrm{c}} f_{\mathrm{c}} \,. \tag{4.18}$$

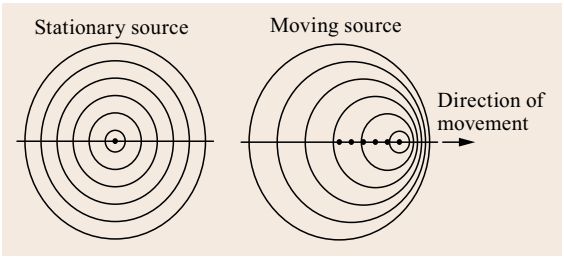

**Fig. 4.2** Doppler effect for a moving source of a radio wave

### 4.1.2 Modulation and Complex Baseband Representation of Signals

In the following, signals are described in time domain. Doing so, signals are denoted by lower case italic letters and are written as functions of the time $t$, for example, $x(t)$. Figure 4.3a depicts a signal example. Alternatively, signals can be described in frequency domain as functions of the frequency $f$. Signals in frequency domain are denoted by upper case italic letters, for example, $X(f)$. $X(f)$ is termed spectrum of $x(t)$ and is achieved by Fourier transformation

$$X(f) = \mathcal{F}\{x(t)\} = \int_{-\infty}^{\infty} x(t)\, \mathrm{e}^{-\mathrm{j}2\pi f t} \mathrm{d}t \,. \tag{4.19}$$

of the time domain signal $x(t)$. Figure 4.3b shows a corresponding example of a spectrum $X(f)$.

Let us consider an incoming electromagnetic wave which leads at the receiver to the received radio frequency (RF) signal of the form

$$x_{\mathrm{RF}}(t) = d_{\mathrm{c}}(t) \cos[2\pi f_{\mathrm{c}}(t)\, t + \varphi_{\mathrm{c}}(t)] \,, \tag{4.20}$$

where $d_{\mathrm{c}}(t)$, $f_{\mathrm{c}}(t)$, and $\varphi_{\mathrm{c}}(t)$ define the amplitude, frequency, and phase of the harmonic signal, respectively.

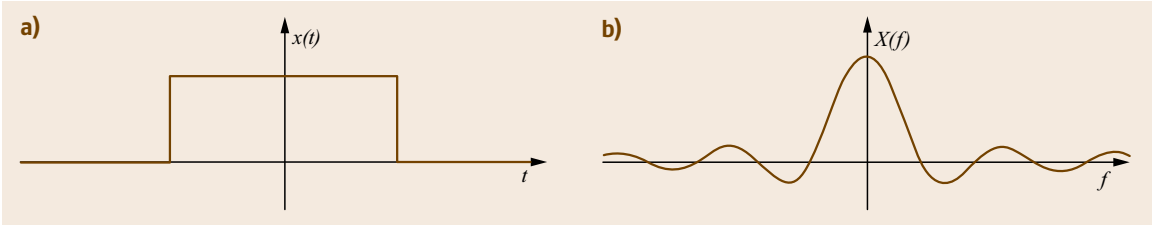

**Fig. 4.3a,b** Example of a signal in (a) time domain and (b) frequency domain

In case of constant parameters $d_c(t)$, $f_c(t)$, and $\varphi_c(t)$, the signal $x_{RF}(t)$ is a pure sinusoidal carrier which does not carry any information. However, it is desired in satellite navigation as well as communications to put additional information onto the signal, for example, in order to transfer navigation data from the transmitter to the receiver or simply to distinguish one signal from the other. By varying one or several of the aforementioned three parameters over time, additional information can be put onto the signal. This process is termed modulation. Depending on whether $d_c(t)$, $f_c(t)$, or $\varphi_c(t)$ are varied over time, we distinguish between amplitude modulation, frequency modulation, and phase modulation. Let us now consider the case where only $d_c(t)$ and $\varphi_c(t)$ vary over time, that is,

$$x_{RF}(t) = d_c(t)\cos(2\pi f_c + \varphi_c(t)) \tag{4.21}$$

holds for the received signal with constant $f_c$. $d_c(t)$ is termed envelope or baseband signal. In Sect. 4.2 it will be shown how the baseband signal $d_c(t)$ has to be chosen in order to carry data as well as further structural information (termed spreading code for uniquely identifying signals in satellite navigation). Using the trigonometric identity

$$\cos(\alpha+\beta) = \cos(\alpha)\cos(\beta) - \sin(\alpha)\sin(\beta)\,, \tag{4.22}$$

the RF signal (4.21) can be reformulated as

$$\begin{aligned} x_{RF}(t) &= \underbrace{d_c(t)\cos(\varphi_c(t))}_{=\sqrt{2}x_I(t)}\cos(2\pi f_c t) \\ &\quad - \underbrace{d_c(t)\sin(\varphi_c(t))}_{=\sqrt{2}x_Q(t)}\sin(2\pi f_c t) \\ &= +\sqrt{2}x_I(t)\cos(2\pi f_c t) - \sqrt{2}x_Q(t)\sin(2\pi f_c t)\,. \end{aligned} \tag{4.23}$$

The baseband signals $x_I(t)$ and $x_Q(t)$ are termed inphase and quadrature component of the RF signal $x_{RF}(t)$. The factors $\sqrt{2}$ are introduced for power normalization as shown in [4.9]. The process of modulating an in-phase and quadrature component onto the carrier signal is termed quadrature amplitude modulation (QAM) and is visualized in Fig. 4.4.

It is compact and convenient to write QAM radio signals as

$$x_{RF}(t) = \sqrt{2}\mathrm{Re}\{\tilde{x}(t)e^{j2\pi f_c t}\}\,. \tag{4.24}$$

The complex-valued signal

$$\tilde{x}(t) = x_I(t) + jx_Q(t) \tag{4.25}$$

is termed complex baseband signal or complex envelope. The notation of complex baseband signals provides the basis for the following sections.

Let us shortly revisit the monochromatic sinusoidal wave (4.12) moving in the positive $z$-direction, which can be rewritten in a slightly modified form as

$$\boldsymbol{E}(z,t) = \boldsymbol{E}_0\cos(kz - 2\pi f_c t)\,. \tag{4.26}$$

As $z$ or $t$ change, so does the phase $kz-2\pi f_c t$ of the wave. The phase is constant if $kz-2\pi f_c t$ is constant, that is, if

$$z = \frac{2\pi f_c}{k}t = v_p t\,, \tag{4.27}$$

where $v_p$ is the phase velocity introduced in (4.10). As the wave propagates, the whole sinusoidal pattern moves with velocity $v_p$ toward the positive $z$-axis [4.10].

Now let us consider a simple amplitude-modulated signal

$$x_{RF}(t) = \cos(2\pi f_d t)\cos(2\pi f_c t)\,, \tag{4.28}$$

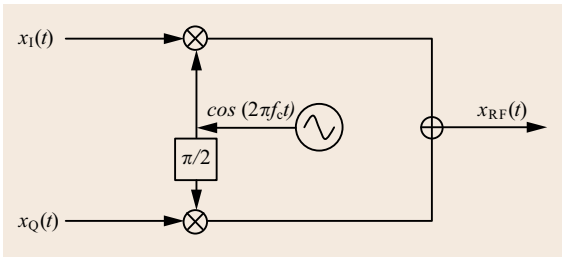

**Fig. 4.4** Quadrature modulation with in-phase and quadrature components $x_I(t)$ and $x_Q(t)$

where $\cos(2\pi f_d t)$ describes the baseband message signal with modulation frequency $f_d \ll f_c$, modulated onto the carrier signal. The signal is visualized in Fig. 4.5a. Applying trigonometric identities, (4.28) may also be written as

$$x_{RF}(t) = \frac{1}{2}(\cos[2\pi(f_c + f_d)t] + \cos[2\pi(f_c - f_d)t]) \,. \tag{4.29}$$

Obviously, the modulated signal $x_{RF}(t)$ is the sum of two sinusoidal components with slightly different frequencies $f_c + f_d$ and $f_c - f_d$.

Now let us further assume that the signal described by (4.29) is the source of an electromagnetic wave (4.26), which propagates through a dispersive medium. A dispersive medium is characterized by the fact that dielectric permittivity $\varepsilon$ and/or the magnetic permeability $\mu$, and therefore the phase velocity $v_p$ of (4.10), are frequency dependent. Consequently, both sinusoidal components of (4.29) propagate with slightly different phase velocities and have slightly different wavelengths $\lambda$ and wave numbers $k$.

Let the wave number for a carrier of frequency $f_c$ be $k$ and the wave numbers corresponding to the slightly deviating frequencies $f_c + f_d$ and $f_c - f_d$ be $k + \Delta k$ and $k - \Delta k$, respectively. Then we obtain for the electromagnetic wave after traveling a distance of $z$ from the origin along the $z$-axis

$$\boldsymbol{E}(z,t) = \frac{1}{2}\boldsymbol{E}_0(\cos[(k+\Delta k)z - 2\pi(f_c + f_d)t] + \cos[(k-\Delta k)z - 2\pi(f_c - f_d)t]) \,. \tag{4.30}$$

Applying the same trigonometric identity used earlier, (4.30) can be rewritten as

$$\begin{aligned}\boldsymbol{E}(z,t) &= \boldsymbol{E}_0 \cos(\Delta k z - 2\pi f_d t)\cos(kz - 2\pi f_c t) \\ &= \boldsymbol{E}_0 \cos\left[2\pi f_d\left(t - \frac{1}{2\pi}\frac{\Delta k}{f_d}z\right)\right] \\ &\quad \times \cos\left[2\pi f_c\left(t - \frac{1}{2\pi}\frac{k}{f_c}z\right)\right].\end{aligned} \tag{4.31}$$

As $f_d$ gets smaller, $\Delta k/f_d$ approaches $\mathrm{d}k/\mathrm{d}f$ [4.10] and the electromagnetic wave can be expressed as

$$\begin{aligned}\boldsymbol{E}(z,t) &= \boldsymbol{E}_0 \cos\left[2\pi f_d\left(t - \frac{1}{2\pi}\frac{\mathrm{d}k}{\mathrm{d}f}z\right)\right] \\ &\quad \times \cos\left[2\pi f_c\left(t - \frac{1}{2\pi}\frac{k}{f_c}z\right)\right].\end{aligned} \tag{4.32}$$

This result implies that the carrier and the modulation of a electromagnetic wave in a dispersive medium propagate at different speeds. The carrier travels with the phase velocity $v_p$ of (4.10) and the modulation, that is, the baseband message signal $\cos(2\pi f_d t)$, propagates with the group velocity

$$v_g = 2\pi \left.\frac{\mathrm{d}f}{\mathrm{d}k}\right|_{f=f_c} \,. \tag{4.33}$$

Using (4.10) and (4.33), we can reformulate (4.32) to obtain the alternative expression

$$\begin{aligned}\boldsymbol{E}(z,t) &= \boldsymbol{E}_0 \cos\left[2\pi f_d\left(t - \frac{z}{v_g}\right)\right] \\ &\quad \times \cos\left[2\pi f_c\left(t - \frac{z}{v_p}\right)\right].\end{aligned} \tag{4.34}$$

The consequence of the difference between phase velocity and group velocity is a divergence in propagation between carrier and modulation of an electromagnetic wave. In Fig. 4.5b, this effect is well observable. This phenomenon is referred to as code-carrier divergence in satellite navigation [4.10].

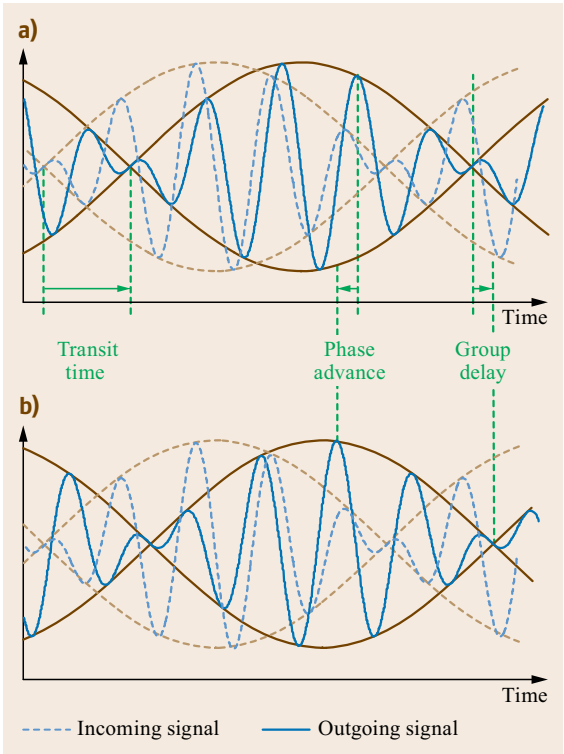

**Fig. 4.5a,b** Propagation of a modulated signal in (a) nondisperive and (b) dispersive medium

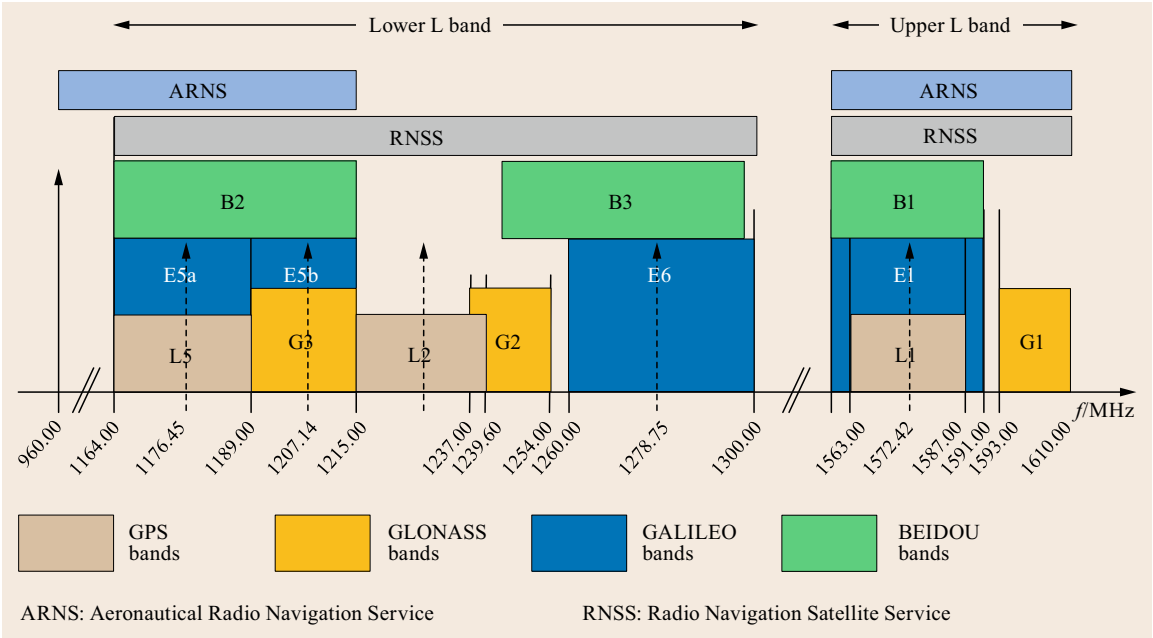

**Fig. 4.6** Frequency bands used by global satellite navigation systems – ITU frequency allocations

### 4.1.3 Frequency Bands and Polarization

The carrier frequency influences many aspects of satellite navigation signals. This reaches from the propagation behaviors including Doppler effect over interference environment to aspects of necessary hardware components and related imperfections. Today's global satellite navigation systems all make use of the frequency band between 1 and 2 GHz which is termed L-band. In the L-band several subfrequency bands have been allocated and made available by the International Telecommunications Union (ITU). The L-band offers several advantages for the usage in satellite navigation: the propagation conditions are quite good including especially moderate attenuation and impact of atmospheric effects, rain etc. The antenna size for signals in L-band is quite limited which is the basis for miniaturized satellite navigation receivers and mobile applications. Moreover, a large variety of mature hardware components is available at low costs.

Two different swaths of spectrum, the upper L-band (1559–1610 MHz) and the lower L-band (1164–1300 MHz) have been established for worldwide satellite navigation use. This portion of spectrum is termed RNSS (radio navigation satellite service) band. For safety-critical applications such as aeronautical applications a certain protection of the navigation signals against interferences is necessary. For such services, the ARNS (aeronautical radio navigation service) band is allocated which offers specific protection against such threats (see also Chap. 16). Figure 4.6 gives an overview of the available frequency bands as filed at ITU also showing the RNSS and ARNS band allocations. Details on the individual usage of the subfrequency bands by different global systems can be found in Annex B. The use of two or more distinct carrier frequencies within one satellite navigation system service offers several advantages and improved receiver performance. This includes robustness aspects as well as the possibility to mitigate ionospheric propagation errors.

Global satellite navigation systems consistently use right-handed circularly polarized waves (Sect. 4.1.1) for the transmitted signals. The circular polarization of GNSS signals is preferred over linear polarization to limit possible losses caused by orientation mismatch between the incident electromagnetic field and the receiving antenna. The exclusive choice of right-handed polarization (which was first adopted by GPS) in all other GNSSs is motivated by the intention to improve interoperability among different systems. It ensures that a user antenna capable of receiving right-handed polarized signals can be jointly used with a multitude of different satellite navigation systems.

## 4.2 Spread Spectrum Technique and Pseudo Random Codes

In this section, the main properties of spread spectrum signals are presented. We explore the motivation for GNSS to use spread spectrum signals and we discuss the use of pseudo-random (PR) binary sequences which are used as spreading codes to spread GNSS signals.

It is shown that design of GNSS signals can be separated into two problems, that is, the design of PR binary sequences and the design of chip pulse shapes which are convolved with these sequences. Both, the PR binary sequences and the respective chip pulse shapes define the performance of synchronization parameter estimation, that is, time-delay, carrier phase, and Doppler frequency, and consequently the performance of pseudo range as well as position estimation.

Basic principles of correlation and time-delay estimation are presented. It is shown how a standard GNSS receiver is performing time-delay estimation and based on this, important properties of PR binary sequences and chip pulse shapes are discussed and their influence on synchronization parameter estimation performance is demonstrated.

### 4.2.1 Spread Spectrum Signals for Ranging

Several satellites need to share the same transmission medium and broadcast to the GNSS users in order to enable positioning. The satellites need to share the transmission medium such that the GNSS users can separate different satellites, perform ranging, and receive the navigation data. The satellites need to share the available bandwidth by using propagation channel access or multiple access (MA) techniques. In general there are three basic MA techniques:

- Time division multiple access (TDMA)
- Frequency division multiple access (FDMA)
- Code division multiple access (CDMA).

These three MA techniques separate signals in time, in frequency or by codes with the aim to ensure that the signals will be separated or even orthogonal. Each of these techniques can achieve, in principle, the same aggregate spectral efficiency, as they achieve the same symbol rate per channel user (satellite), the same number of channel users (satellites), and the same total bandwidth. However, each scheme has advantages and disadvantages. These basic MA techniques can also be combined to form hybrid combinations, for example, frequency division and time division (FD/TDMA) or combined frequency division and code division (FD/CDMA), and others [4.11].

The principle of TDMA, FDMA, and CDMA is illustrated in Fig. 4.7, where different shaded blocks resemble different channel users (satellites). In the case of TDMA (Fig. 4.7a), channel users occupy the complete available bandwidth but at different time slots; thus, they transmit in turns in assigned time slots. In the case of FDMA (Fig. 4.7b), channel users all transmit at the same time, but they occupy different sub-bands of the total available bandwidth. In the case of CDMA (Fig. 4.7c), all channel users transmit at the same time and use the complete available bandwidth, but the channel users are separated by codes.

Since for GNSS, the number of in-view satellites (channel users) is quite low (around maximum 12 per system) and data transmission demands in general do not play a prominent role, mainly other performance measures have to be considered when choosing the appropriate MA technique, this includes, for example:

- Synchronization accuracy
- Intersystem multiple access interference (MAI-R) or spectral separation
- Intrasystem multiple access interference (MAI-A)
- Interference robustness
- Multipath performance
- Signal flexibility
- Bandwidth efficiency
- Implementation issues etc.

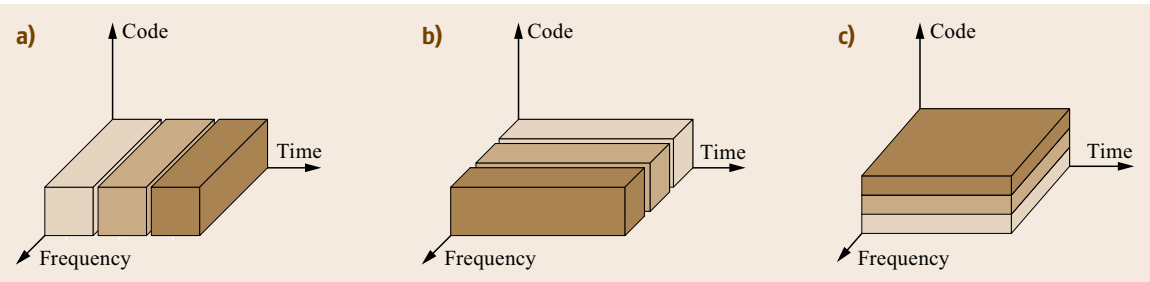

**Fig. 4.7** (a) Time division multiple access (TDMA), (b) frequency division multiple access (FDMA), and (c) code division multiple access (CDMA)

For GNSSs, either CDMA or FDMA and when considering spectral separation between GNSSs, either FD/CDMA or CD/FDMA concepts are applied in order to establish MA for different satellites of different GNSSs with respect to the allocated time–frequency resources. Most GNSSs basically use direct sequence CDMA (DS-CDMA) [4.11] for which the signal energy of each satellite is continuously distributed throughout the entire time-frequency plane. The different satellites transmit their signals in the same frequency band at the same time. Each satellite uses a different code for transmitting its signal. Spectral separation between different GNSSs in the same frequency band can be achieved by usage of different modulation schemes. The GLONASS system uses FDMA where each visible satellite uses a different frequency slot and also uses a code sequence for synchronization and channel parameter estimation purposes.

We assume phase coherent frequency down-conversion of the radio frequency signal to baseband of either considering the carrier frequency with respect to a DS-CDMA system (e.g., GPS, Galileo, and Beidou; see Chapters 7, 9, 10) or each carrier of the respective satellite of a CD/FDMA system (e.g., GLONASS; Chap. 8). This implies that the carrier phase was estimated without error and the Doppler effect could be compensated perfectly. Baseband means that the frequency support of the signal is centered around the origin at 0 Hz. Thus, the received DS-CDMA or CD/FDMA baseband signal of one satellite can be given as

$$y(t) = \sqrt{P}\, m(t)\, c(t-\tau) + n(t)\,, \tag{4.35}$$

where $P$ denotes the signal power, $c(t)$ is the PR spreading sequence, $\tau$ is the time-delay, $m(t) \in \{-1, 1\}$ is the binary navigation message data, and $n(t)$ is white Gaussian noise with power spectral density $N_0/2$. Thus, the PR sequence can be represented as a convolution

$$c(t) = \sum_{k=-\infty}^{\infty} d_k \sqrt{T_c}\, p(t - kT_c)\,, \tag{4.36}$$

where $p(t)$ denotes the chip pulse shape which is not necessarily restricted to be time-limited to only one chip interval $T_c$, that is, the PR sequence $c(t)$ can contain overlapping pulses, so interchip interference can be present. The PR sequence can be assumed as a binary, zero mean wide-sense cyclostationary (WSCS) [4.12, p. 473] sequence with $\{d_k\} \in \{-1, 1\}$ and has period $T = N_d T_c$. $N_d \in \mathbb{N}$ denotes the number of chips of the PR sequence $c(t)$. The multiplication of the navigation data sequence $m(t)$ with the much faster oscillating PR sequence $c(t)$ introduces a spreading of the spectrum of the navigation signal by a factor of

$$G = \frac{B}{B_m}\,, \tag{4.37}$$

where $B$ is the one-sided bandwidth of the PR sequence $c(t)$ and $B_m$ denotes the one-sided bandwidth of the navigation message data signal $m(t)$. $G$ is often called spreading gain or processing gain. The signal-to-noise ratio (SNR) after despreading, that is, after correlation of the signal $y(t)$ with $c(t-\tau)$ in the receiver, can be given by

$$\mathrm{SNR_d} = \frac{P}{\tilde{\sigma}_n^2} = \mathrm{SNR_s} G = \frac{P}{\sigma_n^2} G\,, \tag{4.38}$$

where $\mathrm{SNR_s}$ denotes the SNR before despreading, $P$ denotes the signal power, $\sigma_n^2 = BN_0$ is the noise power before despreading, and $\tilde{\sigma}_n^2 = B_m N_0$ is the noise power after despreading. In general $B_m \ll B$. Furthermore, it is assumed that

$$\frac{1}{T} \int_{-\frac{T}{2}}^{\frac{T}{2}} c(t)\, c^*(t)\, \mathrm{d}t = 1\,, \tag{4.39}$$

where the superscript $^*$ denotes complex conjugation. For DS-CDMA systems that use a rectangular chip pulse shape $p(t)$ the processing gain can also be given by

$$G = \frac{T}{T_c}\,. \tag{4.40}$$

The processing gain $G$ and change in bandwidth of a DS-CDMA signal with rectangular chip pule shape $p(t)$ by despreading is illustrated in Fig. 4.8.

Spread spectrum systems have interference rejection capability (Chap. 16). Let the interference power at the input of the correlator (matched filter) be $J$, and assume it is uniformly distributed across the spread spectrum bandwidth $B$ (wideband interference). Consequently, we can assume the average interference power spectral density (PSD) to be $J/2B$. Thus, in this case the signal-to-interference-plus-noise-ratio (SINR) before despreading can be given as

$$\mathrm{SINR_s} = \frac{P}{BN_0 + J}\,, \tag{4.41}$$

and the SINR after despreading for a wideband interference can be given by

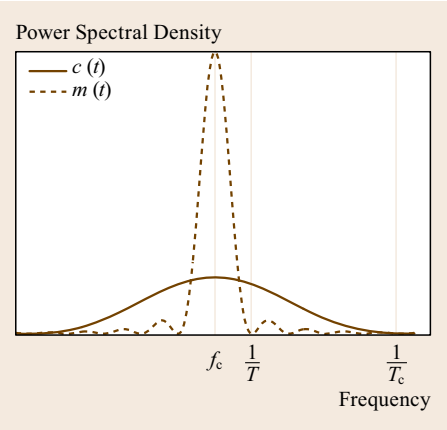

**Fig. 4.8** Spread and despread signal with carrier frequency $f_c$

$$\mathrm{SINR}_d = \frac{P}{B_m N_0 + (B_m/B)J} = \frac{P}{B_m N_0 + J/G} \,. \tag{4.42}$$

We can observe that for broadband interference the SINR increase after despreading is dependent on the processing gain $G$. Thus, the system design can incorporate certain interference robustness. In the case of narrowband or partial band interference correlation of the received signal with $c(t-\tau)$ spreads the partial band or single-frequency jamming signal so that it appears as wideband Gaussian noise at the output of the correlator.

The autocorrelation of $c(t)$ can be given as

$$\begin{aligned} R_c(\varepsilon) &= \frac{1}{T}\int_{-\frac{T}{2}}^{\frac{T}{2}} c(t)c^*(t+\varepsilon)\mathrm{d}t \,, \\ &= \int_{-\infty}^{\infty} |P(f)|^2 \Phi_d(f) \mathrm{e}^{\mathrm{j}2\pi f\varepsilon}\mathrm{d}f \,, \\ &= \int_{-\infty}^{\infty} |P(f)|^2 \mathrm{e}^{\mathrm{j}2\pi f\varepsilon}\mathrm{d}f \,, \end{aligned} \tag{4.43}$$

where $P(f)$ denotes the Fourier transform of the chip pulse shape $p(t)$ with

$$\int_{-\infty}^{\infty} |P(f)|^2 \mathrm{d}f = 1 \,. \tag{4.44}$$

This implies that the WSCS sequence $\{d_k\}$ is not only pseudo random but random, and hence the PSD of the sequence $\{d_k\}$ is given as

$$\Phi_d(f) = 1 \,. \tag{4.45}$$

In general, any deterministically generated sequence is not truly random, but the target of sequence design is to achieve sequences that are random as we will see in Sect. 4.2.2. Hence, for well-designed sequences the above given assumption $\Phi_d(f) = 1$ can be justified, and thus the problem of optimizing cross-correlation and autocorrelation properties of PR sequences $c(t)$ can be treated separately as two different problems: on the one hand the problem of optimizing properties of the WSCS sequence $\{d_k\}$ and on the other hand the problem of optimizing properties of the chip pulse shape $p(t)$. This is a convenient assumption not only for GNSS signal design but also for the analysis and understanding of the properties of chip pulse shapes and PR sequences. A proof for (4.43) can found in [4.12, p. 473].

### 4.2.2 Pseudo-Random Binary Sequences

As already mentioned earlier, DS-CDMA systems apply spreading or code sequences to separate different channel users (satellites) which are transmitting at the same time within the available transmission bandwidth. These spreading sequences in case of GNSS usually are so-called PR binary sequences. While such deterministically generated sequences can never be truly random, their design ensures well-defined properties associated with randomness. Those kind of sequences are therefore called pseudo random [4.13].

A PR binary sequence is a sequence $a_0, a_1, \ldots, a_{K-1}$ with $K$ code bits (also named as *chips*) with $\{a_k\} \in \{-1, 1\}$, where the binary states are represented by $-1$ and 1. We can apply the mapping $\tilde{a}_k = (1-a_k)/2$ with $\{\tilde{a}_k\} \in \{0, 1\}$ and thus the binary states can be represented by 1 and 0. This mapping preserves the multiplication property on the numbers $\pm 1$ with modulo 2 addition of 0 and 1. The representation of the binary states by 0 and 1 is useful when discussing properties of sequences in the following. The representation of the binary states by $-1$ and 1 is used for waveform generation.

The autocorrelation function of the sequence $\{a_k\}$ or $\{\tilde{a}_k\}$ can be given as

$$\begin{aligned} R_a[\ell] &= R_{\tilde{a}}[\ell] \\ &= \sum_{k=0}^{K-1} a_k a_{k+\ell} = \sum_{k=0}^{K-1} (-1)^{\tilde{a}_k + \tilde{a}_{k+\ell}} \,. \end{aligned} \tag{4.46}$$

Thus, $R_a[0] = R_{\tilde{a}}[0] = K$ when all code bits align. In order to obtain good autocorrelation properties, it is desirable that all other phases $\ell$ result in very small values of $R_a[\ell]$ and $R_{\tilde{a}}[\ell]$. In a real system, the sequences are finite of length $K$ and thus are repeated after $K$ code bits and thus the signal is periodic. *Solomon Golomb* and

*Guang Gong* proposed the following three randomness postulates to measure apparent randomness of binary periodic sequences [4.13]:

- In every period, the number of 0's is nearly equal to the number of 1's. (More precisely, the disparity is not to exceed 1; i. e., $|\sum_{k=0}^{K-1}(-1)^{\tilde{a}_k}| \le 1$
- In every period, half the runs have length 1, one-fourth have length 2, one-eighth have length 3, and so on, as long as the number of runs so indicated exceeds 1. Moreover, for each of these lengths, there are equally many runs of 0's and 1's. For a binary sequence $\{\tilde{a}_k\}$ with period $K$, $l$ consecutive 0's (1's) preceded by 1 (or 0) and followed by 1 (or 0) is called a run of 0's (or 1's) of length $l$.
- The autocorrelation function $R_a[\ell]$ or $R_{\tilde{a}}[\ell]$ is two-valued and it can be given by

$$R_a[\ell] = \begin{cases} K & \text{if } \ell = 0 \,(\text{mod}\, K)\,, \\ \tilde{K} & \text{if } \ell \neq 0 \,(\text{mod}\, K)\,, \end{cases} \tag{4.47}$$

where $\tilde{K}$ is a constant. If $\tilde{K} = -1$ for $K$ odd and $\tilde{K} = 0$ for $K$ even, then we say that the sequence has the (ideal) two-level autocorrelation function.

For the special case $K = 2^n - 1$, the resulting sequences are called maximum length sequences or m-sequences. The following properties of m-sequences can be stated [4.13]:

- In every period, 0's occur $2^{n-1} - 1$ (or $2^{n-1}$) times and 1's occur $2^{n-1}$ (or $2^{n-1} - 1$) times. This property is referred to as the balance property [4.13].
- In every period, runs of 0's (or 1's) of length $l$: $1 \le l \le n-2$ occur $2^{n-2-l}$ times. A run of 0's of length $n-1$ occurs once and a run of 1's of length $n$ occurs once. This is referred to as the run property.
- The autocorrelation function $R_a[\ell]$ or $R_{\tilde{a}}[\ell]$ is two-valued and it can be given by

$$R_a[\ell] = \begin{cases} K & \text{if } \ell = 0 \,(\text{mod}\, K)\,, \\ -1 & \text{if } \ell \neq 0 \,(\text{mod}\, K)\,. \end{cases} \tag{4.48}$$

m-Sequences can be generated by linear feedback shift registers (LFSR). A LFSR is a shift register whose input binary state (0 or 1) is a linear function of its previous states. A $Q$-stage shift register consists of $Q$ consecutive two-state stages (flip–flops) driven by a clock. At each pulse of the clock the state of each stage is shifted to the next stage in line to the right of the register. In order to convert the $Q$-stage shift register into a sequence generator a feedback loop is incorporated, which calculates a new term for the left-most stage, based on the states of the $Q$ previous states. At the right-most stage of the register the generated sequence is outputted. A block diagram of a LFSR is depicted in Fig. 4.9. The Boolean feedback function of a LFSR can be expressed as a modulo 2 sum of the $Q$-stages $z_q \in \{0, 1\}$ element-wise multiplied by feedback coefficients $c_q \in \{0, 1\}$

$$\begin{aligned} &f(z_0, \ldots, z_q, \ldots z_{Q-1}) \\ &\quad = c_0 z_0 \oplus \cdots \oplus c_q z_q \oplus \cdots \oplus c_{Q-1} z_{Q-1}\,. \end{aligned} \tag{4.49}$$

The definition of modulo 2 sum (exclusive or) and multiplication are shown in Fig 4.10.

The content of the $Q$ stages of a LFSR (regarded as a binary number or a binary vector of $Q$ bits in length) is called a state of the shift register. $(\tilde{a}_0, \ldots, \tilde{a}_q, \ldots, \tilde{a}_{Q-1})$ is called the initial state of the shift register which generates the sequence $\{\tilde{a}_k\}$.

Sequences that can be generated based on LFSRs are widely used in many applications, as the sequences can be generated by the LFSR with very low complexity. At the same time, no memory is needed for storing the required sequences. Still today, sequences that can be generated by a LFSR are preferred, as the cost and area demands of memory in chip design are quite high. Nevertheless, the open service (OS) of Galileo (Chap. 9) applies memory codes, which were especially designed with the objective to achieve good autocorrelation and especially good cross-correlation properties.

Besides autocorrelation properties of PR binary sequences also their cross-correlation properties play an important role in terms of system performance of DS-CDMA systems. Especially, the MA interference shall be minimum. As different signals of different satellites are received asynchronously and as their sequences are also modulated by the binary navigation message data $m(t) \in \{-1, 1\}$ (4.35), different cross-correlation properties have to be assessed for good cross-correlation

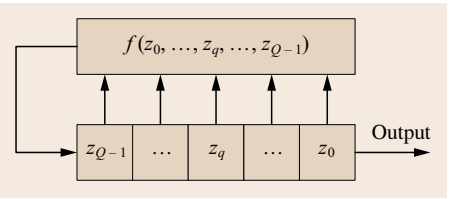

**Fig. 4.9** Block diagram of a linear feedback shift register

properties. Only the signals received from one satellite are received synchronously.

As discussed in Sect. 4.2.3, time-delay estimation and subsequently ranging is performed by correlation of the received signal with a local replica of the binary PR sequence used by a certain satellite. Thus, the sequence of the local replica $\{a_k\}$ in general is not synchronous to the sequence $\{b_k\} = b_0, b_1, b_2, \ldots, b_K$ with $\{b_k\} \in \{-1, 1\}$ of an interfering signal or of the desired signal $\{a_k\}$ when performing initial correlation in signal acquisition. Furthermore, either the periodic sequence of the interfering signal or the periodic sequence of the desired signal might experience a navigation message data bit transition within the correlation time. So the general situation where the sequence of the local replica $\{a_k\}$ is correlated with part of a sequence of an interfering signal $\{b_k\}$ modulated with a navigation message bit $m_0$ and with part of a subsequent sequence $\{b_k\}$ modulated with a navigation message bit $m_1$ needs to be considered.

Thus, we can define the so-called even cross-correlation for $m_1 = 1$ and $m_0 = 1$

$$\begin{aligned} R^{\mathrm{e}}_{a,b}[\ell] &= m_0 \sum_{k=0}^{K-\ell-1} a_k b_{k+\ell} + m_1 \sum_{k=K-\ell}^{K-1} a_k b_{k+\ell} \\ &= \sum_{k=0}^{K-\ell-1} a_k b_{k+\ell} + \sum_{k=K-\ell}^{K-1} a_k b_{k+\ell} \,, \end{aligned} \tag{4.50}$$

and the so-called odd cross-correlation for $m_0 = 1$ and $m_1 = -1$

$$\begin{aligned} R^{\mathrm{o}}_{a,b}[\ell] &= m_0 \sum_{k=0}^{K-\ell-1} a_k b_{k+\ell} + m_1 \sum_{k=K-\ell}^{K-1} a_k b_{k+\ell} \\ &= \sum_{k=0}^{K-\ell-1} a_k b_{k+\ell} - \sum_{k=K-\ell}^{K-1} a_k b_{k+\ell} \,. \end{aligned}$$

Both, even and odd cross-correlation are important performance measures in spreading sequence selection or design for DS-CDMA systems and especially for GNSSs, as until today usually no MA interference suppression schemes are applied as discussed in [4.14, 15]. *Lloyd Welch* [4.16] derived the following bound on even cross-correlation, the so-called Welch's bound. Consider a set of $|S|$ sequences of length $K$, then for any two sequences $\{a_k\} \in S$ and $\{b_k\} \in S$ with $\{a_k\} \neq \{b_k\}$ the following bound holds

$$\max_{\substack{\{a_k\},\{b_k\}\in S \\ \{a_k\}\neq\{b_k\}}} \frac{1}{K} R^{e}_{a,b}[\ell] \geq \sqrt{\frac{|S|-1}{|S|K-1}} \,. \tag{4.51}$$

Since both $|S|$ and $|S|K$ are typically large, the bound is well approximated by $1/\sqrt{K}$. Welch's bound can be used to derive sequences with good autocorrelation and even cross-correlation properties.

A prominent family of codes that are based on m-sequences and which can be generated by LFSRs are the so-called Gold sequences named after *Robert Gold* [4.17]. Gold codes are a class of sequences, which provide reasonably large sets of codes with good periodic cross-correlation nearly reaching Welch's bound as well as good autocorrelation properties. They provide better cross-correlation, but worse autocorrelation properties than m-sequences. Gold sequences are produced by modulo 2 sum of two m-sequences each of length $K = 2^n - 1$ in their various phases, and they inherit the balance and run properties of the used m-sequences which have been described before. They have a length of $K = 2^n - 1$ and $|S| = 2^n + 1$ different sequences can be generated. However, if the m-sequences that are modulo 2 added to produce a Gold sequence are chosen just randomly, the cross-correlation of the resulting Gold sequences may be quite poor. Thus, Gold codes are generated using pairs of preferred m-sequences. A method for choosing pairs of preferred m-sequences was given by *Robert Gold* [4.17]. The preferred sequences $\{g_k\}$ and $\{g'_k\}$ are chosen such that the resulting Gold codes have a three-valued even cross-correlation

$$R^{e}_{a,b}[\ell] = \begin{cases} -1 \,, \\ -\varrho \,, \\ \varrho - 2 \,, \end{cases} \tag{4.52}$$

with

$$\varrho = \begin{cases} 2^{(n+1)/2} + 1 & \text{if } n \text{ odd} \,, \\ 2^{(n+2)/2} + 1 & \text{if } n \text{ even} \,. \end{cases} \tag{4.53}$$

The resulting autocorrelation function is four valued with

$$R_a[\ell] = \begin{cases} -1 & \text{if } \ell \neq 0 \,, \\ -\varrho & \text{if } \ell \neq 0 \,, \\ \varrho - 2 & \text{if } \ell \neq 0 \,, \\ K & \text{if } \ell = 0 \,. \end{cases} \tag{4.54}$$

Gold codes of the length $K = 1023$ with $n = 10$ are used for the GPS C/A L1 signal (Chap. 7). They are generated with two LFSRs with $Q = 10$ stages. The feedback functions for the two LFSRs are

$$f_1(z_0, \ldots, z_9) = z_0 \oplus z_7 \,, \tag{4.55}$$

$$f_2(z_0, \ldots, z_9) = z_0 \oplus z_1 \oplus z_2 \oplus z_4 \oplus z_7 \oplus z_8 \,. \tag{4.56}$$

The sequences used for GPS and all other GNSSs, including most Galileo services can be generated by LFSRs, as they are based on m-sequences. They were designed to achieve good autocorrelation and cross-correlation properties as discussed earlier. Galileo E1 OS uses memory codes, which were especially designed with the objective to fulfill the earlier-defined properties for randomness in order to achieve good autocorrelation and cross-correlation properties for application with GNSS (Chap. 9).

For some GNSS signals, additionally so-called tiered codes are applied which are a combination of primary code sequences which are repeated multiplied with code bits of a secondary code. The secondary code is much shorter than the primary code and also repeats periodically. This structure enables to use primary codes only during acquisition in the GNSS receiver while the secondary codes help to further reduce even and odd cross-correlation (Chap. 14) during signal tracking.

### 4.2.3 Correlation and Time-Delay Estimation

In a GNSS receiver, time-delay estimation is performed using an approximation of a maximum likelihood estimator (MLE). In the receiver, the observations are collected at $N$ time instances with $y[n] = y(nT_s)$, where $T_s = 1/(2B)$ is the sampling duration and $n = 1, 2, \ldots, N$. The basic sampling and filtering of the signal using a low-pass filter of bandwidth $B$ with spectral representation

$$H(f) = \begin{cases} 1 & |f| \le B\,, \\ 0 & \text{else}\,, \end{cases} \tag{4.57}$$

and time-domain representation

$$h(t) = 2B\frac{\sin(2\pi Bt)}{2\pi Bt} \tag{4.58}$$

is illustrated in Fig. 4.11. Thus, we can write

$$\boldsymbol{y} = \sqrt{P}\boldsymbol{c}(\boldsymbol{\tau}) + \boldsymbol{n}\,, \boldsymbol{y} \in \mathbb{R}^{N\times 1}\,, \tag{4.59}$$

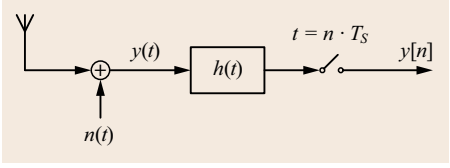

**Fig. 4.11** Sampling and low-pass filtering of the received signal

where

$$\begin{aligned} \boldsymbol{y} &= [y(T_s), \ldots, y(n\,T_s), \ldots, y(N\,T_s)]^\top\,, \\ \boldsymbol{n} &= [n(T_s), \ldots, n(n\,T_s), \ldots, n(N\,T_s)]^\top\,, \\ \boldsymbol{c}(\boldsymbol{\tau}) &= [c(T_s - \boldsymbol{\tau}), \ldots, c(nT_s - \boldsymbol{\tau}), \ldots, c(NT_s - \boldsymbol{\tau})]^\top\,. \end{aligned} \tag{4.60}$$

Let us assume a random variable $\boldsymbol{y}$ which has a multivariate Gaussian probability density function (pdf) parameterized by the parameter $\boldsymbol{\tau}$, denoted by $\mathrm{p}_y(\boldsymbol{y};\boldsymbol{\tau})$. Here, $\boldsymbol{y}$ denotes a realization of $\boldsymbol{y}$, which in our case means observations taken in order to estimate $\boldsymbol{\tau}$. After filtering with $h(t)$ the noise is not white Gaussian anymore. Its PSD is given by

$$\Phi_n^B(f) = \begin{cases} \frac{N_0}{2} & |f| \le B\,, \\ 0 & \text{else}\,, \end{cases} \tag{4.61}$$

and its autocorrelation is

$$R_n^B(\varepsilon) = N_0 B\frac{\sin(2\pi Bt)}{2\pi Bt}\,. \tag{4.62}$$

As $R_n^B(\varepsilon = k/2B) = 0$, with $k \in \mathbb{Z}\setminus\{0\}$ the noise after sampling with $T_s = 1/2B$ is white Gaussian with $\mathcal{N}(0, \sigma_n^2)$ and the noise power is given by $\sigma_n^2 = 2\,B\,N_0/2 = B\,N_0$. Note that, if the sampling duration is chosen $T_s < 1/2B$ or in other words the sampling frequency is chosen $f_s > 2B$, the noise after sampling is not white Gaussian, but so-called colored Gaussian with significant time correlation given by (4.62).

However, if we chose $T_s = 1/2B$ considering the low-pass filter given in (4.58), we can write

$$\mathrm{p}_y(\boldsymbol{y};\boldsymbol{\tau}) = \frac{1}{(2\pi\sigma_n^2)^{N/2}}\exp\left(-\frac{\|\boldsymbol{y} - \sqrt{P}\boldsymbol{c}(\boldsymbol{\tau})\|_2^2}{2\sigma_n^2}\right). \tag{4.63}$$

The likelihood function with respect to the parameter vector $\boldsymbol{\tau}$ is given as

$$L(\boldsymbol{y};\boldsymbol{\tau}) = \mathrm{p}_y(\boldsymbol{y};\boldsymbol{\tau})\,. \tag{4.64}$$

The likelihood function $L(\boldsymbol{y};\boldsymbol{\tau})$ is a function of the parameter $\boldsymbol{\tau}$, which is to be estimated at a given realization of the random variable $\boldsymbol{y}$, in our case the vector $\boldsymbol{y}$, which contains the samples of the real baseband signal at the output of an antenna. On the other hand, the pdf $\mathrm{p}_y(\boldsymbol{y};\boldsymbol{\tau})$ is a function of the realization of the random variable $\boldsymbol{y}$ for a fixed value of the parameter $\boldsymbol{\tau}$. Now the maximum likelihood estimator (MLE) can be given as

$$\begin{aligned} \hat{\boldsymbol{\tau}} &= \arg\max_{\boldsymbol{\tau}}\{L(\boldsymbol{y};\boldsymbol{\tau})\} \\ &= \arg\max_{\boldsymbol{\tau}}\{\log(L(\boldsymbol{y};\boldsymbol{\tau}))\}\,. \end{aligned} \tag{4.65}$$

The MLE is asymptotically (large $N$) unbiased and efficient. When further deriving the estimator we get

$$\begin{aligned}\hat{\boldsymbol{\tau}} &= \arg\max_{\boldsymbol{\tau}} \{\log(L(\boldsymbol{y};\boldsymbol{\tau}))\} \\ &= \arg\max_{\boldsymbol{\tau}} \left\{\log(1) - \log\left((2\pi\sigma_n^2)^{N/2}\right) \right. \\ &\quad \left. -\frac{1}{2\sigma_n^2}\|\boldsymbol{y}-\boldsymbol{c}(\boldsymbol{\tau})\|_2^2\right\} \\ &= \arg\max_{\boldsymbol{\tau}} \left\{-\|\boldsymbol{y}\|_2^2 + 2\sqrt{P}\boldsymbol{y}^\top\boldsymbol{c}(\boldsymbol{\tau}) \right. \\ &\quad \left. - P\,\|\boldsymbol{c}(\boldsymbol{\tau})\|_2^2\right\}. \end{aligned} \tag{4.66}$$

As the first term does not depend on $\boldsymbol{\tau}$ and the third term is constant with $\|\boldsymbol{c}(\boldsymbol{\tau})\|_2^2 \approx N, \forall_{\boldsymbol{\tau}}$ as well as dropping the constant factor $2\sqrt{P}$, we can write

$$\hat{\boldsymbol{\tau}} = \arg\max_{\boldsymbol{\tau}} \left\{\boldsymbol{y}^\top\boldsymbol{c}(\boldsymbol{\tau})\right\}. \tag{4.67}$$

The MLE of $\boldsymbol{\tau}$ is the value for which the power at the output of a correlator matched to the signal is maximized. The cost function is

$$J(\boldsymbol{\tau}) = \boldsymbol{y}^\top\boldsymbol{c}(\boldsymbol{\tau}). \tag{4.68}$$

In practice, the maximum of (4.67) is approached using a delay locked loop (DLL), which is the result of applying a gradient ascent method (Chap. 14). Following this gradient ascent method the $k+1$th iteration can be given as

$$\hat{\boldsymbol{\tau}}^{k+1} = \hat{\boldsymbol{\tau}}^k + \mu\frac{\partial J(\hat{\boldsymbol{\tau}}^k)}{\partial\boldsymbol{\tau}}, \tag{4.69}$$

while for the $k$th iteration the approximation to the maximum is $\hat{\boldsymbol{\tau}}^k$. Here, $\mu$ is employed to adjust the step size of the gradient method ($\mu > 0$). In a DLL, the derivative within each iteration is approximated using the central difference quotient of length $2\Delta$,

$$\begin{aligned}\hat{\boldsymbol{\tau}}^{k+1} &= \hat{\boldsymbol{\tau}}^k + \frac{\mu}{2\Delta}[J(\hat{\boldsymbol{\tau}}^k+\Delta) - J(\hat{\boldsymbol{\tau}}^k-\Delta)] \\ &= \hat{\boldsymbol{\tau}}^k + \frac{\mu}{2\Delta}\left[\boldsymbol{y}^\top\boldsymbol{c}(\hat{\boldsymbol{\tau}}^k+\Delta) - \boldsymbol{y}^\top\boldsymbol{c}(\hat{\boldsymbol{\tau}}^k-\Delta)\right]. \end{aligned} \tag{4.70}$$

In order to derive the central difference quotient, a common DLL uses a correlator pair where one correlator is advanced by $\Delta$ and the other is delayed by $\Delta$, these two correlators are called early and late correlator, respectively. In order to obtain a stochastic version of the gradient method, we consider that observations are successively collected in intervals with $\boldsymbol{y}[k]$ being the vector of observations of the $k$th interval. Thus, we can write

$$\begin{aligned}\hat{\boldsymbol{\tau}}^{k+1} = \hat{\boldsymbol{\tau}}^k + \frac{\mu}{2\Delta}\Big[&\boldsymbol{y}^\top(k+1)\boldsymbol{c}(\hat{\boldsymbol{\tau}}^k+\Delta) \\ &-\boldsymbol{y}^\top(k+1)\boldsymbol{c}(\hat{\boldsymbol{\tau}}^k-\Delta)\Big]. \end{aligned} \tag{4.71}$$

The DLL performs the time-delay estimation and provides information for pseudo-range estimates. The DLL is initialized by signal acquisition which provides initial time-delay estimates and initial Doppler frequency estimates (Chap. 14). In a GNSS receiver, the so-called discriminator realizes the earlier-described central difference quotient. Without noise and assuming that the receiver uses signal-matched correlators, the discriminator S-curve for a coherent early–late DLL can be given in terms of the autocorrelation function of the signal $R_\mathrm{c}(\varepsilon)$ as

$$S(\varepsilon,\Delta) = R_\mathrm{c}(\varepsilon-\Delta) - R_\mathrm{c}(\varepsilon+\Delta), \tag{4.72}$$

while the term $\mu/(2\Delta)$ resembles the filter coefficient of the so-called loop filter that reduces the noise, in this case a first-order infinite impulse response (IIR) filter, that drives the DLL (Chap. 14). In (4.72) $\varepsilon = \boldsymbol{\tau} - \hat{\boldsymbol{\tau}}$ denotes the tracking error of the DLL. The basic functionality of a DLL is illustrated in Fig. 4.12.

In order to perform precise synchronization and then positioning the time-delay $\boldsymbol{\tau}$ needs to be estimated with high accuracy. If

$$\mathrm{E}\left(\frac{\partial\log(L(\boldsymbol{y};\boldsymbol{\tau}))}{\partial\boldsymbol{\tau}}\right) = 0, \tag{4.73}$$

the variance of the time-delay estimation error $\sigma_{\hat{\tau}}^2$ of any unbiased estimator is lower bounded by the Cramer Rao

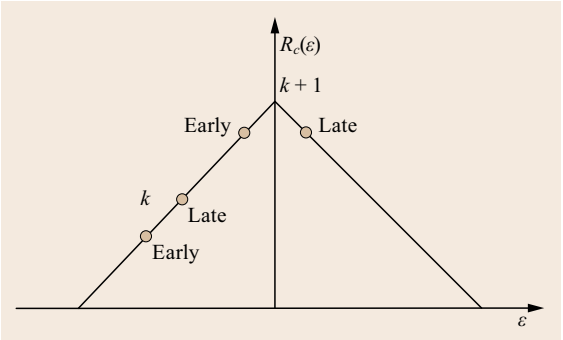

**Fig. 4.12** Basic functionality of a DLL

lower bound (CRLB) [4.18]

$$\mathrm{var}(\hat{\boldsymbol{\tau}}) = \sigma_{\hat{\tau}}^2 \geq \frac{1}{-\mathrm{E}\left(\frac{\partial^2 \log(L(\boldsymbol{y};\boldsymbol{\tau}))}{\partial \boldsymbol{\tau}^2}\right)} = \frac{\frac{\sigma_n^2}{P}}{\frac{\partial \boldsymbol{c}^{\top}(\boldsymbol{\tau})}{\partial \boldsymbol{\tau}} \frac{\partial \boldsymbol{c}(\boldsymbol{\tau})}{\partial \boldsymbol{\tau}}} ,$$

which leads to

$$\sigma_{\hat{\tau}}^2 \geq \frac{B_n}{\frac{P}{N_0} 4\pi^2} \frac{1}{\int_{-\infty}^{\infty} f^2 |P(f)|^2 \mathrm{d}f} . \tag{4.74}$$

Here, $B_n$ denotes the equivalent noise bandwidth [4.19, 20] of the generic estimator and

$$\int_{-\infty}^{\infty} |P(f)|^2 \mathrm{d}f = 1 . \tag{4.75}$$

A formulation of the CRLB considering quantization effects can be found in [4.21]. The term $\int_{-\infty}^{\infty} f^2 |P(f)|^2 \mathrm{d}f$ is the second moment of the power spectrum, the so-called RMS (root mean square) or Gabor bandwidth [4.22]. This is equal to the curvature of the autocorrelation function $R_\mathrm{c}(\varepsilon)$ at $\varepsilon = 0$, as

$$\int_{-\infty}^{\infty} f^2 \, |P(f)|^2 \mathrm{d}f = -\frac{1}{4\pi^2} \left. \frac{\mathrm{d}^2 R_\mathrm{c}(\varepsilon)}{\mathrm{d}\varepsilon^2} \right|_{\varepsilon=0} \tag{4.76}$$

from basic theorems of the Fourier transform [4.23, p. 142] and (4.43). Thus, the synchronization accuracy that can be achieved with a GNSS signal in terms of the CRLB increases with the the second moment of the power spectrum of the signal. It can be shown that the second moment of the power spectrum of a signal with bandwidth $B$ is upper bounded by $B^2$ [4.24]. This means that a higher available signal bandwidth enables a better synchronization accuracy.

In general, higher sidelobes of the autocorrelation function of the signal $R_\mathrm{c}(\varepsilon)$ result in higher sidelobes of the chip pulse shape and thus a lower time concentration of the chip pulse shape [4.24, 25]. To quantify the impact of the sidelobe height on the time-delay estimation, we make use of the quantity $\kappa \in [0, 1]$, which denotes the maximum of the absolute values of $R_\mathrm{c}(\varepsilon)$ at the local peak values but excluding the the global maximum of at $\varepsilon = 0$.

The higher the value of $\kappa$, the less robust the time-delay estimation procedure becomes [4.24, 25]. For the MLE of the time-delay $\boldsymbol{\tau}$, $R_\mathrm{c}(\varepsilon)$ can be considered the respective loss function. Time-delay estimation in a nominal GNSS receiver is performed by rather simple methods, for example, an acquisition process or a DLL for time-delay tracking. Hence, it is important for signal design or maybe choice of receiver filtering $h(t)$ to keep the time sidelobes of $R_\mathrm{c}(\varepsilon)$ as small as possible in order to ensure robust time-delay estimation.

As a consequence of the objective of some GNSSs to be interoperable with other GNSSs, they have chosen to use common frequency bandwidths to transmit their signals. Different systems in general use PR binary sequences in order to separate channel users (satellites) from each other. Interoperability with respect to GNSS is defined by the International Committee on Global Navigation Satellite Systems (ICG) as [4.26]:

> *[. . . ] the ability of global and regional navigation satellite systems and augmentations and the services they provide to be used together to provide better capabilities at the user level than would be achieved by relying solely on the open signals of one system.*

Interoperability is often discussed at two different levels, that is, system and signal level. Interoperability at signal level is to be considered in the design of the chip pulse shape as well as the PR binary sequences and is also resulting in MAI-R on top of MAI-A affecting estimation of the time-delay and consequently positioning.

In [4.27], an analysis of MAI-R and MAI-A is presented for different GNSSs. As more and more GNSSs are sharing the same frequency bands, and additionally as they also transmit more and more signals (as well as services) with increasing power, GNSSs become more and more limited not only by noise but also by noise plus MA interference. This may give rise to the application of MA interference suppression methods in the GNSS receiver, as discussed in [4.14, 15].

Following [4.28, pp. 23], [4.29], and other work on chip pulse shape design [4.30–32], MAI-A and MAI-R can be considered as additional interference components with zero mean. In general, both MAI-A and MAI-R are dependent on the propagation characteristics of the transmitted signal. We consider $U$ users (e.g., visible GNSS satellites) with $u = 1, \ldots, U$ and power $P_u$ causing MAI-A. Further, we assume that $V$ users of another system (e.g., visible satellites of a different GNSS) with $v = 1, \ldots, V$ and power $P_v$ are causing MAI-R. The received signal of another system (e.g., different GNSS) in the same frequency band has PSD $\Phi_\mathrm{R}(f)$.

We assume that the reference PR sequence generator is perfectly synchronized with the received desired signal with power $P$, so the time-delay $\boldsymbol{\tau}$ of the desired signal is known. Thus, the receiver was able to perform down conversion, correlation with signal matched reference code, so-called matched filtering with $P^*(f)$, and sampling at the chip duration.

Now, we can define the statistics of the matched filter output for a WSCS sequence $\{d_k\} \in \{-1, 1\}$ with

period $T = N_d T_c$ in the following. The SINR can be given as

$$\mathrm{SINR} = \frac{P}{P_N + P_A + P_R} , \tag{4.77}$$

where the noise power can be given as

$$P_N = \frac{1}{N_d T_c} \frac{N_0}{2} \int_{-\infty}^{\infty} |P(f)|^2 \mathrm{d}f = \frac{N_0}{2 N_d T_c} , \tag{4.78}$$

the power of the interference component related to MAI-A can be given as

$$P_A = \frac{1}{2 N_d T_c} \sum_{u=1}^{U} P_u \int_{-\infty}^{\infty} |P(f)|^4 \mathrm{d}f , \tag{4.79}$$

and the power of the interference component related to MAI-R can be given as

$$P_R = \frac{1}{2 N_d T_c} \sum_{v=1}^{V} P_v \int_{-\infty}^{\infty} |P(f)|^2 \, \Phi_R(f) \, \mathrm{d}f . \tag{4.80}$$

The background noise is assumed as white Gaussian noise with spectral density of $N_0/2$. The variance due to background noise can be considered as white noise of density $N_0/2$ filtered by the transfer function of the receive filter $P^*(f)$ (correlation with signal matched reference code). Hence, the power of the background white noise can be given by (4.78).

All $U$ users (e.g., visible GNSS satellites) are assumed to be independent and unsynchronized with the desired signal. It is assumed that their time-delays are independently uniformly distributed in $[0, T_c]$ and their phases are independently uniformly distributed in $[0, 2\pi]$. Thus, following [4.28, p. 28], [4.11, p. 772], and [4.29] the effect of the $u$th user (e.g., GNSS satellite) on the matched filter output of the desired signal will be that of white noise passed through the tandem combination of two filters with the transfer functions $|P(f)|^2$. Thus, the component related to the MAI-A can be defined as given in (4.79). In GNSS, the term $\int_{-\infty}^{\infty} |P(f)|^2 \, \Phi_R(f) \mathrm{d}f$ is often called spectral separation coefficient (SSC) and the term $\int_{-\infty}^{\infty} |P(f)|^4 \mathrm{d}f$ is often called self-SSC [4.29].

Similar assumptions as for the $U$ users above can be taken for the $V$ users and thus the component related to MAI-R can be given as in (4.80). Hence, the ratio of the SNR to the SINR can be given as

$$\Delta\mathrm{SNR} = \frac{\mathrm{SNR}}{\mathrm{SINR}} . \tag{4.81}$$

In order to compare different final pulse shapes $p(t)$ with different values of the design parameter $\kappa$ and other common chip pulse shapes we adopt the CRLB for time-delay estimation as given in (4.74) and we define the CRLB-I as the CRLB which considers noise plus interference (MAI-A, MAI-R)

$$\tilde{\sigma}_{\hat{\tau}}^2 \geq \sigma_{\hat{\tau}}^2 \Delta\mathrm{SNR} . \tag{4.82}$$

The variance of the MAI-A component as given in (4.79) can be lower bounded by

$$\int_{-B}^{B} |P(f)|^4 \mathrm{d}f \geq \frac{1}{2B} , \tag{4.83}$$

subject to

$$\int_{-B}^{B} |P(f)|^2 \mathrm{d}f = 1 . \tag{4.84}$$

A proof for this lower bound can be found in [4.28, pp. 33].

In order to illustrate the earlier discussed signal or pulse-shape properties we consider three example pulse shapes $p(t)$ with $\kappa = 0.1$, $\kappa = 0.5$, $\kappa = 0.7$, $B = 1.023\,\mathrm{MHz}$, and $BT_c = 1$. Such pulse shapes can be generated following the GNSS signal design methodologies described in [4.24, 25]. The pulse shapes $p(t)$ with $\kappa = 0.1$, $\kappa = 0.5$, and $\kappa = 0.7$, the respective $|P(f)|^2$, and their autocorrelation functions $R_c(\varepsilon)$ are depicted in Figs. 4.13, 4.14, and 4.15, respectively.

The CRLB-I for these pulse shapes is shown in Fig. 4.16, where we choose $P_u = -154\,\mathrm{dBW}$ as defined for the Galileo open service (OS) [4.27, 33]

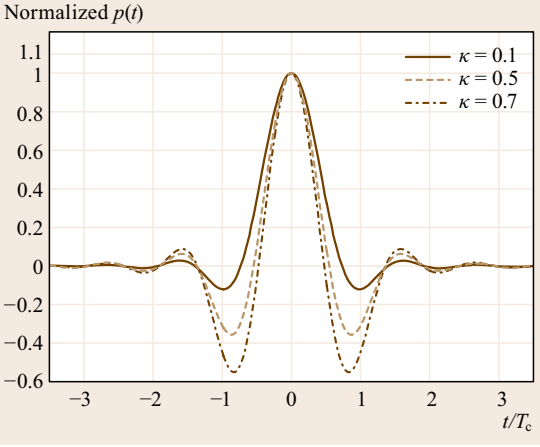

**Fig. 4.13** Time domain of example pulse shapes

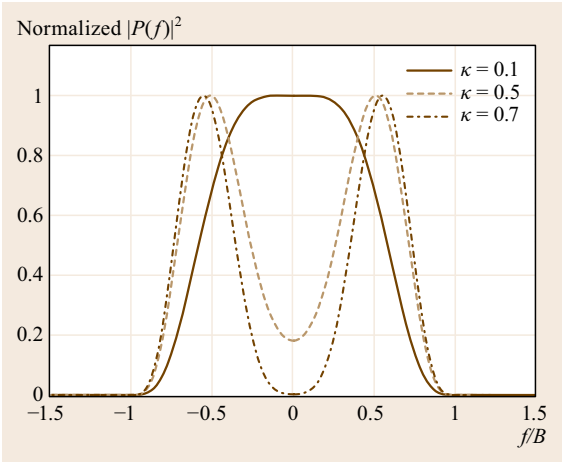

**Fig. 4.14** Frequency domain of example pulse shapes

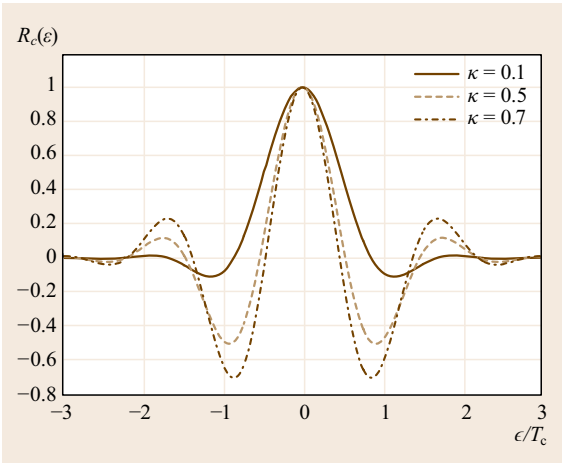

**Fig. 4.15** Autocorrelation function of example pulse shapes

and a maximum number of visible Galileo satellites, which contribute to MAI-A of $U = 11$ and $N_0 = -204\,\mathrm{dBW/Hz}$ [4.27, 33]. For this example, we assume that no MAI-R is present. The resulting MAI-A and $\Delta$SNR are given in Table 4.1.

Furthermore, we also assess the multipath performance for these example pulse shapes (Chap. 15). In GNSS signal design multipath performance can be shown by the multipath error envelope [4.34, p. 555] and [4.35]). The multipath error envelope gives the maximum bias of a nominal DLL in case that in addition to the line-of-sight signal a single reflective multipath signal with signal-to-multipath ration of 6 dB is present. The envelope is defined by the cases if the multipath signal has a relative phase of 0 or of $\pi$ with respect to the line-of-sight (LOS) signal. The multipath error envelope is dependent on the kind of discriminator

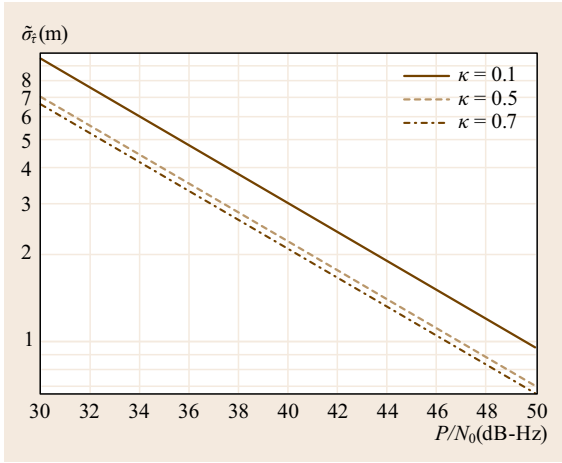

**Fig. 4.16** CRLB-I, for example, pulse shapes. The graph shows the time-delay estimation error $\tilde{\sigma}_{\hat{\tau}}$ (4.82) as a function of the power-to-noise-density ratio for a DLL bandwidth of 1 Hz

**Table 4.1** $\Delta$SNR and MAI-A, for different example pulse shapes and the lower bound as given in (4.83)

| $p(t)$ | $\kappa = 0.1$ | $\kappa = 0.5$ | $\kappa = 0.7$ | Lower bound (4.83) |
|---|---|---|---|---|
| MAI-A | 0.79 | 0.80 | 0.99 | 0.54 |
| $\Delta$SNR | 1.79 (2.53 dB) | 1.80 (2.55 dB) | 1.99 (3.0 dB) | 1.54 (1.87 dB) |

used in the DLL [4.36, 37] and obviously on the shape of the autocorrelation function $R_c(\varepsilon)$. The discriminator can be designed in order to optimize tracking performance with respect to a given $R_c(\varepsilon)$. We will consider a simple coherent narrow correlator DLL with $2\Delta = 0.1T_c$ two-sided correlator spacing [4.38]. The multipath error envelope for the example pulse shapes with $\kappa = 0.1$, $\kappa = 0.5$, and $\kappa = 0.7$ are provided in Fig. 4.17.

Finally, we also present the loop S-curve of a so-called narrow correlator coherent earlylate DLL in Fig. 4.18. The loop S-curve provides insight on the DLL behavior and also shows the linear region around the main stable lock point. The negative slope of $S(\varepsilon, \Delta)$ at $\varepsilon = 0$ is equal to the curvature of the autocorrelation function $R_c(\varepsilon)$ at $\varepsilon = 0$.

Thus, we have assessed two important properties of GNSS signals, time-delay estimation accuracy and on the other hand time concentration and time-delay robustness given by the absolute value of the sidelobes of $R_c(\varepsilon)$ given by $\kappa$ [4.24]. These properties besides others like multipath behavior, MAI-A, MAI-R, signal flexibility, bandwidth efficiency, implementation issues, and others have to be considered when trying to assess ranging performance provided by dif-

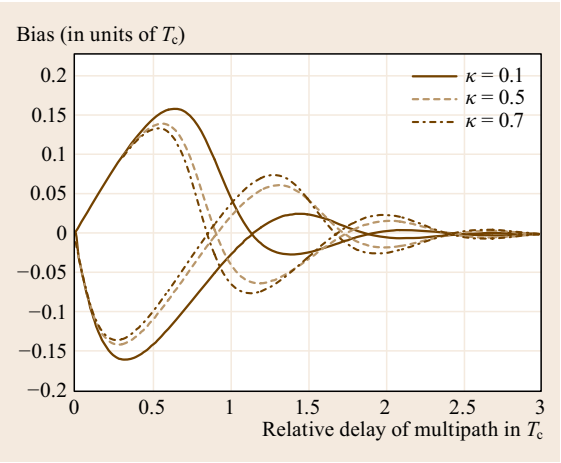

**Fig. 4.17** Multipath error envelope for time-delay estimation with example pulse shapes scaled in units of the chip length $T_c$

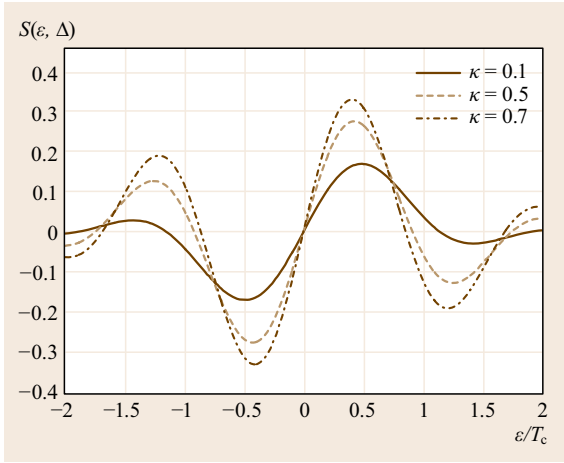

**Fig. 4.18** Normalized early-late discriminator S-curve

ferent GNSS signals. These properties also need to be considered for GNSS signal design and choices of receiver bandwidth $B$ for $h(t)$ of future services and signals.

Let us recapitulate the most important findings on signal properties for spread spectrum ranging from the previous sections:

1. The higher the Gabor bandwidth of the signal, the higher is the synchronization accuracy that can be achieved in terms of the CRLB.
2. Minimizing the CRLB for $\boldsymbol{\tau}$ and maximizing time concentration are contradictive tasks.
3. The higher the processing gain $G$ (large bandwidth $B$), the higher are the synchronization accuracy and the higher interference robustness.
4. The lower the CRLB for $\boldsymbol{\tau}$, the lower is the time concentration of $p(t)$
5. The higher the sidelobes of $R_c(\varepsilon)$, the higher are the sidelobes of $p(t)$, the lower is the time concentration of $p(t)$
6. The higher the slidelobes of $R_c(\varepsilon)$, the higher $\kappa$, the less robust is the estimation of $\boldsymbol{\tau}$ (likelihood has local maxima besides the global maximum)
7. MAI-A and MAI-R have to be considered in the signal design (chip pulse-shape design) or can be treated in the receiver (multiuser detection and mitigation).

## 4.3 Modulation Schemes

In this section, an overview on the most commonly used modulation schemes is provided. The different modulation schemes can also be described by their respective chip pulse shapes. The different common chip pulse shapes for different GNSSs were not only chosen because of the aforementioned properties and their relation to time-delay estimation performance, but also because of an relatively easy implementation on the satellite.

### 4.3.1 Binary Phase Shift Keying

A rectangular chip pulse shape $p(t)$ can be considered as the *classical* chip pulse shape, which originally was used for early spread spectrum signals [4.11]. If a rectangular chip pulse shape is used the signal is called binary phase shift keying BPSK signal. It can be described by

$$p_{\sqcap}(t) = \frac{1}{\sqrt{T_c}}\left[U\left(t+\frac{T_c}{2}\right) - U\left(t-\frac{T_c}{2}\right)\right], \quad (4.85)$$

where $U(t)$ denotes the unit step or Heaviside's unit step function

$$U(t) = \begin{cases} 0 & t < 0\,, \\ 1 & t \geq 0\,, \end{cases} \quad (4.86)$$

and

$$\int_{-\infty}^{\infty} |p_{\sqcap}(t)|^2 \mathrm{d}t = 1\,. \quad (4.87)$$

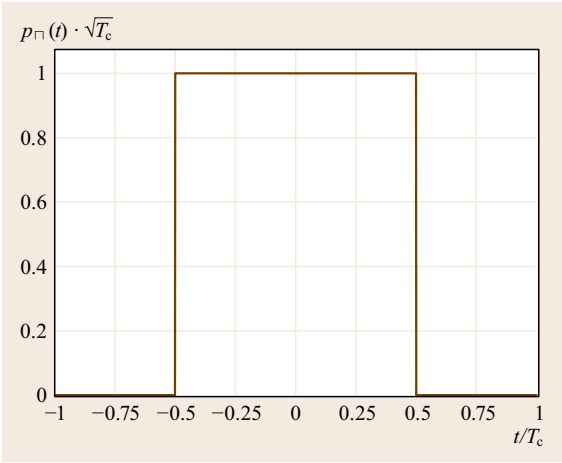

**Fig. 4.19** Rectangular chip pulse shape

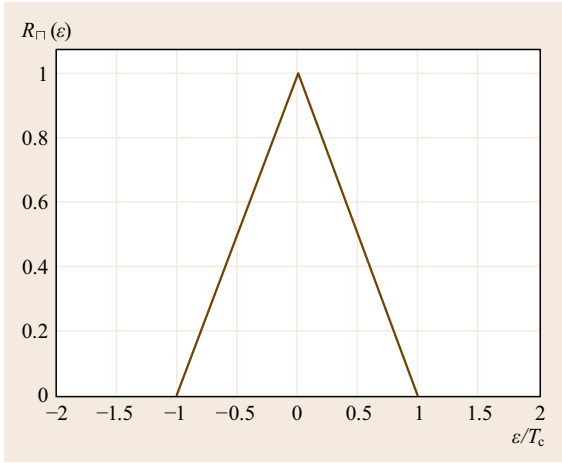

**Fig. 4.20** Autocorrelation function for a rectangular chip pulse shape

In Fig. 4.19 $p_\sqcap(t)$ is depicted.

The Fourier transform of $p_\sqcap(t)$ reads

$$\begin{aligned} P_\sqcap(f) &= \frac{1}{\sqrt{T_c}}\left[\frac{1}{2}\delta(f)+\frac{1}{\mathrm{j}2\pi f}\right]\mathrm{e}^{\mathrm{j}2\pi f\frac{T_c}{2}} \\ &\quad -\frac{1}{\sqrt{T_c}}\left[\frac{1}{2}\delta(f)+\frac{1}{\mathrm{j}2\pi f}\right]\mathrm{e}^{-\mathrm{j}2\pi f\frac{T_c}{2}} \\ &= \frac{\sqrt{T_c}\,\sin(\pi f T_c)}{\pi f T_c} \\ &= \sqrt{T_c}\mathrm{sinc}(fT_c)\,. \end{aligned} \tag{4.88}$$

Here, $\delta(f)$ denotes the Dirac delta function and the sinc function is defined according to [4.23, p. 62]

$$\mathrm{sinc}(t) = \frac{\sin(\pi t)}{\pi t}\,. \tag{4.89}$$

In Fig. 4.20, the autocorrelation function $R_\sqcap(\varepsilon)$ for a rectangular chip pulse shape is depicted. The autocorrelation function $R_\sqcap(\varepsilon)$ has a triangular shape and can be given as

$$R_\sqcap(\varepsilon) = \begin{cases} 1-\frac{|\varepsilon|}{T_c} & |\varepsilon|\le T_c\,, \\ 0 & \text{else}\,. \end{cases} \tag{4.90}$$

In Fig. 4.21, the PSD $|P_\sqcap(f)|^2 = T_c\,\mathrm{sinc}^2(fT_c)$ for a rectangular chip pulse shape is shown. The PSD $|P_\sqcap(f)|^2$ has a main lobe between $-fT_c=-1$ and $fT_c=1$. Besides the main lobe the PSD has many sidelobes which are decaying rapidly.

As the GNSS signal is band-limited either at the transmitter (satellite payload) or at the receiver, it is useful to also use a formulation for a strictly band-limited

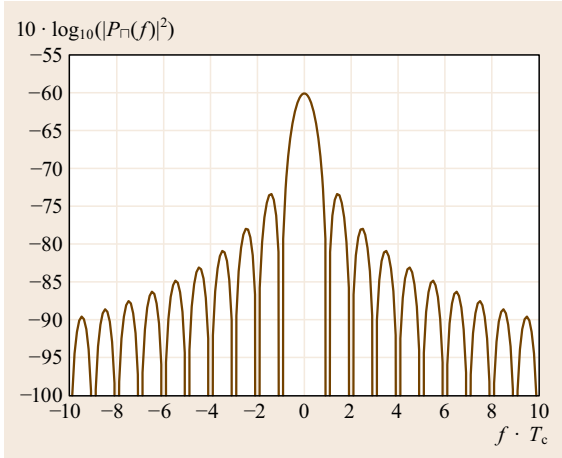

**Fig. 4.21** PSD for a rectangular chip pulse shape

and normalized rectangular pulse shape. We assume that the signal is band-limited by an ideal low-pass filter $h(t)$ as defined in (4.58). Such a formulation can be given as

$$\begin{aligned} p_\sqcap^B(t) = \frac{1}{\xi\pi\sqrt{T_c}}\Bigg(&\mathrm{Si}\left[2\pi B\left(t+\frac{T_c}{2}\right)\right] \\ &-\mathrm{Si}\left[2\pi B\left(t-\frac{T_c}{2}\right)\right]\Bigg)\,, \end{aligned} \tag{4.91}$$

with

$$\mathrm{Si}(t) = \int_0^t \frac{\sin(\tilde{t})}{\tilde{t}}\mathrm{d}\tilde{t} \tag{4.92}$$

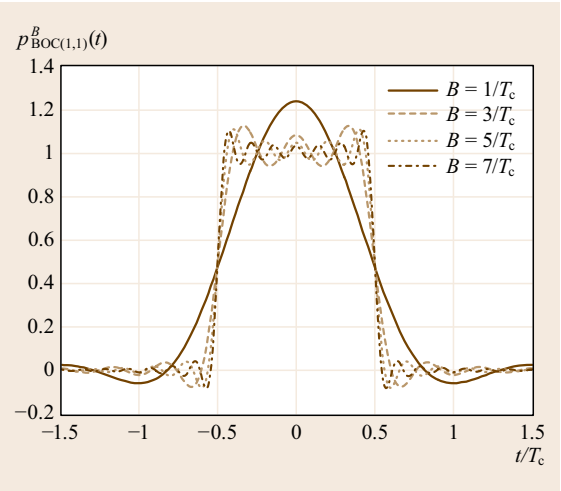

**Fig. 4.22** Band-limited and normalized rectangular chip pulse shape

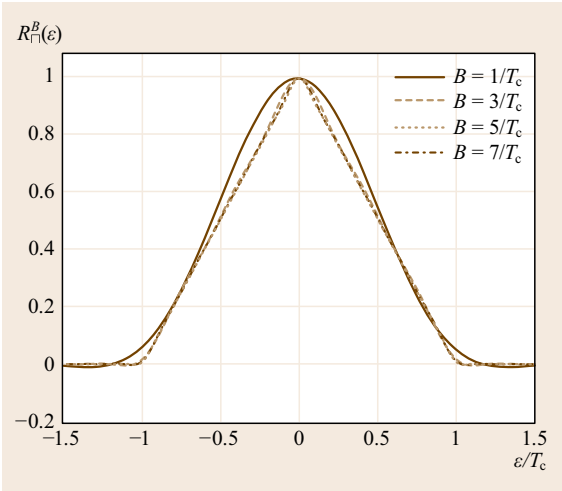

**Fig. 4.23** Autocorrelation function of band-limited and normalized rectangular chip pulse shape

denoting the sine integral function [4.23, p. 62] and with the normalization coefficient

$$\xi = \sqrt{\frac{\int_{-B}^{B} |P_{\sqcap}(f)|^2 \mathrm{d}f}{\int_{-\infty}^{\infty} |P_{\sqcap}(f)|^2 \mathrm{d}f}} \,. \tag{4.93}$$

In Fig. 4.22 $p^B_{\sqcap}(t)$ is depicted for different bandwidth $B$ in relation to the the chip duration $T_c$. The overshoot or *ringing* of the band-limited rectangular chip pulse shapes is called Gibbs' phenomenon which occurs at the simple discontinuities of the nonband-limited rectangular chip shape when filtering it with an ideal low-pass filter [4.39, p. 30]. We can also observe that due to band-limitation the rectangular chip pulse shape is not time-limited anymore and thus interchip interference occurs. The autocorrelation function of the band-limited and normalized rectangular chip pulse shape $R^B_{\sqcap}(\varepsilon)$ is shown in Fig. 4.23.

In comparison to Fig. 4.20, the peak of the autocorrelation function of the band-limited signal $R^B_{\sqcap}(\varepsilon)$ becomes rounded due to the band-limitation of the signal. Thus, the curvature of $R^B_{\sqcap}(\varepsilon)$ at $\varepsilon = 0$ becomes smaller and consequently the CRLB is higher than for the nonband-limited signal.

### 4.3.2 Binary Offset Carrier Modulation and Derivatives

Binary offset carrier BOC signals [4.40, 41] became a kind of standard in GNSS signal design besides using rectangular chip pulse shapes [4.33, 42]. Their chip pulse shapes are formed by the product of a rectangular pulse

$$p_{n_c}(t) = \sqrt{n_c f_r}\left[U\left(t + \frac{1}{2n_c f_r}\right) - U\left(t - \frac{1}{2n_c f_r}\right)\right], \tag{4.94}$$

and a sine or a cosine square wave subcarrier which is given as

$$g_{n_s}(t) = \begin{cases} \mathrm{sgn}[-\sin(2\pi n_s f_r t)] \,, \\ \mathrm{sgn}[-\cos(2\pi n_s f_r t)] \,, \end{cases} \tag{4.95}$$

where $n_c$ and $n_s$ define the chip rate and the subcarrier rate respectively, and $f_r$ is the reference frequency. In general, BOC signals are denoted as $\mathrm{BOC}(n_s, n_c)$ or $\mathrm{BOC}_{\cos}(n_s, n_c)$ for the BOC signals with sine or cosine subcarrier, respectively [4.40, 41] and their pulse shapes are given as

$$p_{\mathrm{BOC}(n_s,n_c)}(t) = \begin{cases} h_{n_c}(t) g_{n_s}(t) & |t| \le \frac{1}{2n_c f_r} \,, \\ 0 & \text{else} \,. \end{cases} \tag{4.96}$$

For GNSS signals, for example, for GPS [4.42–44], or the European Galileo system [4.33], $f_r = 1.023\,\mathrm{MHz}$. The special case of BOC(1,1) with a sine square wave subcarrier is also known as biphase Manchester pulse [4.45, p. 66].

In Figs. 4.24 and 4.25 the chip pulse shapes for a BOC(1,1) signal and a $\mathrm{BOC}_{\cos}(1,1)$ signal are depicted, respectively. When increasing the subcarrier rate several cycles of the binary subcarrier are included within one chip. In the case of $n_s = 4$, we get a chip pulse shape for BOC(4,1) and $\mathrm{BOC}_{\cos}(4,1)$ which com-

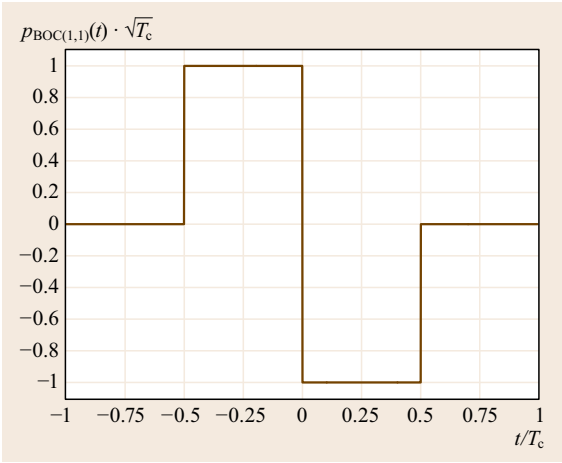

**Fig. 4.24** Chip pulse shape for BOC(1,1) signal

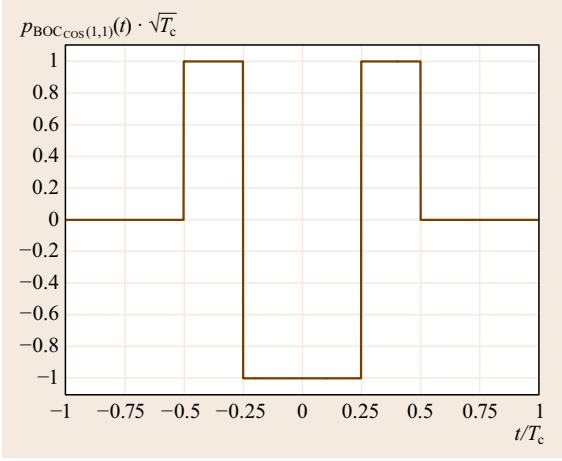

**Fig. 4.25** Chip pulse shape for $\mathrm{BOC_{cos}}$ (1,1) signal

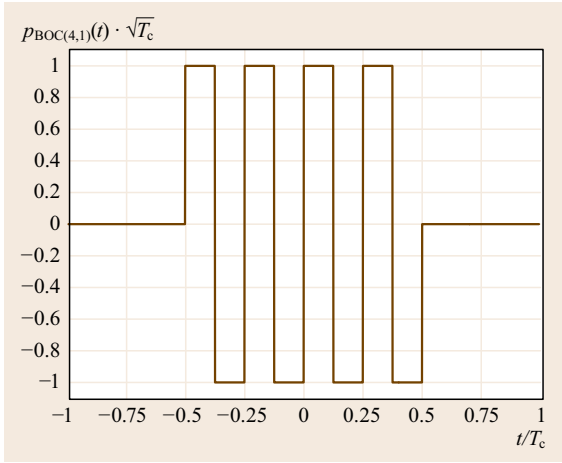

**Fig. 4.26** Chip pulse shape for BOC(4,1) signal

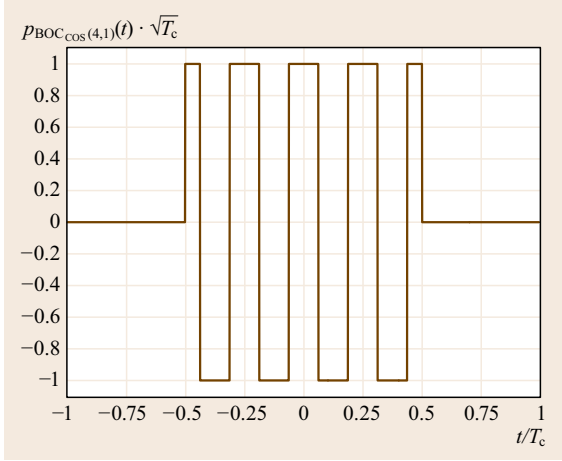

**Fig. 4.27** Chip pulse shape for $\mathrm{BOC_{cos}}$ (4,1) signal

prise four cycles of the binary subcarrier as shown in Figs. 4.26 and 4.27, respectively.

BOC signals are applied in GNSS in order to fulfill spectral separation requirements between different non-interoperable signals of different GNSS and to enhance synchronization performance [4.33, 40, 42]. Comprehensive derivation of the Fourier transform and the PSD of BOC signals can be found in [4.40, 41, 46]. Thus, following [4.40, 41] we define $n = 2\,n_s/n_c$ to be the number of half-periods of the subcarrier within the duration of one chip and for BOC signals with sine subcarrier and $n$ even

$$P_{\mathrm{BOC}(n_s,n_c)}(f) = \mathrm{j}\,\sqrt{n_c f_r}\,\frac{\sin\left(\pi\,\frac{f}{n_c f_r}\right)}{\pi f}\,\tan\left(\pi\,\frac{f}{2n_s f_r}\right), \tag{4.97}$$

for BOC signals with sine subcarrier and $n$ odd

$$P_{\mathrm{BOC_{cos}}(n_s,n_c)}(f) = \sqrt{n_c f_r}\,\frac{\cos\left(\pi\,\frac{f}{n_c f_r}\right)}{\pi f}\,\tan\left(\pi\,\frac{f}{2n_s f_r}\right), \tag{4.98}$$

for BOC signals with cosine subcarrier and $n$ even

$$P_{\mathrm{BOC}(n_s,n_c)}(f) = \sqrt{n_c f_r}\,\frac{\sin\left(\pi\,\frac{f}{n_c f_r}\right)}{\pi f}\,\frac{1-\cos\left(\pi\,\frac{f}{2n_s f_r}\right)}{\cos\left(\pi\,\frac{f}{2n_s f_r}\right)}, \tag{4.99}$$

and for BOC signals with cosine subcarrier and $n$ odd

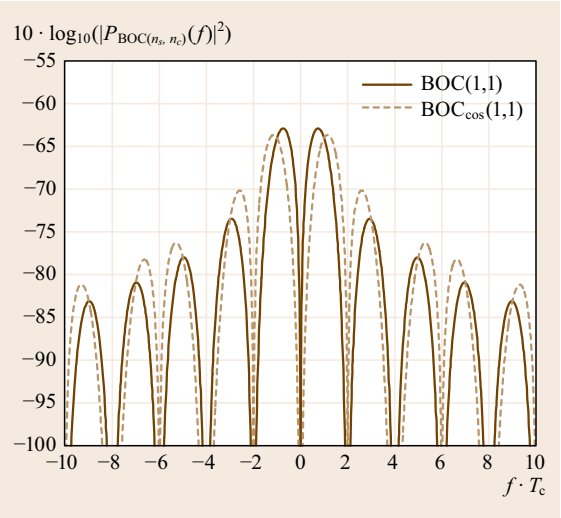

**Fig. 4.28** PSD of BOC(1,1) and $\mathrm{BOC}_{\cos}$ (1,1) signals

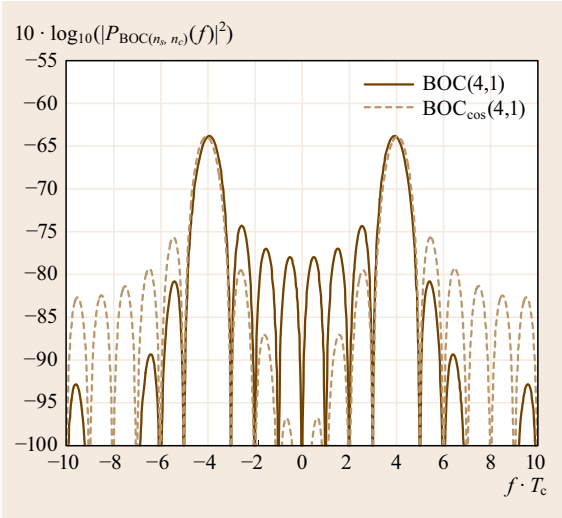

**Fig. 4.29** PSD of BOC(4,1) and $\mathrm{BOC}_{\cos}$ (4,1) signals

$$P_{\mathrm{BOC}_{\cos}(n_s,n_c)}(f) = \mathrm{j}\sqrt{n_c f_r}\,\frac{\cos\left(\pi\frac{f}{n_c f_r}\right)}{\pi f}\,\frac{1-\cos\left(\pi\frac{f}{2n_s f_r}\right)}{\cos\left(\pi\frac{f}{2n_s f_r}\right)}\,, \tag{4.100}$$

where

$$\int_{-\infty}^{\infty} |p_{\mathrm{BOC}(n_s,n_c)}(t)|^2 \mathrm{d}t = \int_{-\infty}^{\infty} |P_{\mathrm{BOC}(n_s,n_c)}(f)|^2 \mathrm{d}f = 1\,, \tag{4.101}$$

and

$$\int_{-\infty}^{\infty} |p_{\mathrm{BOC}_{\cos}(n_s,n_c)}(t)|^2 \mathrm{d}t = \int_{-\infty}^{\infty} |P_{\mathrm{BOC}_{\cos}(n_s,n_c)}(f)|^2 \mathrm{d}f = 1\,. \tag{4.102}$$

We can observe that if the chip pulse shape is of even symmetry in time domain then its Fourier transform is real (4.98) and (4.99). On the other hand, in case the chip pulse shape is of odd symmetry in time domain its Fourier transform is imaginary (4.97) and (4.100).

As mentioned earlier, BOC signals are applied in order to fulfill spectral separation requirements between different noninteroperable signals of different GNSS. Following the multiplication of the chips with a sine or cosine binary subcarrier, the spectrum of the signal is divided into two parts; therefore, BOC modulation is also known as a split-spectrum modulation.

In Fig. 4.28, the PSD of a BOC(1,1) and a $\mathrm{BOC}_{\cos}$ (1,1) signal are shown. The larger the subcarrier rate $n_s$ is chosen, the further the two main lobes of the split-spectrum signal are shifted apart. This effect is illustrated in Fig. 4.29 which shows the PSD of a BOC(4,1) and a $\mathrm{BOC}_{\cos}$ (4, 1) signal.

The autocorrelation function of BOC signals has quite high sidelobes. This is illustrated in Fig. 4.30 for a BOC(1,1) signal and a $\mathrm{BOC}_{\cos}(1,1)$ signal where the sidelobes' amplitude amounts to $\kappa \approx 0.5$.

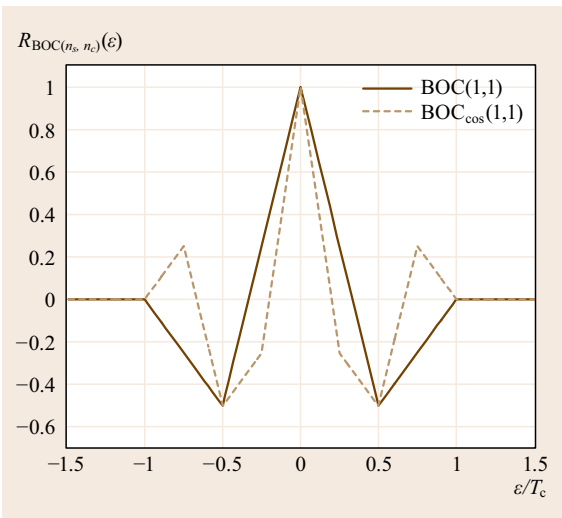

**Fig. 4.30** Autocorrelation function of BOC(1,1) and $\mathrm{BOC}_{\cos}$ (1,1) signals

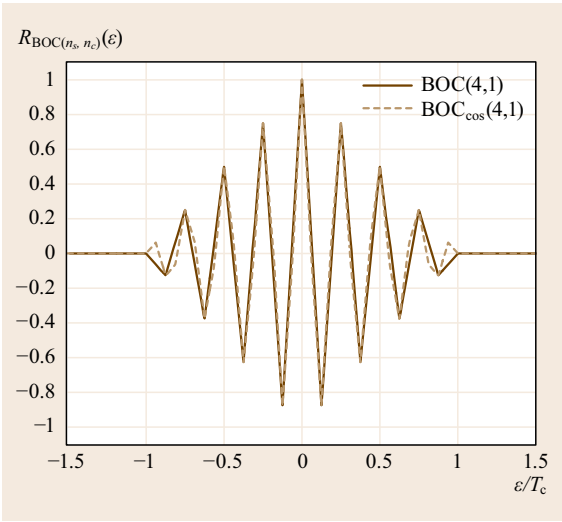

**Fig. 4.31** Autocorrelation function of BOC(4,1) and $\mathrm{BOC}_{\cos}$ (4,1) signals

For larger subcarrier rates $n_s$ the autocorrelation function of split-spectrum signals has even higher sidelobes. In Fig. 4.31, the autocorrelation function of a BOC(4,1) and a $\mathrm{BOC}_{\cos}(4,1)$ signal are depicted for which $\kappa \approx 0.9$. As discussed in Sect. 4.2.3, high sidelobes of the autocorrelation function, that is, high $\kappa$, cause less robust time-delay estimation. Consequently, high $\kappa$ is to be avoided in order to achieve robust time-delay estimation and signal acquisition.

Further, there exist several extensions of BOC signals, CBOC (composite BOC), MBOC (multiplexed BOC), TMBOC (time-multiplexed BOC), and AltBOC which are applied for the Galileo, GPS, and Beidou signals [4.33, 42, 47]. The AltBOC modulation is rather to be considered a multiplexing/mapping scheme which enables us to multiplex/map several binary signal components to form one signal with a common carrier frequency and thus forming a phase shift keying (PSK) signal. PSK is a digital modulation scheme that conveys data by modulating the phase of a carrier wave. CBOC signals are composed of a linear combination of several BOC signals. A CBOC signal with two BOC signals can be given as

$$p_{\mathrm{CBOC}}(t) = \left[\sqrt{\omega}\, p_{\mathrm{BOC}(a,b)}(t) \pm \sqrt{1-\omega}\, p_{\mathrm{BOC}(c,d)}(t)\right], \tag{4.103}$$

where $\omega \in \mathbb{R}_0^+$ and the Fourier transform is given by

$$P_{\mathrm{CBOC}}(f) = \left[\sqrt{\omega}\, P_{\mathrm{BOC}(a,b)}(f) \pm \sqrt{1-\omega}\, P_{\mathrm{BOC}(c,d)}(f)\right] \tag{4.104}$$

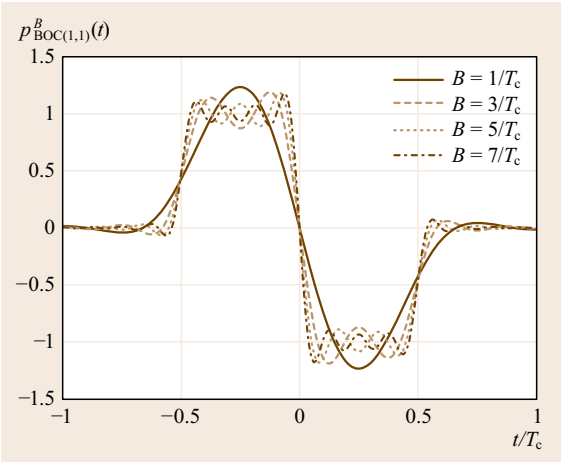

**Fig. 4.32** Band-limited BOC(1,1) signal

the PSD is given as

$$|P_{\mathrm{CBOC}}(f)|^2 = \left[\omega |P_{\mathrm{BOC}(a,b)}(f)|^2 + (1-\omega)\,|P_{\mathrm{BOC}(c,d)}(f)|^2 \pm 2\sqrt{\omega-\omega^2}\,\mathrm{Re}\{P_{\mathrm{BOC}(a,b)}(f)P^*_{\mathrm{BOC}(c,d)}(f)\}\right]. \tag{4.105}$$

For TMBOC different chip pulse shapes are used for different chips of the PR sequence. A TMBOC chip pulse shape with two different BOC chip pulse shapes which are emitted each $T_c$ seconds can be described by

$$p_{\mathrm{TMBOC}}(t) = \begin{cases} p_{\mathrm{BOC}(a,b)}(t) & \text{probability } p\,, \\ p_{\mathrm{BOC}(c,d)}(t) & \text{probability } 1-p\,. \end{cases} \tag{4.106}$$

In case the signaling source, that is, the binary PR sequence with chip pulse shapes, is negative equally probable (NEP), it has the following properties [4.45, p. 64]:

- For each chip pulse shape $p_i(t)$ out of the set of chip pulse shapes that form the signaling source also the negative chip pulse shape $-p_i(t)$ has to be in the set (PR binary sequence $\{d_k\} \in \{-1, 1\}$).
- The stationary probabilities of each chip pulse shape $p_i(t)$ and its negative form $-p_i(t)$ are equal.
- The transition probability $p_{ik} = p_{rs}$ whenever $p_i(t) = \pm p_r(t)$ and $p_k(t) = \pm p_s(t)$, where the transition probability $p_{ik}$ denotes the probability that chip pulse shape $p_k(t)$ is transmitted in the chip after occurrence of the chip pulse shape $p_i(t)$ in the previous chip.

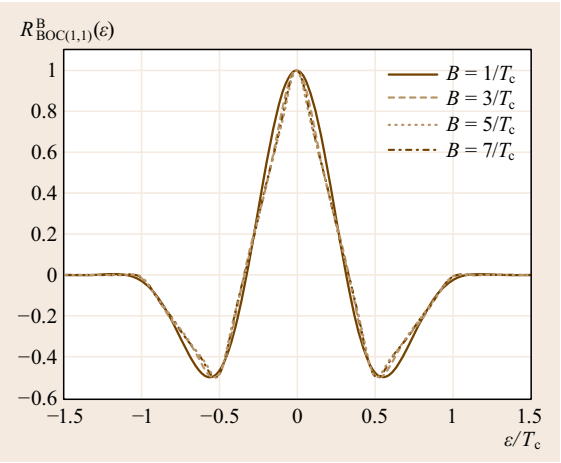

**Fig. 4.33** Autocorrelation function of band-limited and normalized BOC(1,1) chip pulse shape

For such a signaling source, the spectrum is characterized by the absence of a line spectrum and further is independent of the transition probabilities themselves. Thus, for a NEP TMBOC signal the PSD can be written as

$$|P_{\mathrm{TMBOC}}(f)|^2 = p\,|P_{\mathrm{BOC}(a,b)}(f)|^2 + (1-p)\,|P_{\mathrm{BOC}(c,d)}(f)|^2\,, \qquad (4.107)$$

and the autocorrelation function is given by

$$R_{\mathrm{TMBOC}}(\varepsilon) = p\,R_{\mathrm{BOC}(a,b)}(\varepsilon) + (1-p)\,R_{\mathrm{BOC}(c,d)}(\varepsilon)\,. \qquad (4.108)$$

In the same manner as for the rectangular chip pulse shape, we can also derive strictly band-limited BOC chip pulse shapes. By way of example, we show this in the following for the case of BOC(1,1) with a sine square wave subcarrier, where $T_\mathrm{c} = 1/f_\mathrm{r}$. The strictly band-limited and normalized BOC(1,1) pulse shape can be given as

$$p^{B}_{\mathrm{BOC}(1,1)}(t) = \frac{1}{\xi\pi\sqrt{T_\mathrm{c}}}\left(2\mathrm{Si}(2\pi Bt)\mathrm{Si}\left[2\pi B\left(t+\frac{T_\mathrm{c}}{2}\right)\right] - \mathrm{Si}\left[2\pi B\left(t-\frac{T_\mathrm{c}}{2}\right)\right]\right), \qquad (4.109)$$

with the normalization

$$\xi = \sqrt{\frac{\int_{-B}^{B}|P_{\mathrm{BOC}(1,1)}(f)|^2\mathrm{d}f}{\int_{-\infty}^{\infty}|P_{\mathrm{BOC}(1,1)}(f)|^2\mathrm{d}f}}\,. \qquad (4.110)$$

In Fig. 4.32, a band-limited BOC(1,1) chip pulse shape is shown. Similar to the band-limited rectangular pulse in Fig. 4.22 the band-limited BOC(1,1) chip pulse shape is clearly not time-limited anymore. The autocorrelation function of the band-limited and normalized BOC(1,1) chip pulse shape $R^{\mathrm{B}}_{\mathrm{BOC}(1,1)}(\varepsilon)$ is shown in Fig. 4.33. The peak of the autocorrelation function $R^{\mathrm{B}}_{\mathrm{BOC}(1,1)}(\epsilon)$ becomes rounded due to band-limitation and its curvature is smaller and consequently the CRLB is higher than for the nonband-limited signal.

## 4.4 Signal Multiplexing

In the past years, several multiplexing/mapping schemes have been developed and assessed for GNSS use. The overall goal of multiplexing schemes is to map several signals onto one carrier with minimal cross-talk and maximal power and bandwidth efficiency. Moreover, preserving a constant or *quasi*-constant envelope is very beneficial for the amplification of the signals by the high-power amplifier on board the satellite payload, as out-of band emissions and power inefficiencies are mostly avoided. A constant envelope of the signal is given, if the peak-to-average power ratio (PAPR)

$$\mathrm{PAPR} = \frac{\max|x(t)|^2}{\mathrm{E}(|x(t)|^2)} = 1\,, \qquad (4.111)$$

where $x(t)$ denotes the multiplexed/mapped signal. Thus, in order to achieve high-power efficiency a small PAPR is desirable.

In general, there are two main strategies to realize a constant envelope: time-multiplex, or so-called frequency multiplex. The interplex scheme defined in [4.48] is a form of multiplex that can be seen as belonging to both the above mentioned categories [4.49]. The interplex is a special case of a phase-shift-keyed/phase-modulated (PSK/PM) multichannel system that is characterized by a high-power efficiency for a number of components less or equal to five [4.48]. Higher power efficiency is achieved by suppressing the carrier reference power and introducing a smaller cross-modulation product. The interplex method is equivalent to the so-called coherent adaptive subcarrier modulation (CASM) [4.50]. Time-multiplexing of several signals can be established on a code-by-code basis or on a chip-by-chip basis as it is the case for the L2C signal of GPS. Furthermore, there are other methods like

majority voting [4.51, 52] or [4.53] different modifications like intervote combining [4.52], which can also be considered as a time-code-multiplex approach.

The interplex is particularly interesting because of its power efficiency, when less or equal than five signal components are multiplexed/mapped on one carrier. Moreover, the efficiency is higher if one component is strong and many weak components are combined [4.48]. However, an intermodulation product is needed in order to establish the quasi-constant envelope constellation. We use here the term quasi-constant envelope as in real systems nonbandlimited signals cannot really be generated and thus the signals which are interplexed are not strictly binary anymore. Thus, interplexing/mapping schemes also need to be applicable for nonbandlimited and only quasi-constant envelope signals. In the configuration and power allocation of the current Galileo interplex at E1, around 11% of the total power is spend on the intermodulation product. Even for the very efficient AltBOC modulation for four signal components the power efficiency is around 85%.

In the following, we will study two different multiplexing schemes that are used for GNSS in more detail, the interplex and AltBOC schemes.

### 4.4.1 Interplex

A phase-modulated radio frequency signal in a phase-shift-keyed/phase modulated (PSK/PM) system can be denoted as [4.48]

$$x(t) = \sqrt{2P}\sin[2\pi f_c t + \Theta(t)]\,, \tag{4.112}$$

where $P$ is the total average power, $f_c$ denotes the carrier frequency, and $\Theta(t)$ is the phase modulation. For an $N$-channel interplex the phase modulation is

$$\Theta(t) = \left(\beta_1 + \sum_{n=2}^{N} \beta_n y_n(t)\right) y_1(t)\,, \tag{4.113}$$

where $N$ is the number of channels, $\beta_n$ are the modulation angles, and $y_n(t) = \in \{-1, 1\}$ are the binary data streams or binary GNSS signals.

#### Two-Channel Interplex with $N = 2$

A two-channel interplex signal is given by

$$x(t) = \sqrt{2P}\sin[2\pi f_c t + \beta_1 y_1(t) + \beta_2 y_1(t) y_2(t)]\,. \tag{4.114}$$

In the following, we will use the trigonometric identities

$$\begin{aligned}\sin(\alpha \pm \beta) &= \sin(\alpha)\cos(\beta) \pm \cos(\alpha)\sin(\beta)\,,\\ \cos(\alpha \pm \beta) &= \cos(\alpha)\cos(\beta) \mp \sin(\alpha)\sin(\beta)\,.\end{aligned} \tag{4.115}$$

Furthermore, we will use the the identities

$$\begin{aligned}\cos[\beta_n y_n(t)] &= \cos(\beta_n)\,,\\ \sin[\beta_n y_n(t)] &= y_n(t)\sin(\beta_n)\,,\end{aligned} \tag{4.116}$$

which are valid for binary signals $y_n(t) \in \{-1, 1\}$. Using these identities, we can reformulate (4.114) to obtain

$$\begin{aligned}x(t) = {} & \sqrt{2P}\sin(2\pi f_c t)[\cos(\beta_1)\cos(\beta_2)\\ & - y_2(t)\sin(\beta_1)\sin(\beta_2)]\\ & + \sqrt{2P}\cos(2\pi f_c t)\,[y_1(t)\sin(\beta_1)\cos(\beta_2)\\ & + y_1(t)y_2(t)\cos(\beta_1)\sin(\beta_2)]\,.\end{aligned} \tag{4.117}$$

Furthermore,

$$\begin{aligned}P_c &= P\,\cos^2(\beta_1)\cos^2(\beta_2)\,,\\ P_1 &= P\,\sin^2(\beta_1)\cos^2(\beta_2)\,,\\ P_2 &= P\,\sin^2(\beta_1)\sin^2(\beta_2)\,,\\ P_{\text{im}} &= P\,\cos^2(\beta_1)\sin^2(\beta_2)\,,\end{aligned} \tag{4.118}$$

are carrier power ($P_c$), the power in channels 1 and 2 ($P_1$, $P_2$), as well as the power of the intermodulation product ($P_{\text{im}}$).

When chosing $\beta_1 = \pi/2$ and $\beta_2 = \pi/4$, we get

$$\begin{aligned}P_c &= 0\,,\\ P_2 &= \frac{P}{2}\,,\\ P_1 &= \frac{P}{2}\,,\\ P_{\text{im}} &= 0\,,\end{aligned} \tag{4.119}$$

which is equivalent to a quadrature phase shift keying (QPSK) modulation. In Fig. 4.34, such a two-channel interplex signal is shown as equivalent baseband signal

$$\tilde{x}(t) = \sqrt{P_1}y_1(t) + \mathrm{j}\sqrt{P_2}y_2(t) \tag{4.120}$$

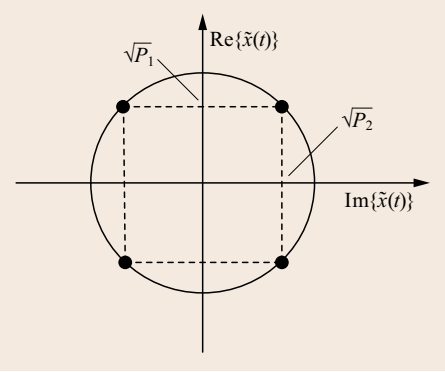

**Fig. 4.34** Quadrature phase shift keying (QPSK)

with

$$x(t) = \sqrt{2}\,\mathrm{Re}\{\tilde{x}(t)\mathrm{e}^{\mathrm{j}2\pi f_c t}\} \tag{4.121}$$

for the case of equal amplitudes $\sqrt{P_1} = \sqrt{P_2}$. Power balance between real and imaginary part of the QPSK signal is not necessary, though. For GNSS, QPSK is often used with $\sqrt{P_1} \neq \sqrt{P_2}$. The possible phase transitions of standard QPSK are illustrated in Fig. 4.35.

In order to decrease the PAPR (especially when the signals have a finite bandwidth before amplification on the satellite) and thus to avoid phase transitions crossing the origin, staggering of the signal components can be applied. This means that in the case of QPSK the two components are time-delayed with respect to each other by a time-delay $\tau_s$. In general the time-delay $\tau_s$ needs to be chosen with respect to the used chip pulse shapes for the signals $y_1(t)$ and $y_2(t)$. A two-channel interplex system with staggering is also called offset-QPSK (OQPSK). The resulting phase transitions for a rectangular chip pulse shape for both $y_1(t)$ and $y_2(t)$ as well as a time-delay $\tau_s = T_c/2$ is depicted in Fig. 4.36. The resulting equivalent baseband signal can be expressed as

$$\tilde{x}_o(t) = \sqrt{P_1}y_1(t) + \mathrm{j}\sqrt{P_2}y_2(t-\tau_s)\,. \tag{4.122}$$

### Three-Channel Interplex with $N = 3$

A three-channel interplex signal is described by the relation [4.48]

$$x(t) = \sqrt{2P}\sin[2\pi f_c t + \beta_1 y_1(t) + \beta_2 y_1(t)y_2(t) + \beta_3 y_1(t)y_3(t)]\,,$$

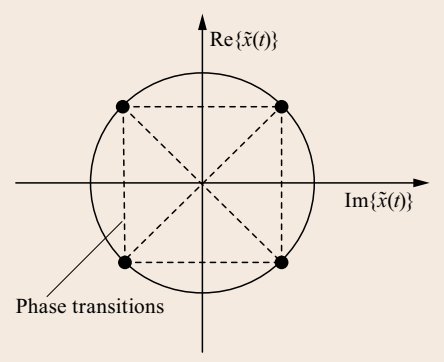

**Fig. 4.35** QPSK phase transitions

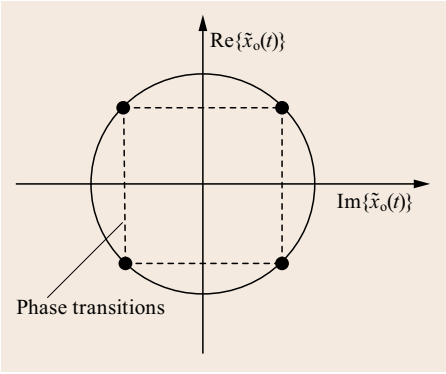

**Fig. 4.36** OQPSK phase transitions

which may also be expressed as

$$\begin{aligned} x(t) = {} & \sqrt{2P}\sin(2\pi f_c t) \\ & \underbrace{\cos[\beta_1 y_1(t) + \beta_2 y_1(t)y_2(t) + \beta_3 y_1(t)y_3(t)]}_{=A_1} \\ & + \sqrt{2P}\cos(2\pi f_c t) \\ & \underbrace{\sin[\beta_1 y_1(t) + \beta_2 y_1(t)y_2(t) + \beta_3 y_1(t)y_3(t)]}_{=A_2}\,. \end{aligned} \tag{4.123}$$

Now, we can write

$$\begin{aligned} A_1 = {} & \cos(\beta_1)\cos(\beta_2)\cos(\beta_3) \\ & - y_2(t)y_3(t)\cos(\beta_1)\sin(\beta_2)\sin(\beta_3) \\ & - y_2(t)\sin(\beta_1)\sin(\beta_2)\cos(\beta_3) \\ & - y_3(t)\sin(\beta_1)\cos(\beta_2)\sin(\beta_3) \end{aligned} \tag{4.124}$$

and

$$\begin{aligned} A_2 = {} & y_1(t)\sin(\beta_1)\cos(\beta_2)\cos(\beta_3) \\ & - y_1(t)y_2(t)y_3(t)\sin(\beta_1)\sin(\beta_2)\sin(\beta_3) \\ & + y_1(t)y_2(t)\cos(\beta_1)\sin(\beta_2)\cos(\beta_3) \\ & + y_1(t)y_3(t)\cos(\beta_1)\cos(\beta_2)\sin(\beta_3)\,. \end{aligned} \tag{4.125}$$

In order to eliminate most of the intermodulation terms, we can choose $\beta_1 = \pi/2$ and obtain

$$\begin{aligned} P_1 &= P\,\cos^2(\beta_2)\cos^2(\beta_3)\,, \\ P_2 &= P\,\sin^2(\beta_2)\cos^2(\beta_3)\,, \\ P_3 &= P\,\cos^2(\beta_2)\sin^2(\beta_3)\,, \\ P_{\mathrm{im}} &= P\,\sin^2(\beta_2)\sin^2(\beta_3)\,, \end{aligned} \tag{4.126}$$

for the powers of the three signal components and the intermodulation product. The equivalent baseband signal for this three-channel interplex signal then can be

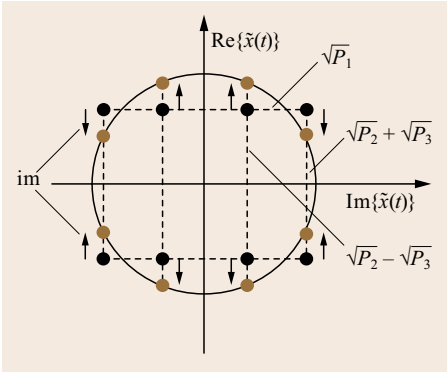

**Fig. 4.37** Three-channel interplex signal; impact of intermodulation product (im) shown

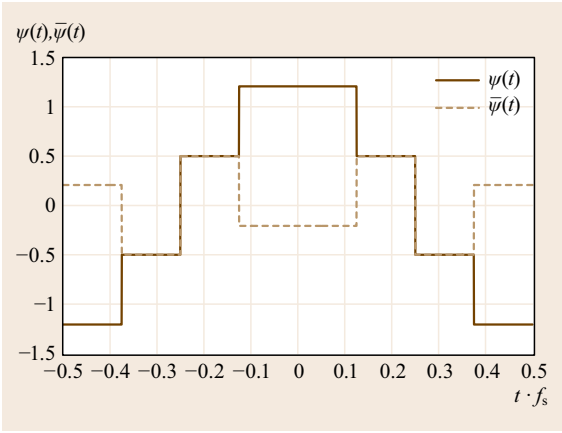

**Fig. 4.38** Subcarriers of AltBOC signal

described as

$$\tilde{x}(t) = \sqrt{P_1}y_1(t) - \sqrt{P_{\text{im}}}y_1(t)y_2(t)y_3(t) + \text{j}\left[\sqrt{P_2}y_2(t) + \sqrt{P_3}y_3(t)\right]. \quad (4.127)$$

This equivalent baseband signal is illustrated in Fig. 4.37 by the brown dots. The black dots denote this interplex signal without any intermodulation product, a nonconstant envelop interplex signal. The effect of the inter-modulation product is indicated by black arrows and the label *im*. Higher orders of interplex signals ($N > 3$) with nearly equal power of the interplex signal components $y_n(t)$ leads to quite high intermodulation power $P_{\text{im}}$ and thus high power inefficiency.

In order to increase power efficiency, staggering of all signal components can be applied [4.54] as well as a technique called scalable interplex [4.55] which introduces a shaping of the phase states of the signal constellation (constellation shaping) by weighting different intermodulation products. These techniques provide significant enhancement of power efficiency and they provide the possibility to adapt the interplex signal $x(t)$ to the respective characteristics of the amplifier.

### 4.4.2 AltBOC

In order to achieve a constant envelope with four signal components, the AltBOC multiplexing/modulation can be used. Four binary signal components can be multiplexed on one carrier frequency with

$$\tilde{x}(t) = \frac{1}{2\sqrt{2}}\Big[(y_1(t)+\text{j}y_2(t))\psi'_{\text{M}}(t) + (y_3(t)+\text{j}y_4(t))\psi_{\text{M}}(t) + (\bar{y}_1(t)+\text{j}\bar{y}_2(t))\bar{\psi}'_{\text{M}}(t) + (\bar{y}_3(t)+\text{j}\bar{y}_4(t))\bar{\psi}_{\text{M}}(t)\Big]$$

with the intermodulation products

$$\begin{aligned}\bar{y}_1(t) &= y_2(t)y_3(t)y_4(t)\,,\\ \bar{y}_2(t) &= y_1(t)y_3(t)y_4(t)\,,\\ \bar{y}_3(t) &= y_1(t)y_2(t)y_4(t)\,,\\ \bar{y}_4(t) &= y_1(t)y_2(t)y_3(t)\,,\end{aligned} \quad (4.128)$$

and the multilevel complex subcarriers

$$\begin{aligned}\psi_{\text{M}}(t) &= \psi(t)+\text{j}\psi\left(t-\frac{1}{4f_{\text{s}}}\right),\\ \psi'_{\text{M}}(t) &= \psi(t)-\text{j}\psi\left(t-\frac{1}{4f_{\text{s}}}\right),\\ \bar{\psi}_{\text{M}}(t) &= \bar{\psi}(t)+\text{j}\bar{\psi}\left(t-\frac{1}{4f\text{s}}\right),\\ \bar{\psi}'_{\text{M}}(t) &= \bar{\psi}(t)-\text{j}\bar{\psi}\left(t-\frac{1}{4f_{\text{s}}}\right).\end{aligned} \quad (4.129)$$

The two four-valued subcarriers are given by

$$\begin{aligned}\psi(t) = &+\frac{\sqrt{2}}{4}\text{sgn}\left[\cos\left(2\pi f_{\text{s}}t-\frac{\pi}{4}\right)\right]\\ &+\frac{1}{2}\text{sgn}\left[\cos(2\pi f_{\text{s}}t)\right]\\ &+\frac{\sqrt{2}}{4}\text{sgn}\left[\cos\left(2\pi f_{\text{s}}t+\frac{\pi}{4}\right)\right],\end{aligned} \quad (4.130)$$

$$\begin{aligned}\bar{\psi}(t) = &-\frac{\sqrt{2}}{4}\text{sgn}\left[\cos\left(2\pi f_{\text{s}}t-\frac{\pi}{4}\right)\right]\\ &+\frac{1}{2}\text{sgn}[\cos(2\pi f_{\text{s}}t)]\\ &-\frac{\sqrt{2}}{4}\text{sgn}\left[\cos\left(2\pi f_{\text{s}}t+\frac{\pi}{4}\right)\right].\end{aligned} \quad (4.131)$$

and illustrated in Fig. 4.38. The resulting equivalent baseband signal is shown in Fig. 4.39.

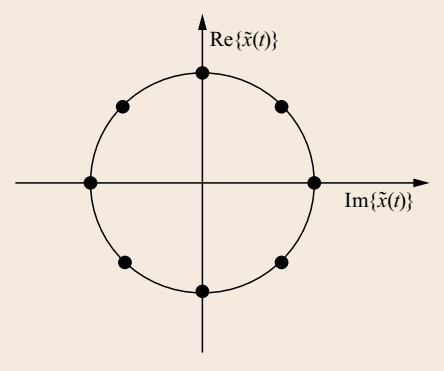

**Fig. 4.39** Equivalent baseband signal of AltBOC with $f_s = 15 \times 1.023\,\text{MHz}$

In the case of four signals with $1/T_c = 10 \times 1.023\,\text{Mcps}$ and rectangular chip pulse shapes as well as a subcarrier frequency $f_s = 15 \times 1.023\,\text{MHz}$, as used for the Galileo E5 signal we get the spectra for different signals (E5a and E5b) and intermodulation products shown in Fig. 4.40. The sum of all spectra resembles the overall spectrum of the Galileo E5 AltBOC constant envelop signal. Note that after amplification on the satellite each payload has also an output filter which filters the AltBOC or interplex signal. Thus, the spectrum of the received signal on ground is then bandlimited with respect to the employed output filter.

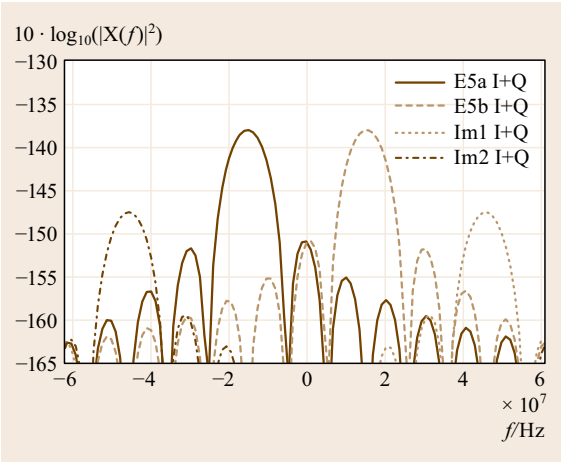

**Fig. 4.40** Spectrum of different signal components of AltBOC Galileo E5 signal

## 4.5 Navigation Data and Data-Free Channels

In general, there are two kinds of channels known as data channel and pilot channels. In data channels, the symbols modulated onto the transmitted PR binary sequences are unknown to the receiver in advance. These symbols are used to transmit the navigation message data $m(t)$ to the user. The navigation message contains all the information that is necessary to allow the user to perform positioning. It includes the ephemeris parameters, needed to compute the satellite coordinates, the time parameters and clock corrections, in order to derive satellite clock offsets and time conversions, several so-called service parameters which indicate satellite health information, parameters to feed the ionospheric model needed for single-frequency receivers, as well as the almanac, which provides orbit and clock information for the entire constellation.

In a pilot channel, the symbols that are modulated onto the transmitted PR binary sequence are known to the receiver. Therefore, a long coherent integration time can be used in the DLL and the code phase estimates can be derived with high accuracy. Also for pilot channels tiered codes are used in order to reduce cross-correlation, as described in Sect. 4.2.2.

Both data and pilot channel are transmitted synchronously by the same satellite as two different components of the multiplex (interplex, AltBOC, etc.) signal. They use different PR binary sequences in order to be separable by the receiver. Thus, MA interference among data and pilot signals being transmitted synchronously from the same satellite is very low. Data and pilot channels can be processed jointly in the GNSS receiver as they are synchronous and usually coherent.

For some GNSSs, forward error correction (FEC) or channel coding is applied in order to control errors in data transmission noisy over the channel [4.56]. The navigation message data is encoded in a redundant way by using an error-correcting code. The included redundancy allows the GNSS receiver to detect a limited number of errors that may have occurred during symbol detection due to channel impairments and to correct these errors without any retransmission. Error correction and navigation data extraction are further discussed in Sect. 14.5 of this Handbook.

# 5. Clocks

Ron Beard, Ken Senior

This chapter provides an overview of clock technology and typical clocks (Cs, Rb, H-Maser) in use today for onboard and ground systems and identifies future trends such as fountain clocks, etc. Concepts such as clock drift, trend, random variations and the statistical methods for their characterization (Allan deviation (ADEV), etc.) are introduced and performance characteristics of global navigation satellite system (GNSS) onboard clocks are presented. The handling and impact of special and general relativity on timing measurements are discussed. Finally, the generation of a GNSS time from an ensemble of ground clocks is described.

Today's time and frequency standards range from the most sophisticated reference standards to the smallest oscillators for handheld radios. The technical requirements and technologies needed are different for the various applications but they derive from similar physical concepts. These different technologies can be categorized into four major areas: reference standards, mobile systems, handheld and space systems. These areas are the core areas of time and frequency standard applications and different areas of technology are needed to address them.

Clocks and oscillators are needed by reference timescale centers such as those that contribute to the international time scale, Universal Time Coordinated (UTC). This specialized area requires the most highly stable and accurate time standards that are maintained under controlled environmental conditions. Their outputs are processed with special ensembling algorithms designed to produce an absolute reference for all systems. For example, the current suite of clocks used at the US Naval Observatory (USNO) consists of many commercial cesium beam frequency standards and hydrogen masers, and specially built rubidium fountain standards. These clocks are physically separated and operated in a tightly controlled environment. Size, weight and power are not issues pertinent for these clocks; primary emphasis is on performance, mostly for intervals of days and much longer.

Clocks used in mobile applications are typically crystal oscillator-based devices and small atomic clocks or oscillators used for positioning, communications or internal to other remote sensing systems. The requirements for mobile devices typically emphasize size, weight and power rather than time and frequency performance so their performance requirements are not particularly demanding or rigorous.

Devices used in handheld applications are the most demanding in terms of size, weight and power. They

commonly use small quartz crystal oscillators. However, in recent years there have been several efforts to develop extremely small atomic standards. These small atom standards offer better accuracy and stability than crystal oscillators in an extremely small package. Although their performance exceeds that of crystal oscillator-based devices they have yet to perform as well as their larger mobile or timing center devices, although there are efforts underway to attempt to improve performance. The technologies developed for these devices have benefited from development in atomic interrogation different from that used by the conventional commercial standards and will be described later.

Space-qualified atomic standards constitute a unique class of frequency standards next to ground- or aircraft-based standards. They were essential for the development and deployment of global navigation satellite systems (GNSS), which are currently the dominant user of highly precise and stable space-qualified atomic standards. These types of standards provide high stability for navigation performance and a large part of the development of these space devices has been to reliably provide high stability. The GNSS user receiving equipment and the timing capability resulting from their use of the atomic standards in the GNSS satellites produce an inexpensive alternative to high-precision atomic clocks. By displacing higher cost, higher performing atomic clocks, GNSS user equipment receivers or timing receivers with low quality clocks are being deployed in a wide variety of systems. For example, naval tactical and strategic systems are currently utilizing hundreds of Global Positioning System (GPS) units, which are displacing systems on larger ships that may have previously used multiple cesium beam standards on board. Secondary standards such as rubidium vapor cell and crystal oscillators are being used extensively in aircraft, shipboard and man-portable applications, since virtually every system has a clock or oscillator of some quality contained in it.

## 5.1 Frequency and Time Stability

The oscillator is the basic unit on which clocks, timekeeping and timescales are founded. The fundamental relationship between frequency and time is

$$f = \frac{1}{\tau} , \tag{5.1}$$

where $f$ is the frequency of the oscillator, and the period $\tau$ is the time interval that a clock uses for time keeping. A clock mechanism added to an oscillator accumulates or counts the number of time intervals to measure elapsed time thereby generating a clock. The intimate connection between oscillators and clocks is sometimes confused by calling a clock a frequency standard or vice versa. A generic clock system is illustrated in Fig. 5.1.

However, oscillators are not perfect and various types have been developed for different requirements and applications. The determination of oscillator or clock performance under different conditions ranging from ideal laboratory conditions, to harsh field environments, such as military field radios, is an area of special concern.

Oscillators or frequency sources produce noise that appears to be a superposition of causally generated signals and random, nondeterministic noises. Random noises include thermal noise, shot noise, and noises of undetermined origin, such as flicker noise. The end result is time-dependent phase and amplitude fluctuations. Measurement of these fluctuations can be used to characterize the oscillator in terms of amplitude modulation (AM) and phase modulation (PM) noise, and the combination is more commonly called frequency stability. This section describes the basic concepts and measures used to describe the frequency and time stability of precision clocks.

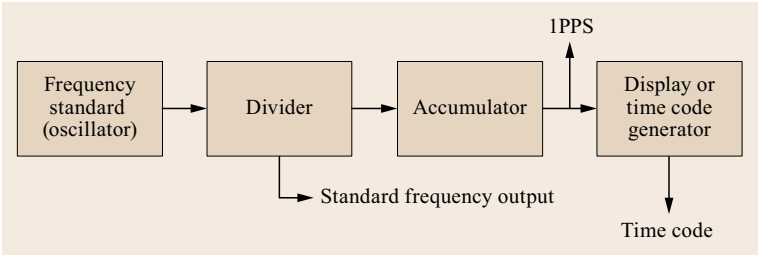

**Fig. 5.1** Generic clock system

### 5.1.1 Concepts

Frequency stability encompasses the concept of random noise, intended and incidental noise, and any other fluctuations in the output frequency of a device. In general, frequency stability is the degree to which an oscillator produces the same frequency throughout a specified period of time. It is implicit in this general definition that the stability of a given frequency decreases if it is anything except a perfect sine wave.

The oscillator produces a signal, whose voltage output may be written as,

$$V(t) = [V_0 + \varepsilon(t)] \sin [2\pi \nu_0 t + \phi(t)] \ ,$$

where $V_0$ is the nominal peak voltage amplitude, $\nu_0$ is the nominal fundamental frequency, and where $\varepsilon(t)$ and $\phi(t)$ represent the fluctuations in amplitude and phase of the oscillator from their nominal value, and $t$ represents elapsed time. The instantaneous angular frequency of the oscillator is defined as the time derivative of its total phase

$$\omega(t) = \frac{\mathrm{d}}{\mathrm{d}t} [2\pi \nu_0 t + \phi(t)]$$

and therefore its instantaneous frequency as $\nu(t) = \omega(t)/(2\pi)$, or

$$\nu(t) = \nu_0 + \frac{1}{2\pi} \frac{\mathrm{d}\phi}{\mathrm{d}t} \ . \tag{5.2}$$

For precision oscillators the amplitude fluctuations $\varepsilon$ may generally be neglected as they are usually very small compared to the nominal amplitude and therefore have no substantial influence on the frequency or phase. Also, the second term of (5.2) is quite small as compared to the nominal frequency $\nu_0$ and so it is more convenient to define the normalized (or factional) frequency as

$$y(t) = \frac{\nu(t) - \nu_0}{\nu_0} = \frac{1}{2\pi \nu_0} \frac{\mathrm{d}\phi}{\mathrm{d}t} \ , \tag{5.3}$$

which is unitless and which may also be used as a basis for comparing oscillators operating at nominally different frequencies. The phase may then be expressed in units of time as

$$x(t) = \frac{\phi(t)}{2\pi \nu_0} \ , \tag{5.4}$$

that is,

$$y(t) = x'(t) \ .$$

A generally applicable model of the time error of a clock, $T(t)$, at an elapsed time, $t$, after synchronization with another, presumably better clock, can be expressed as

$$T(t) = x_0 + y_0 t + \frac{1}{2} D_0 t^2 + \int_0^t E(t)\mathrm{d}t + \varepsilon(t) \ , \tag{5.5}$$

where $x_0$ represents the synchronization error or offset at $t = 0$, $y_0$ represents a constant rate or frequency offset of the clock and $D_0$ represents a constant frequency drift, and $\varepsilon(t)$ represents all the random deviations of the clock's error. The quantity $E(t)$ represents any remaining systematic nonconstant rate difference due to environmental effects (temperature, radiation, accelerations, etc.).

Although the environmental effects are not usually explicitly modeled such effects can be large and should not be ignored especially in field or operating systems. The random fluctuations are often concentrated upon since they may be measured by statistical means after the systematic components, $x_0$, $y_0$, and $D_0$ are removed from the clock data. Characterization of the clock's random error contribution to its total time or frequency error is the subject of the next section on stability.

### 5.1.2 Characterization of Clock Stability

While no single formal definition of stability exists, the characterization of the stability of a clock may be generally considered as any quantification of the stability of the time and frequency output of the device. A number of different measures of stability have been developed over the years to characterize clocks and numerous papers have been published in more detail than presented here. In particular, the information presented here does not include the various methods and special considerations for measuring clocks and oscillators. For a more comprehensive treatment of the characterization methodology refer to the collection of papers in [5.1], and more recent publications [5.2–5].

In an attempt to make uniform the specifications of clocks through the characterization of their stability the Institute of Electrical and Electronic Engineers (IEEE) in the 1970s made several recommended measures of stability, which can broadly be separated into two analysis areas: sample time-averaged or time domain methods and Fourier spectral or frequency domain methods [5.6]. Both approaches may be related mathematically as shown below, though historically either approach was utilized because the particular methods for measuring clocks' error dictated one method over the other. With the progress in digital processing since

the 1960s both methods can usually be applied for clocks measured today [5.7].

The IEEE has recommended as its primary frequency domain measure of a clock's stability the one-sided spectral density $S_y(f)$ of its fractional frequency, or of its spectral density of phase $S_x(f)$ (or $S_\phi(f)$), which, by properties of derivatives and the Fourier transform, are related by

$$S_y(f) = \left(\frac{f}{\nu_0}\right)^2 ,$$
$$S_\phi(f) = (2\pi f)^2 S_x(f) . \tag{5.6}$$

Here note that $f$ represents the Fourier frequency, which should be distinguished from the frequency output of the clock, $\nu$ (or $y$).

The spectral density $S_x(f)$ may be calculated from observations of its corresponding phase or time signal $x(t)$ by using Fourier transforms. The relationship between the Fourier transform $X(f)$ of the signal and the signal itself is given by

$$X(f) = \int_{-\infty}^{\infty} x(t) \mathrm{e}^{-2\pi \mathrm{j} f t} \mathrm{d}t . \tag{5.7}$$

However, not all the measurements of $x(t)$ are practically available at all continuous values of $t$. Given evenly spaced discrete measurements $x(k\tau_0)$ of $x$, where $\tau_0$ is the smallest sampling interval, and $k$ is an integer, the discrete Fourier transform may be invoked where the integral is replaced by an infinite sum

$$X(f) = \sum_{k=-\infty}^{+\infty} x(k\tau_0) \mathrm{e}^{-2\pi \mathrm{j} f} . \tag{5.8}$$

If the timing signals are assumed to be periodic, that is $x(t+T) = x(t)$ for all $t$ and some period $T$, then its Fourier series is also discrete.

Assuming together that the signal $x$ is periodic with period $T$ and there are $N$ evenly spaced phase measurements $x(k\tau_0)$, such that $N\tau_0 = T$, the Fourier series at a finite number of Fourier frequencies may be calculated using just a finite sum

$$X\left(\frac{n}{N\tau_0}\right) = \sum_{k=0}^{N-1} x(k\tau_0) \mathrm{e}^{-2\pi \mathrm{j}(kn/N)} \tag{5.9}$$

for each $n = 0, 1, \ldots, N-1$. In other words, the full Fourier frequency content occurs at an exact finite number of frequencies $f_n = n/(N\tau_0)$ with smallest nonzero Fourier frequency $f_1$ and largest frequency $f_{N-1}$. Any Fourier frequency content occurring at frequencies larger than the Nyquist frequency $(1/(2\tau_0))$, or half the sampling frequency) or content in violation of the periodicity assumption will alias into the spectrum calculated from (5.9).

The spectral density of phase (time) may be calculated from (5.9) by combining the squares of the real and imaginary components and dividing by the total time interval $T$

$$S_x(f_n) = \frac{\mathrm{Re}\{X(f_n)\}^2 + \mathrm{Im}\{X(f_n)\}^2}{T} . \tag{5.10}$$

A generally applicable model for the random fluctuations of most clocks describes the spectral density of phase as a sum of seven independent pure power laws up to a limiting frequency

$$S_x(f) = \begin{cases} \sum_{\beta=-6}^{0} g_\beta f^\beta & \text{for } 0 < f < f_\mathrm{h} \\ 0 & \text{for } f_\mathrm{h} < f . \end{cases} \tag{5.11}$$

Here, $\beta$ are integers, the $g_\beta$ are constants indicating the spectral level of the noise, and $f_\mathrm{h}$ is the high frequency cutoff of a low-pass filter. The high frequency cutoff is necessary since variances involving integration of $S_x(f)$ over $f$ would yield unrealistic infinite energies. Also, it is assumed that only integer values of $\beta$ may be present as the model was mostly empirically derived. For an excellent treatment of the continuous $\beta$ case see [5.4].

Figure 5.2 shows the phase fluctuations of five simulated clocks having spectral densities of phase, $S_x(f) \sim f^\beta$ for $\beta = 0, -1, -2, -3$, and $-4$. $\beta = -5$ and $-6$ were not included since their variations would outscale the other series in the plot. Note that although the series in the figure show realizations of each power law independently a clock may consist of any or all of the processes simultaneously as per the sum in (5.11). These common clock pure power-law noises are often referred to as white phase noise (WHPH, $f^0$), flicker phase (FLPH, $f^{-1}$), random walk phase (RWPH, $f^{-2}$), flicker frequency (FLFR, $f^{-3}$), random walk frequency (RWFR, $f^{-4}$), flicker drift (FLDR, $f^{-5}$), and random walk drift (RWDR, $f^{-6}$). It is usually the case that one of the noise processes will dominate at a given Fourier frequency so that a plot of Fourier frequency $f$ versus the logarithm of spectral density of phase $S_x(f)$ would indicate the $\beta$ noise type that is dominant.

Several time-domain or time-averaged measures have been recommended by the IEEE for characterization of stability. The most well-known measure is the two-sample variance (or Allan variance) for quantify-

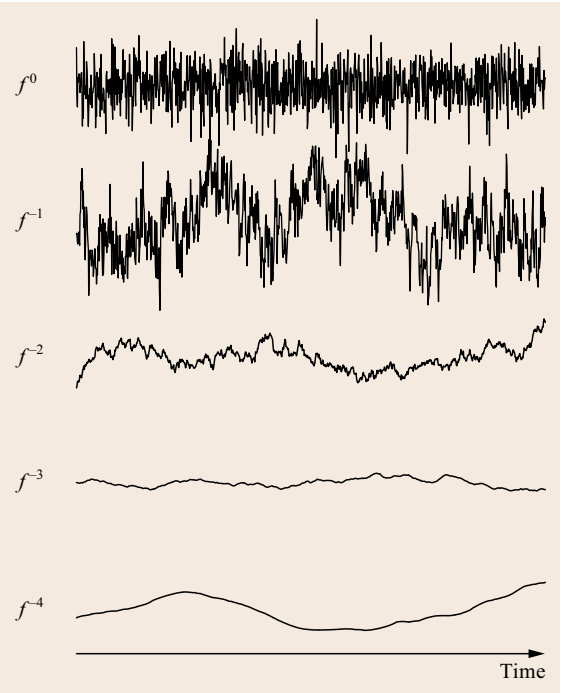

**Fig. 5.2** Example simulated realizations of phase (time) fluctuations of five random processes each having respectively from top to bottom spectral densities of phase, $S_x(f) \sim f^\beta$ for $\beta = 0, \ldots, -4$

ing frequency stability. It is defined as

$$\sigma_y^2(\tau) = \left\langle \frac{(\bar{y}_{k+1} - \bar{y}_k)^2}{2} \right\rangle , \tag{5.12}$$

where $\langle\cdot\rangle$ denotes infinite time average (or expectation) and where

$$\bar{y}_k = \frac{1}{\tau} \int_{t_k}^{t_k+\tau} y(t)\mathrm{d}t = \frac{x_{k+1} - x_k}{\tau}$$

is the average fractional frequency over the interval $\tau = t_{k+1} - t_k$. It is assumed in this definition that the average frequency values are adjacent, that is, no dead time exists between the phase measurement samples $x_k$. If dead time exists between the samples the resulting calculations will be biased such that the result is no longer considered the Allan variance. The Allan variance is insensitive to an overall systematic frequency or rate offset, $y_0$, because fractional frequency averages are differenced in (5.12).

The Allan variance is actually a special case ($N = 2$) of the more general classical $N$-sample variance,

$$\sigma_y^2(N, \tau) = \left\langle \frac{1}{N-1} \sum_{i=1}^{N} \left( \bar{y}_i - \sum_{j=1}^{N} \bar{y}_j \right)^2 \right\rangle , \tag{5.13}$$

which is an infinite time average of the variance of the $N$-sample mean of fractional frequency averages. One advantage of the two-sample variance over the $N$-sample variance is that (5.12) is a well-defined (finite) value for most of the power-law processes in (5.11) (namely for $\beta >= -4$). Expression (5.13), in contrast, diverges as $N \to \infty$ for $\beta < 0$ since it depends on the sample interval length $T$.

Another advantage of the Allan variance is that for power-law processes $\beta = 0, -1, \ldots, -4$ in (5.11) the Allan variance $\sigma_y^2(\tau)$ has a $\tau$-relationship similar to the relationship of $f$ to $S_x(f)$. In particular $\sigma_y^2(\tau) \sim |\tau|^\mu$, where $\mu = -3 - \beta$ for $\beta = -2, -3, -4$, while $\mu = -2$ for both $\beta = 0$ and $\beta = -1$. Thus on a log-log plot of $\tau$ versus $\sigma_y^2(\tau)$ the slope of the Allan variance curve can be used to indicate the type of noise dominant over that $\tau$ interval, except for the WHPH and FLPH noises, which have the same slope $\tau$-Allan variance relationship.

Although the definition of the Allan variance is based on infinite time averaging, a means of estimating it from only a finite portion of the clock's phase realization is required in practice. A common formula used to estimate (5.12) utilizing $N$ discrete samples of the average fractional frequency (or $M = N + 1$ phase samples) is

$$\sigma_y^2(\tau) \approx \frac{1}{2(N-1)} \sum_{i=1}^{N-1} (\bar{y}_{i+1} - \bar{y}_i)^2 \tag{5.14}$$

$$= \frac{1}{2(M-2)\tau^2} \sum_{i=1}^{M-2} (x_{i+2} - 2x_{i+1} + x_i)^2 . \tag{5.15}$$

An example clock realization of phase fluctuations is shown in Fig. 5.3, where $N+1$ measured phase samples are labeled and used to calculate the $N$ average frequencies for a given interval $\tau$. Confidence limits on the variance estimates of (5.14) and (5.12) must also be considered. As in the case of the spectral methods, the estimates obtained are highly dependent on the band-limiting elements of the measurement system. This includes the low-pass filter, which may not be specified as having a sharp cutoff frequency $f_h$, as assumed in the definition above [5.3].

Confidence limits can be improved by utilizing overlapping samples in the Allan variance calculation. However, the determination of confidence limits is

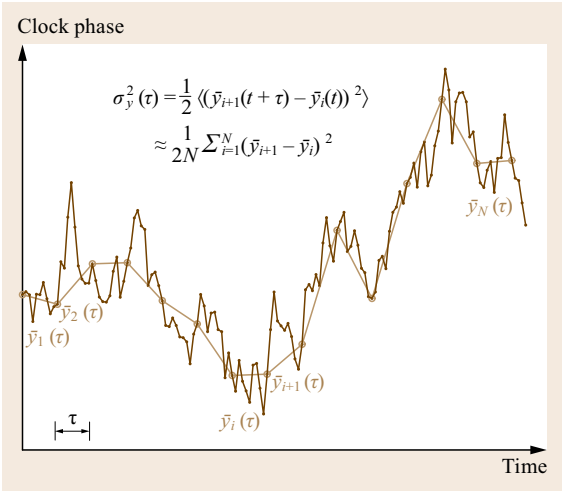

**Fig. 5.3** Example of estimating the two-sample (Allan) variance for a given discrete series of clock phase measurements

more complex in this case, since the overlapping fractional frequency samples are no longer independent as in the nonoverlapping case. An estimate of the Allan variance calculated using all possible overlapped $\bar{y}$ samples may be written as

$$\sigma_y^2(\tau) \approx \frac{1}{2m^2(N-2m+1)} \times \sum_{j=1}^{N-2m+1}\left[\sum_{i=j}^{j+m-1}(\bar{y}_{i+1} - \bar{y}_i)\right]^2 . \quad (5.16)$$

Most manufacturers of precision clocks or oscillators as well as timing laboratories now routinely publish their clock stability specifications or performances using the Allan variance (or its square root, the Allan deviation). While the Allan variance may be the most widely used measure of frequency stability there are situations where spectral measures might be preferred. The following formula shows the relationship between the Allan variance and spectral density of phase [5.4]

$$\sigma_y^2(\tau) = \int_0^\infty 2S_x(f)\sin^4(\pi\tau f)\mathrm{d}f . \quad (5.17)$$

It is valid for all (continuous) $\beta > -5$ and shows that the Allan variance has a very broad Fourier response to energies that are purely harmonic. In this case a spectral approach is preferred over the Allan variance as any such bright lines are more easily identified with frequency domain techniques.

Other time-domain measures of stability include the modified Allan variance, $\mathrm{mod}\,\sigma_y^2(\tau)$, and the Hadamard variance. The modified Allan variance was introduced in order to address the deficiency of the Allan variance in distinguishing between WHPH and FLPH noises. It does so by effectively varying the (software) bandwidth of the variance calculation to establish the additional $\tau$ sensitivity. The Hadamard variance provides yet another time domain measure that converges for all the power-law processes in (5.11) and is insensitive to both an overall systematic rate, $y_0$, as well as an overall systematic drift $D_0$. Definitions of these variances along with the approximating formulas may be found in [5.1] and [5.5]. Because frequency stability values are commonly expressed as either Allan or Hadamard variances the relationship between the spectral density of phase and these statistics is shown in Table 5.1 for several of the common noise types.

**Table 5.1** Relationship between the spectral density of phase $S_x(f)$, the Allan variance $\sigma_y^2(\tau)$, and the Hadamard variance $\mathrm{H}\sigma_y^2(\tau)$ for several common power-law noises

| Noise name | Spectral density of phase | Allan variance | Hadamard variance |
|---|---|---|---|
| WHPH | $g_0$ | $\tau^2\sigma_y^2(\tau)/(3f_\mathrm{h})$ | $3\tau^2\mathrm{H}\sigma_y^2(\tau)/(10f_\mathrm{h})$ |
| RWPH | $g_{-2}f^{-2}$ | $\tau\sigma_y^2(\tau)$ | $\tau\mathrm{H}\sigma_y^2(\tau)$ |
| RWFR | $g_{-4}f^{-4}$ | $3\sigma_y^2(\tau)/\tau$ | $6\mathrm{H}\sigma_y^2(\tau)/\tau$ |
| RWDR | $g_{-6}f^{-6}$ | $20\sigma_y^2(\tau)/\tau^3$ | $120\mathrm{H}\sigma_y^2(\tau)/(11\tau^3)$ |

## 5.2 Clock Technologies

As introduced in the previous section, clocks are based on oscillators that generate a periodic signal of a given frequency. The stability of this frequency and the resulting time count depends on the underlying physical principals and design properties and may vary widely between different classes of oscillators.

Key types of oscillators presented in this section include quartz crystal oscillators as well as cesium, rubidium, and hydrogen maser atomic clocks, which constitute the conventional atomic clock technology available today. An overview of the stability that can be expected from the different clock types is shown in Fig. 5.4.

### 5.2.1 Quartz Crystal Oscillators

The most common and ubiquitous oscillators available are those made with quartz crystals [5.8]. They are a basic form of harmonic oscillator beyond the simple electronic oscillators based on resistor-capacitor (RC) and inductor-capacitor (LC) circuits. Crystal oscillators are used in many forms of electronics and all GNSS receiving equipment operates with these devices to provide the necessary frequencies for radio frequency (RF) signal processing and to form an actual clock.

Quartz is a piezoelectric crystal material that can produce electrical signals by mechanical deformation of the material. Conversely, electrical signals can produce mechanical deformation [5.9]. Crystal oscillators have a higher quality factor (i. e., ratio of resonance frequency and resonance bandwidth) than the simpler RC and LC circuitry. They have better temperature stability but do use some of the same circuit designs as the LC oscillators with a quartz resonator replacing the tuned circuit portion. Other types of piezoelectric resonators use a surface acoustic waves (SAWs) mechanism, where the signals travel along the surface of the crystal material rather than the more traditional bulk acoustic wave (BAW) mechanism, in which the signals propagate through the crystal. Other types of physically mechanical oscillators are implemented with micro-electro-mechanical system (MEMS) techniques that use devices made from silicon processed through microelectronic fabrication techniques. The advantage in the MEMS devices is that they are simpler to manufacture and more compatible with modern microelectronic circuitry.

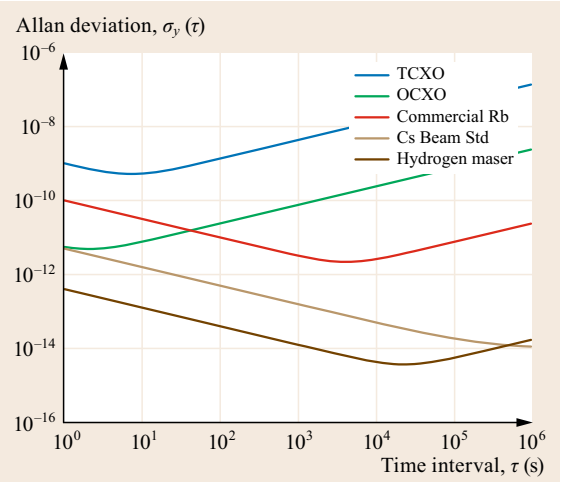

**Fig. 5.4** Performance of the classical microwave atomic frequency standards compared with temperature-compensated (TCXOs) and oven-controlled (OCXOs) crystal oscillators

Crystal resonators are available to cover frequencies from about 1 kHz to over 200 MHz. At the low frequency end, wristwatch and real-time clock applications operate at 32.768 kHz and powers of two times this frequency. The conventional BAW resonators range from 80 kHz to 200 MHz. The frequencies of SAW devices range from above 50 MHz to the low GHz range.

The quartz crystal material is comprised of silicon dioxide and can occur naturally or can be grown synthetically. Oscillators are cut from these crystals in a variety of shapes. The shape, size and orientation within the crystalline structure determines the mode of vibration, its resonant frequency and properties of the oscillator. A voltage applied to the crystal will cause it to vibrate and produce a steady signal dependent upon the way the crystal is cut [5.10]. The process of making a quartz oscillator is very involved and complicated requiring material selection, cutting, polishing, mounting electrical contacts and sealing within an vacuum enclosure. Examples of 5 MHz fifth overtone oscillators are shown in Fig. 5.5 without the vacuum enclosure surrounding the crystal. These crystals are mounted on the contacts that extend through the vacuum enclosure to the electrodes plated on the crystal itself.

The quality of a crystal oscillator is determined by its frequency accuracy, frequency stability, aging effects and environmental effects. The absolute frequency accuracy of a crystal oscillator is between $10^{-6}$ and $10^{-7}$ taking into account environmental effects such as temperature, mechanical shock and aging. Stability can range from $10^{-10}$ to $10^{-12}$ depending upon how protected the crystal is from environmental variations. Aging is defined as the slow change in frequency over a period of time that is associated with long-term changes in the crystal itself or more dominant effects

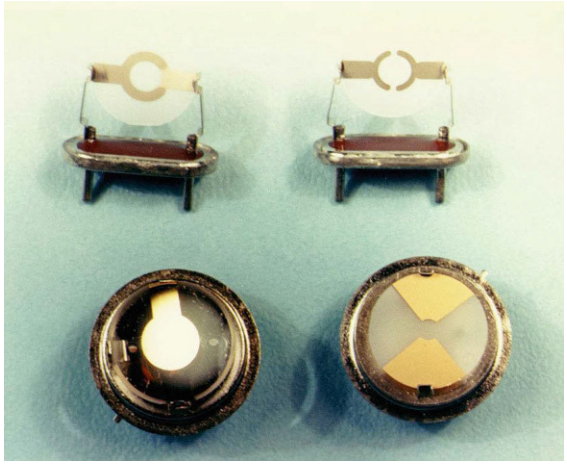

**Fig. 5.5** Mounted crystal oscillators with different electrodes. Image courtesy of NRL

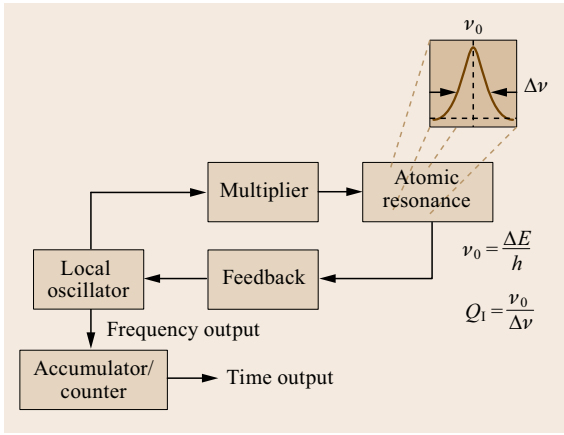

**Fig. 5.6** Generic atomic standard block diagram

such as redistribution of contamination within the vacuum enclosure, slow leaks, mounting and electrode stresses that are relieved with time, and changes in atmospheric pressure. Environmental effects usually have a direct effect on the crystal such as thermal transients, mechanical vibration, shock, radiation, turning the crystal over (tip-over), magnetic fields, voltage changes and variations in the amount of power dissipated in the crystal.

The types of crystal cuts and the method of mitigating the environmental effects on the crystal determines the category of the oscillator. Three configurations in most common use are the room-temperature crystal oscillator (RTXO), the temperature-compensated crystal oscillator (TCXO), and the oven-controlled crystal oscillator (OCXO). The RTXO typically uses a hermetically sealed crystal and individual components for the oscillator circuit. The TCXO encloses the crystal, temperature-compensating components and the oscillator circuit in a container. The OCXO adds heater elements and controls to the oscillator circuit and encloses all the temperature-sensitive components in a thermally insulated container [5.10].

The increased demand for small-scale electronics for cell phones, portable entertainment electronics and miniaturized portable computers has stimulated the development of small-scale quartz oscillators, tuning forks and MEMS oscillators fabricated in silicon. MEMS resonator vibration is based on electrostatic dynamics rather than piezoelectric properties and the MEMS components are micromachined from silicon. They are configured in different complicated shapes such as combs, beam webs, discs and the like that are surrounded by electrodes with transduced gaps on the order of less than 1 μm. All silicon MEMS resonators can be very small and rugged. They are intended for use in integrated circuits at higher frequencies [5.11].

## 5.2.2 Conventional Atomic Standards

Conventional atomic frequency standard designs are passive devices that are functionally illustrated in Fig. 5.6. The basic principle is to coherently excite transitions between two energy levels in the atom selected and detect that the transition has occurred. The frequency of the atomic transition is

$$\nu = \frac{E_2 - E_1}{h} , \tag{5.18}$$

where $E_1$ and $E_2$ are the energy levels of the atom and $h$ is Planck's constant. An important characteristic of the selected transition is the line quality factor

$$Q_l = \frac{\nu}{\Delta\nu} , \tag{5.19}$$

where $\Delta\nu$ is the line width of the transition. The physics unit generating the precise clock signal incorporates a local oscillator to generate the atomic interrogation signal for the atomic transition and produce the stable output signal locked to the response to that signal. These devices are generally called passive devices because the atomic resonance portion does not actually oscillate but is interrogated with a signal that is modified by the atomic transition to the highly stable, or accurate, signal desired. The interrogation signal is produced by a local oscillator that is typically a quartz crystal oscillator frequency locked to the interrogation signal. The local oscillator may itself be an atomic clock used in a hybrid configuration. Selection or development of the local oscillator can be a significant item in itself.

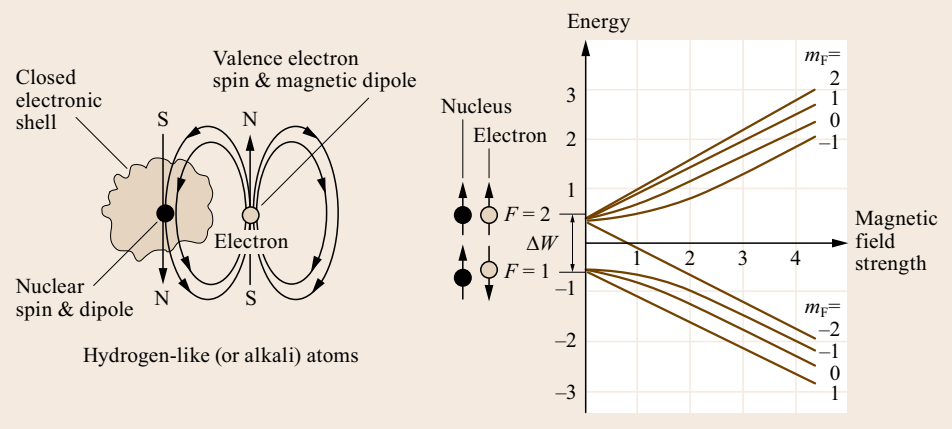

**Fig. 5.7** Hyperfine structure of Rb87 with Zeeman splitting

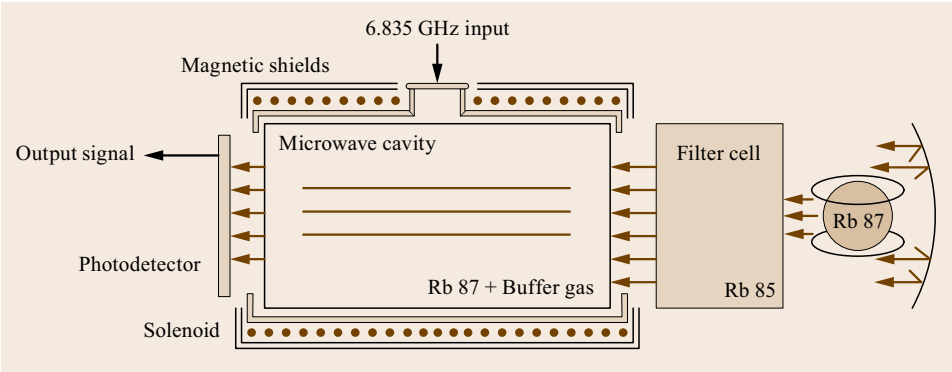

**Fig. 5.8** Rubidium gas cell resonator

### Rubidium Frequency Standards

Rubidium gas cell standards are the most commonly produced commercial atomic clocks. They are small, consuming relatively low power and are inexpensive in general. They are widely used in the telecommunications industry as frequency references for cellular telephone systems. They are also often found as internal frequency standards in laboratory instrumentation such as frequency counters, signal generators, and signal analyzers. Rubidium clocks were the first atomic clocks used in orbiting spacecraft and have become the primary clock technology used in the GPS satellites.

The rubidium transition used is the hyperfine ground state of Rb87. The hyperfine structure is illustrated in Fig. 5.7. $F$ is the total angular momentum of the Rb87 atom and $m_F$ is the quantized projection of $F$ along a magnetic field. A transition between the two allowed energy states of $F$ (which is reversing the spin of the valence electron) releases or absorbs an energy difference known as the hyperfine frequency of the ground state.

The atomic resonator shown Fig. 5.8 is an optically pumped device consisting of a series of glass cells containing small amounts of rubidium in gaseous suspension. The state of the rubidium atoms in the resonance cell are selected using light from an Rb87 lamp, which is filtered through a cell containing Rb85. The resonance cell also contains a buffer gas, typically nitrogen and argon or xenon, to hold the rubidium in suspension and to minimize interactions of the rubidium with the cell walls. The lamp is excited to a plasma with radio frequency (RF) energy creating the full set of Rb87 spectral lines. Only one of these lines is desired for interrogating the Rb87 atoms in the resonance cell. The Rb85 filter cell eliminates most of the unwanted spectral light, allowing a higher signal-to-noise ratio (SNR) at the photodetector. The Rb87 atoms in the resonance cell are at a controlled temperature and magnetic field to minimize environmental effects. The resonance cell is contained in a microwave cavity that creates a uniform RF field in the cell. The nominal frequency of the microwave cavity is about 6.834682611 GHz [5.12].

The overall design of a typical rubidium clock is shown in Fig. 5.9. When the 6.834682611 GHz signal is applied to the microwave cavity in the atomic resonator the level of the spectral light transmitted through the resonance cell is affected depending on how close the signal is to the inherent resonance of the Rb87 atoms.

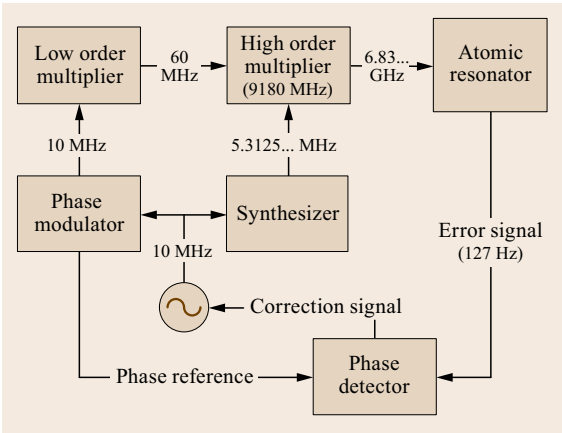

**Fig. 5.9** Generic rubidium standard block diagram

An on-resonance signal will cause a decrease in the level of light transmitted through the resonance cell due to the absorption of the spectra. The microwave cavity signal is then modulated at about 127 Hz about the resonance so that the output of the photodetector provides an output signal proportional to the amount of light reaching it. This output signal is used as an error signal for the feedback loop, which adjusts the frequency of the crystal oscillator to minimize the error. The actual output signal is produced by the local oscillator.

This atomic interrogation technique is known as intensity optical pumping (IOP). Another optical technique employing lasers has been developed, known as coherent population trapping (CPT), which has been applied to Rb and Cs gas cell oscillators in smaller physical packages resulting in so-called miniature atomic clocks. This technique and its application to miniature clocks will be discussed later (Sect. 5.2.4).

Rubidium clocks based on the classic IOP design are considered to be secondary frequency standards because their inherent accuracy is significantly affected by the environment and the nature of the gas cell. These effects lead to environmental sensitivity and frequency drift. While rubidium clocks can be set on frequency very precisely, frequency drift rates exceeding $10^{-11}$/month reduce absolute accuracy to some parts in $10^{-9}$. Gas cell clocks of similar design can also be made using cesium or conceivably other alkali metals. However, using other atoms does not change the basic nature of the clock and does not make them primary standards for the reasons discussed in the next section.

### Cesium Beam Frequency Standards

Cesium beam frequency standards are commercially available clocks and have been widely used for timekeeping and precise frequency generation, particularly in the telecommunications industry where they are used for clocking high-rate data streams. They are inherently much more accurate in frequency than rubidium clocks with accuracies as good as $5 \cdot 10^{-13}$. They also have an inherently very low frequency drift and reduced sensitivity to environmental effects, although the associated electronics in the units may be somewhat affected by environmental conditions, primarily temperature. Specially built cesium beam clocks with large long tubes designed for high accuracy have also been used as primary laboratory standards. Considering the small frequency shifts and the accuracy that can be maintained by a cesium beam frequency standard it is the most accurate device that is easily and commercially available.

The hyperfine frequency of the cesium atom in its ground state is the atomic transition used by these cesium standards. The ground state of Cs133 is the interaction between the hyperfine $F = 3$ and $F = 4$ energy levels. When a magnetic field is applied, the energy levels are divided into sublevels identified by their magnetic quantum number $m_F$. The frequency of the interaction $F = 3$, $m_F = 0$ to $F = 4$, $m_F = 0$ is the Cs hyperfine frequency, $\nu_{\mathrm{hf}} = 9.192631770\,\mathrm{MHz}$.

Because of the increased accuracy available from widely available commercial devices and the primary laboratory standards built for increased accuracy, the atomic second was adopted in 1967 as the basis of time in the Système International (SI) [5.13]. In continuity with previous timescales, the SI second has been defined as [5.14]:

> *[. . . ] the duration of 9192631770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium 133 atom.*

Equivalently, the hyperfine frequency of the cesium atom's ground state amounts to exactly 9 192 631 770 Hz.

The commercial cesium beam tube, Fig. 5.10, is an atomic thermal beam device [5.15, 16]. The frequency $\nu$ of the hyperfine transition has a second-order dependence on the applied magnetic field ($B$ in Teslas) of

$$\nu = \nu_{\mathrm{hf}} + 4.27 \cdot 10^{10}\,\mathrm{Hz} \cdot B^2 \,.$$

In operation, a cesium reservoir at one end of the sealed vacuum enclosure is heated to about 100 °C to produce a small stream of cesium atoms that is collimated into a beam. To limit the atoms in the beam to the useful energy levels, the desired energy states are magnetically selected and atoms in an undesired state are deflected out of the beam. The remaining atoms pass through a two-armed interrogation cavity known as a Ramsey cavity, where they are exposed twice to a microwave field. Here, the atoms change the ground state if the

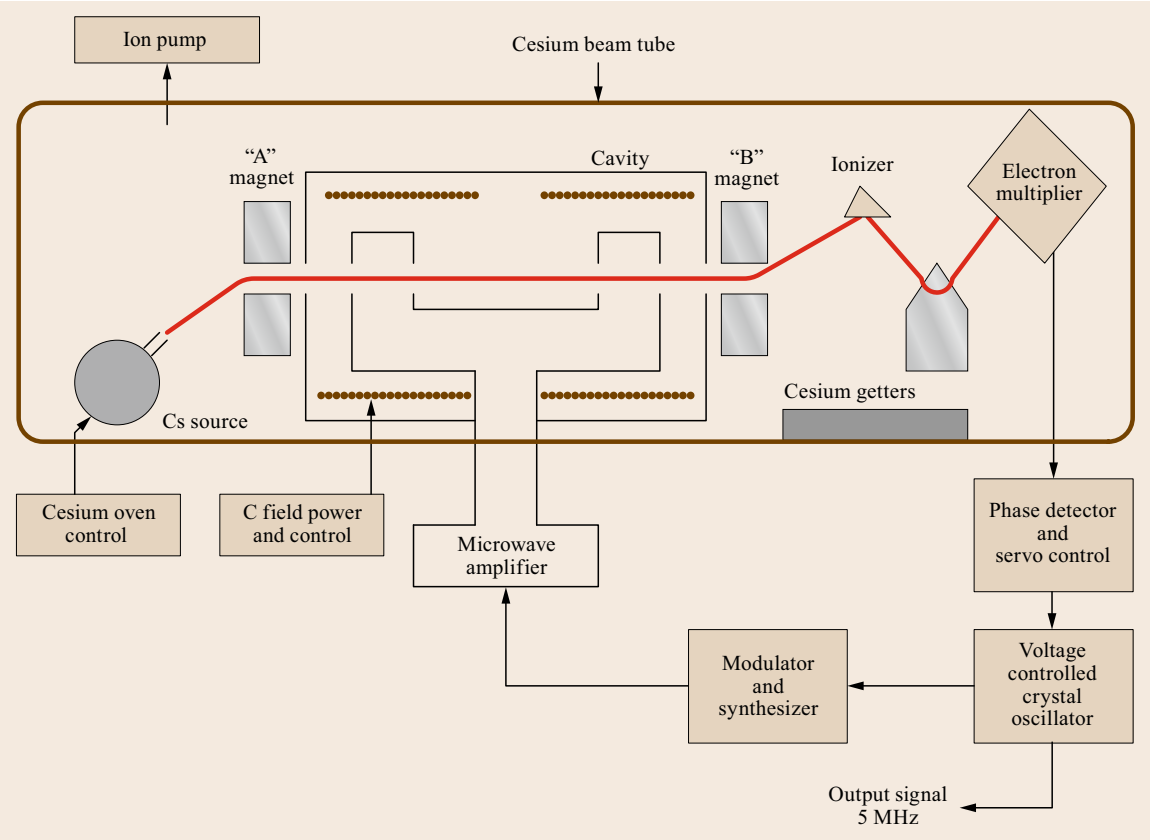

**Fig. 5.10** Cesium beam tube diagram

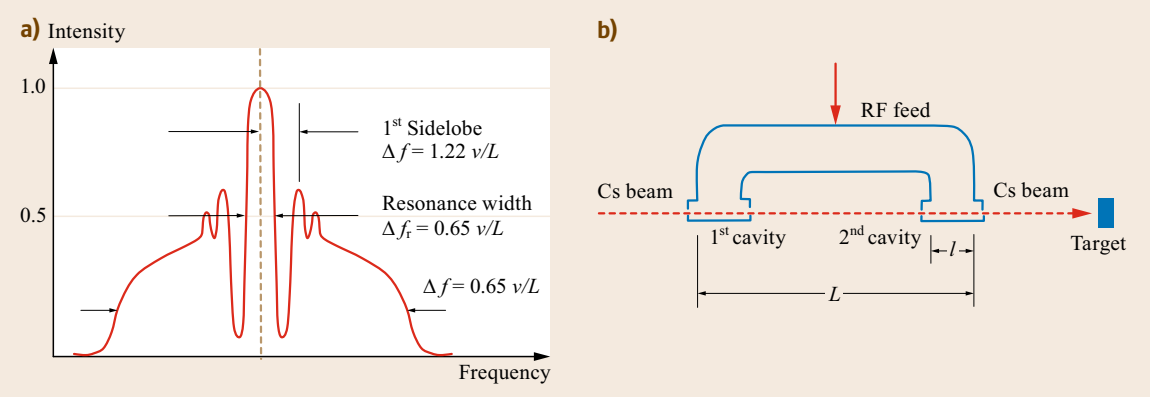

**Fig. 5.11a,b** Relation between the Ramsey pattern (**a**) and the dimensions $L$ and $l$ of the cavity (**b**). $v$ denotes the velocity of atoms in the cesium beam

probing frequency matches the Cs hyperfine frequency. After leaving the cavity, the beam of cesium atoms passes through another magnetic state selector where atoms in the desired state are routed to a detector. Beam current from the electron multiplier is maximized when exactly the right microwave signal is present.

When varying the probing frequency around the nominal value, a resonance pattern with a line width inversely proportional to the cavity length is obtained. The structure of this *Ramsey* pattern is illustrated in Fig. 5.11. Since the slope of the change in frequency is zero at the peak, the direct measurement of the

resonance frequency from the Ramsey pattern is not suitable for a precise determination. Consequently, the microwave frequency is phase- or frequency-modulated so that an error signal can be generated by synchronous demodulation of the detector response. The frequency stability of the cesium beam standard then depends upon factors such as the modulation used in the microwave interrogation cavity and the frequency locking scheme. A generic block diagram of a cesium standard is illustrated in Fig. 5.12.

The frequency stability is approximately given by

$$\sigma_y(\tau) = \frac{K_{\mathrm{Cs}}}{Q_{\mathrm{l}} \cdot \left(\frac{S}{N}\right) \cdot \tau^{1/2}} , \qquad (5.20)$$

where $Q_{\mathrm{l}} = \nu/\Delta\nu$ is the line quality factor, $S/N$ is the signal-to-noise ratio of the detected signal (the noise is mostly shot noise at the detector) and $K_{\mathrm{Cs}}$ is a factor dependent upon the modulation used but close to unity. In a typical, well-built laboratory primary standard a stability of $5 \cdot 10^{-12}\,\mathrm{s}^{1/2}/\tau^{1/2}$ over a range extending to 40 days has been measured.

Commercial cesium beam devices are widely available and in use today. However, the wide availability of GNSS timing receivers used to distribute precise time, their superior performance especially coupled with a rubidium clock and most notably their low cost has impacted the cesium frequency standard market. At this time, technology for primary laboratory and precision timekeeping devices has moved into cold atom technology applied to so-called fountain clocks, which will be discussed in Sect. 5.2.3.

### Hydrogen Maser Frequency Standards

Hydrogen masers are the most stable frequency standards commercially available for use in laboratory and ground station environments. They have been developed for scientific, timekeeping and GNSS applications. There are two basic designs of hydrogen masers in use, the active maser where the maser cavity actually oscillates and produces a signal actively [5.17, 18], and the passive maser whose cavity is passively interrogated in a similar manner to the rubidium and cesium devices just discussed [5.19]. A third design of hydrogen maser known as the Q-enhanced maser [5.20] that can operate in either mode is briefly presented in Sect. 5.3.3.

The hydrogen maser operates at the ground state between the two hyperfine levels of atomic hydrogen ($F = 1$, $m_F = 0$ to $F = 0$, $m_F = 0$) at the ground state hyperfine frequency, $\nu_{\mathrm{hf}}$, of 1420.405752 MHz. The hyperfine energy levels of atomic hydrogen are shown in Fig. 5.13. The transition frequency depends on the magnetic field $B$ (expressed in Teslas) and amounts to

$$\nu = \nu_{\mathrm{hf}} + 1399.08 \cdot 10^7\,\mathrm{Hz} \cdot B^2 . \qquad (5.21)$$

At room temperature the population of hydrogen atoms is nearly evenly distributed between four magnetic hyperfine levels designated by $F = 1$, $m_F = 1, 0, -1$ and $F = 0$, $m_F = 0$. These energy levels depend on the relative orientation of the magnetic dipoles associated with the proton and the electron when the atom is in a magnetic field. In the upper level, designated as $F = 1$, the angular momenta of the proton and electron are aligned and added. Their magnetic dipoles are also aligned. In this state the total angular momentum can orient itself with a magnetic field in three different directions and the $F = 1$ energy level splits into three components. The $F = 0$ energy level results from the alignment of protons and electrons that cancel their total angular momentum and their magnetic dipoles oppose each other.

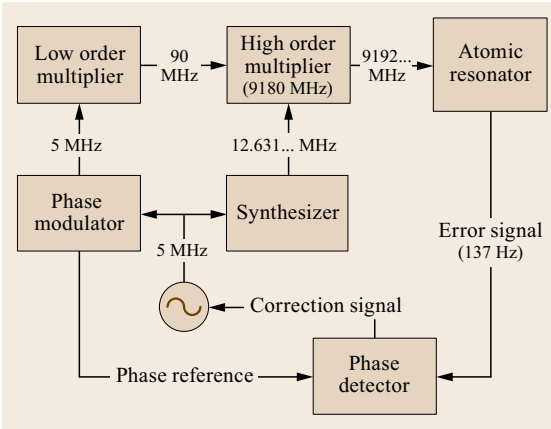

**Fig. 5.12** Generic cesium beam standard block diagram

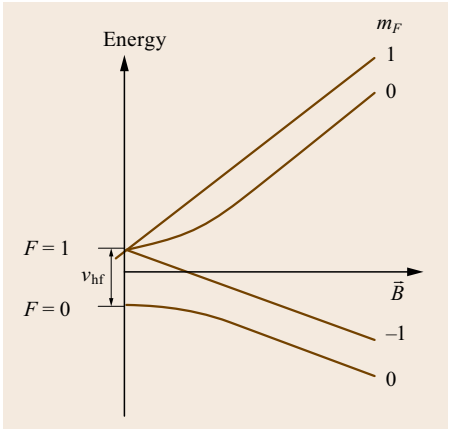

**Fig. 5.13** Energy levels of atomic hydrogen

Figure 5.14 shows a schematic diagram of an active hydrogen maser. Molecular hydrogen at a pressure of about 0.1 Torr is dissociated into atomic hydrogen by an RF plasma discharge and collimated into a beam. Atoms in two of the upper magnetic hyperfine energy levels ($F = 1$, $m_F = 1$, and 0) are selected by passing through a highly inhomogeneous magnetic field generated by a multipole permanent magnet, which causes them to move toward the weak field near the axis of the magnet. These atoms are focused into a storage bulb located in a resonant microwave cavity tuned to the atomic hydrogen hyperfine frequency. The storage volume confines the atoms to a region where the oscillating magnetic field is in the same phase.

As the atoms proceed from the multipole magnet into the cavity bulb, the magnetic field they encounter changes from about 9 kGauss radially in the magnet to about one Gauss along the axis of the beam. In this drift region the atoms remain in the $F = 1$, $m_F = 1$, and 0 state and will be kept in these states along the drift region, if the magnetic field they encounter is reduced to the level of the field in the resonator without sudden interruption or change in direction.

A very important feature of an active hydrogen maser is the monomolecular Teflon surface coating in the storage bulb that enables its operation as an oscillator with a narrow resonance line width. This is achieved by storing the atoms without appreciable loss of phase coherence from collisions with the wall surfaces or each other.

The frequency of the $F = 1, m_F = 0$ to $F = 0, m_F = 0$ transition that powers the oscillator depends on the magnetic field. To avoid frequency shifts from changes in the magnetic field, hydrogen masers are operated at low magnetic fields. To maintain these low fields and provide a spatially uniform field, with variation at the micro-Gauss level throughout the bulb, magnetic shields are placed about the resonator to attenuate the outside magnetic field, and a solenoid is placed within the innermost shield to provide a uniform and controllable field.

Maser oscillation is sustained when the energy released by the incoming atoms resulting from stimulated emission of the microwave fields in the resonator exceeds the energy lost by the resonator. The energy loss includes the signal delivered to the receiver though a pickup loop in the microwave cavity that is mixed and compared to a signal from the local oscillator to produce the final output signal.

The fundamental stability limit for the maser is similar to other oscillators and is given as

$$\sigma_y(\tau) = \frac{1}{Q_l}\sqrt{\frac{kT}{2P\tau}}\,, \tag{5.22}$$

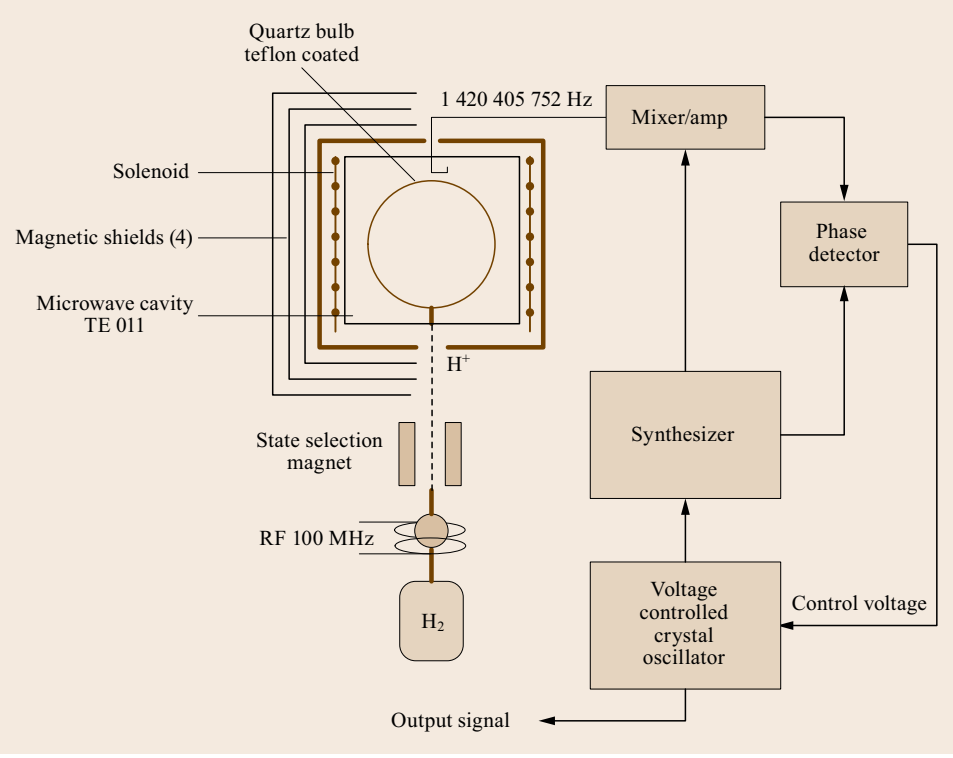

**Fig. 5.14** Active hydrogen maser schematic

where $Q_l$ is the line quality factor of the maser operating at a power level $P$, $k$ is Boltzmann's constant, and $T$ is the absolute temperature. This expression then implies high values for $Q_l$ and power. However, high power also promotes increased interatomic collisions. Consequently masers typically operate with low power in which the signal-to-noise ratio of the receiver of the maser signal has a significant effect on the short-term stability (at $\tau < 100$ s).

A typical active maser uses a microwave cavity resonator operating in the $TE_{011}$ mode. Without appreciable dielectric loading by the bulb, the resonator's dimensions are of a cylinder of 28 cm in diameter and height. These dimensions result in a storage bulb of two to three liters in size and a considerable large size to the overall maser with the levels of magnetic shielding and vacuum enclosure required. A reduced resonator size has been achieved by using dielectrically loaded cavities. In active mode, these smaller resonators tend to suffer larger thermal variations in resonance frequency due to the properties of the dielectric material used for loading the cavity and therefore require more thermal control than the unloaded resonators. However, used in the passive mode a considerable size reduction can be achieved. In those cases magnetron cavity designs have achieved a small resonator size with sufficient line $Q_l$ for maser operation.

The smaller resonators using lumped capacitance loading to reduce dimensions are used in passive hydrogen maser and Q-enhanced hydrogen maser designs. Among others this type of resonator is used in the Russian Ch-176 hydrogen maser, some masers built by the Sigma-Tau Standards Corporation and in the small Q-enhanced spaceborne masers developed at the Hughes corporation for the US Naval Research Laboratory.

The use of a cavity loaded with dielectric material enables a smaller size of the cavity resonator, and is thus an important means for reducing the overall size of a hydrogen maser. However, the penalty is that the cavity $Q_l$ will be lower and may be beneath the self-oscillating limit. Therefore the maser can be operated in the passive mode with two coupling loops whereby one injects a microwave signal into the cavity at the hyperfine frequency and another is used to detect the amplified signal. The energy from the injected signal causes stimulated emission of the atoms in the cavity. These smaller designs usually operate in the passive mode rather than the active mode just described.

A generic passive hydrogen maser design using a probe signal with two modulated frequencies is illustrated in Fig. 5.15. Here, the maser cavity is interrogated with a probe signal that is phase modulated at two different frequencies, $f_1$ that corresponds to the nom-

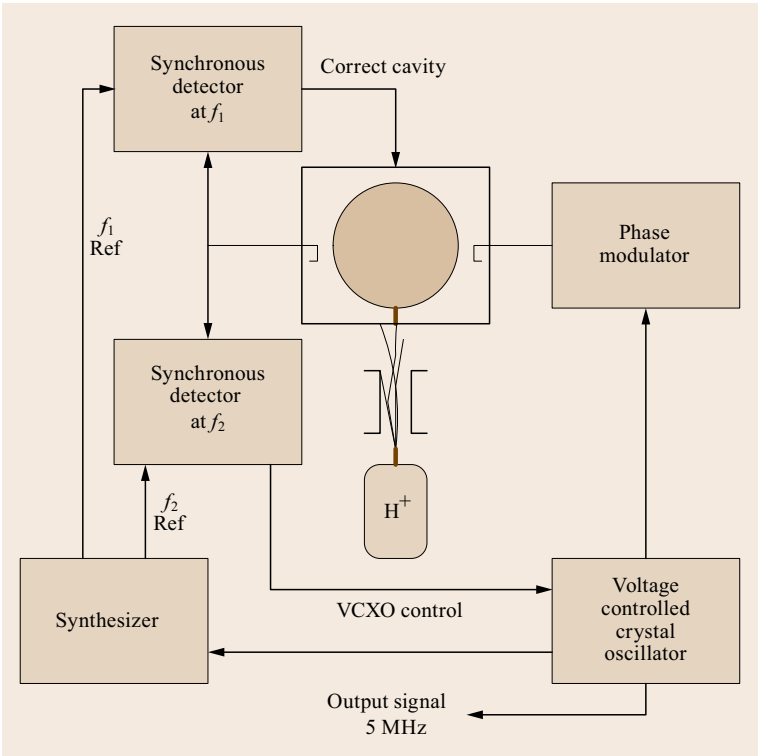

**Fig. 5.15** Passive hydrogen maser schematic

inal half-width of the microwave cavity, and $f_2$ that corresponds to the nominal half-width of the hydrogen resonance. This phase-modulated probe signal is then coupled to the microwave cavity containing atomic hydrogen appropriately state selected. In the resulting spectrum the $f_2$ sidebands primarily interact with the narrow hydrogen line while the $f_1$ sidebands primarily interact with the broad cavity resonance. The signal transmitted from the cavity is amplitude modulated at frequencies $f_1$ and $f_2$. The size and sign of the amplitude modulation at $f_2$ relative to the impressed phase modulation is proportional to the frequency offset between the probe oscillator and the center of the hydrogen line. The microwave signal is envelope detected to recover the $f_2$ amplitude modulation, which is then processed in a synchronous or phase-sensitive detector reference to the $f_2$ phase modulation. The resulting error signal is used to correct the probe oscillator so that it is precisely centered on the hydrogen line.

Similarly, the $f_1$ phase modulation simultaneously probes the cavity resonance causing amplitude modulation of the transmitted microwave signal at $f_1$, which is proportional to the detuning of the microwave cavity from the center of the probe frequency. The error signal produced from the $f_1$ amplitude modulation in a synchronous detector is used to tune the microwave cavity to the probe frequency. This cavity servo technique then effectively stabilizes the mechanical dimensions of the cavity to reduce the effects of the environment, primarily temperature. Consequently, the maser cavity is environmentally stabilized and the interrogation frequency produced by the local voltage-controlled crystal oscillator (VCXO) is locked to the hydrogen resonance. The stability for this type of maser in the short term is not as good as the active maser due to the control servos however in the long term they approach similar performance.

### 5.2.3 Timescale Atomic Standards

Commercial cesium clocks are still the most prevalent standard for timekeeping in other than national timekeeping centers. Second is the active hydrogen maser that is in limited commercial availability. Both of these commercial devices are expensive with the hydrogen masers being about an order of magnitude more expensive than the cesium. The capability of GNSS timing receivers to disseminate time is increasing and many systems are using them to replace precise frequency and time standards as reference standards in timing applications (Chap. 41).

Within national timing centers, such as the National Institute of Standards and Technology (NIST) in the United States [5.21], the laser cooled cesium fountain has largely replaced the large thermal beam standards that were used as primary standards for determination of the SI second and contribution to the international atomic time scale. Unlike these other standards, cesium fountain clocks are not commercially available so that each center has built their own version. A number of different cesium fountain clocks are now in use throughout the world [5.22, 23] and in 2012 some 21 timing centers used cesium fountain clocks as their primary frequency standard. These primary standards serve as the metrologic reference and their performance is therefore determined by comparison and coordination with the Bureau International des Poids et Mesures (BIPM) [5.24].

The atomic fountain was first proposed and attempted by Jerrold Zacharias [5.23]. The original objective was to increase the interrogation time of a particular transition in the atoms beyond that possible in a thermal beam device by the use of gravity. If the atoms are launched upward through the same interaction region twice, the Ramsey fringes are produced with a resolution determined by the time between the two interactions. This significantly reduces the sources of errors since the same cavity would be used for both interactions. The design of fountain clocks has become practical through the use of laser cooling of trapped neutral alkali metals with atomic transitions in the microwave range, such as cesium and rubidium.

The development of the magneto-optical trap (MOT) provided the ideal method for trapping a number of neutral atoms and cooling them with laser radiation to within a few hundred micro-Kelvin of absolute zero [5.25]. The balls of cold atoms collected in the MOT could then be launched by the trapping lasers without significant heating and light shifts. This process is illustrated in Fig. 5.16. The atoms in a MOT are confined through the combination of laser field and magnetic field gradients, which can collect large samples of cold neutral atoms from background vapors or atomic beams. The trap geometry contains three intersecting orthogonal pairs of counter-propagating laser beams tuned just below a strong cycling transition in alkaline-earth and alkaline-earth-like atoms. The trapping region produces a three-dimensional optical molasses, so-called because the trap always provides a net force opposing the atom's propagation direction. The addition of a quadrupole magnetic field supplied by a pair of anti-Helmholtz coils forces the atoms toward the center of the trap. Millions of atoms can then be collected in a fraction of a second with an atomic temperature of approximately 1 mK.

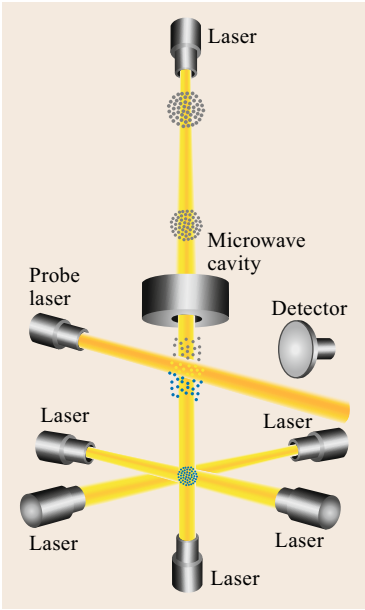

**Fig. 5.16** Cesium fountain conceptual diagram (after [5.26]). Image courtesy of NIST

Atomic fountain clocks are based on this concept of laser cooling a collection of atoms to near absolute zero so that these atoms in a nearly-unperturbed neutral atomic state may be interrogated at the ground state hyperfine frequency [5.27]. Although the balls of atoms launched from the MOT contributing to the signal may have a comparatively small number of atoms, on the order of $10^3$ to $10^6$, the line quality factor $Q_l$ is so large that a gain in frequency stability is obtained over the conventional thermal beam approach. It is shown that the frequency stability is given by the Allan deviation as

$$\sigma_y(\tau) = \frac{1}{\pi Q_l} \frac{\sigma(\Delta N)}{N} \sqrt{\frac{T}{\tau}}\,, \tag{5.23}$$

where $\sigma(\Delta N)$ is a variance measure of the fluctuations of the number of atoms from ball to ball, $N$ is the average number of atoms in the balls and $T$ is the cycle duration. In practice it is found that $\sigma_y(\tau)$ is about $3 \cdot 10^{-13}\,\mathrm{s}^{1/2}/\tau^{1/2}$, which is in agreement with the expression above.

Development of this technology has been facilitated by the availability of the appropriate lasers for the MOT and interrogation lasers. Diode lasers are the lasers of choice for use in fountain clocks and it is expected that there will be a significant synergy between cold atom development and space technology. The launch and operation of the Atomic Clock Ensemble in Space (ACES) experiment, which incorporates a cold atom cesium clock with a passive hydrogen maser, will demonstrate the potential of this type of laser-cooled standard in space [5.28].

### 5.2.4 Small Atomic Clock Technology

The capability of manufacturing very small or miniature atomic clocks was greatly enhanced by the development of a technique known as Coherent Population Trapping (CPT) [5.29]. It makes use of lasers for the optical pumping of clock transitions and been successfully employed with both Rb and Cs. Similar in concept to the classical Rb standard gas cell design, the spectral lamp is replaced by a diode laser at the required $D_1$ and $D_2$ wavelengths for Rb of 780 nm and 794 nm, or for Cs at 852 nm and 894 nm. Using diode lasers, the spectrum is much narrower than that produced by the spectral lamp, which improves the pumping efficiency. If the laser signal is modulated to produce two coherent signals at the wavelengths of the optical transitions corresponding to the levels $F = 2$ and $F = 1$ in the case of Rb a new phenomenon takes place. Coherent population optical pumping at the exact resonances with the optical transitions creates an interference resulting in the absence of the absorption of radiation.

The transition energy levels are illustrated in Fig. 5.17. The atoms are trapped in the ground state and find themselves in a nonabsorbing coherent superposition of the two hyperfine ground states. The atomic medium then becomes transparent at the exact resonance of the optical transition. The transmission of the cell increases at resonance and if the frequency of the laser signals is slowly swept, a resonance signal is observed at the photodetector. The shape of the signal is similar to the signals observed in the classical passive Rb standard described above.

In practice, the two laser signals may be obtained from a single laser modulated in frequency at a submultiple of the hyperfine frequency. The highly correlated sidebands created are used to provide the resonance signals. The technique may be used to implement a passive standard in either using the transmission (bright line) or the fluorescence (dark line).

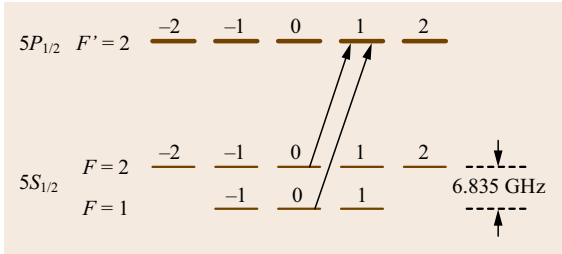

**Fig. 5.17** The Rubidium CPT transition energy levels diagram

A microwave cavity is not needed since no microwave signals are required to excite transitions within the ground state. The design of a passive device is shown in Fig. 5.18.

The frequency stability of the CPT passive standard is expressed as approximately the same as that of the intensity optical pumped standard [5.29]

$$\sigma_y(\tau) = \frac{K}{4\,\nu_{\mathrm{hf}}\,q}\sqrt{\frac{e}{I_{\mathrm{bg}}\,\tau}}\,. \tag{5.24}$$

Here $K$ is a constant depending upon the type of modulation used and is of the order of 0.2, $e$ is the charge of the electron, $I_{\mathrm{bg}}$ is the background current created by the residual transmitted light reaching the photodetector, $\tau$ is the averaging time and $q$ is a quality figure defined as the ratio of the contrast $C$ to the line width. The contrast is defined as the CPT signal intensity divided by the background intensity.

The lack of requiring a microwave cavity facilitates the design of miniaturized atomic clocks down to a size limit determined by the laser and its corresponding performance limitations. The application of the CPT technique to cesium has resulted in a commercial product known as the chip scale atomic clock (CSAC) [5.30]. Preproduction units of the CSAC have demonstrated a stability of better than $3\cdot10^{-10}\,\mathrm{s}^{1/2}/\tau^{1/2}$ at timescales of at least 1–100 s [5.30]. When used in GNSS receivers, the improved stability helps to reduce phase noise, allows clock coasting during periods of reduced satellite visibility, and supports a faster time-to-first-fix (Chap. 13). Use of a stable atomic clock such as the CSAC inside a GNSS receiver has also been demonstrated as a technique for mitigating wideband radio frequency interference generated by GNSS jamming devices [5.31].

### 5.2.5 Developing Clock Technologies

Microwave standards are a mature technology and still have good potential for further significant improvements. For instance, a juggling rubidium fountain clock that launches multiple balls of atoms in rapid succession could greatly improve the SNR and result in short-term fractional frequency stability in the high $10^{-15}$s at one second while still maintaining excellent long-term systematics well below $10^{-16}$. This stability requires a local oscillator with better performance than an OCXO. The Time and Frequency Group at the Jet Propulsion Lab (JPL) in Pasadena has built a cryogenically cooled sapphire-loaded ruby oscillator that achieves $3\cdot10^{-15}$ performance from 1–1000 s, thus meeting the local oscillator requirements for an advanced fountain [5.32]. It is possible that further refinements to the fountain concept could bring that device into the low $10^{-15}$s at a second.

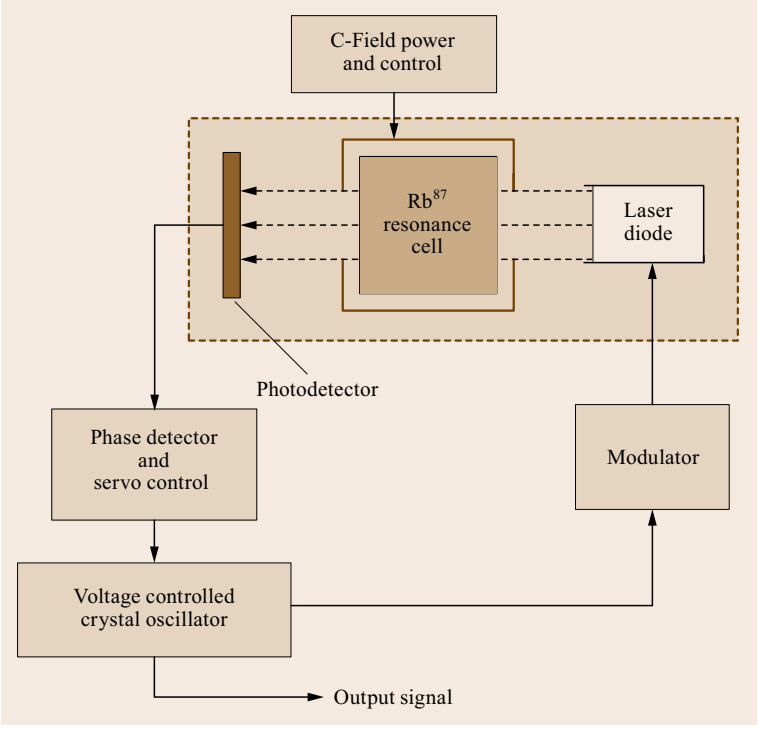

**Fig. 5.18** Passive CPT rubidium clock

Laser-cooled microwave ion standards are expected to have an exceptional long-term systematic noise floor. It is likely that the main limitation will be magnetic field sensitivity, which is largely an engineering problem of providing good shielding while still maintaining good optical access. However, while the systematic floor is likely to be in the low $10^{-17}$s, the short-term stability is probably limited to the low $10^{-13}$s due to the low signal-to-noise ratio inherent in a device with only a few ions. As a result, a microwave laser-cooled ion trap device is unlikely to meet the stated goals.

Buffer-gas-cooled ion standards have already demonstrated a stability of $3 \cdot 10^{-14}$ at one second [5.33]. These devices have large signals (many ions) but only a moderate SNR due to large background signals. A factor of 3–10 improvement in SNR could be achieved with better detection schemes to reduce background. This almost certainly means using lasers instead of lamps as is the current practice. One of these ion standards coupled with an advanced local oscillator (such as the cryogenically-cooled oscillator already discussed) could get close to the short-term stability goal, but the systematic floor is unlikely to be below $10^{-16}$ (larger numbers of ions at higher temperatures means both exposure to higher RF fields and larger Doppler shifts). Nevertheless, this type of approach should not be dismissed too quickly, since this frequency stability still allows several picoseconds (ps) timing stability at one day. The buffer-gas-cooled ion standard with laser interrogation would require the fewest technological advances and would be the simplest to implement.

The next step in atomic clock evolution is to move from microwave clock frequencies to optical frequencies [5.34–36]. With frequencies measured in the $10^{15}$ Hz range instead of $10^{10}$ Hz, optical clocks have a potentially huge gain in line quality factor $Q$. Since short-term stability is inversely proportional to $Q$, it also improves. An ion trap clock based on an optical transition then combines very good short-term stability due to the high $Q$ of the optical transition with an exceptionally low systematic noise floor. An optical clock is shown schematically in Fig. 5.19.

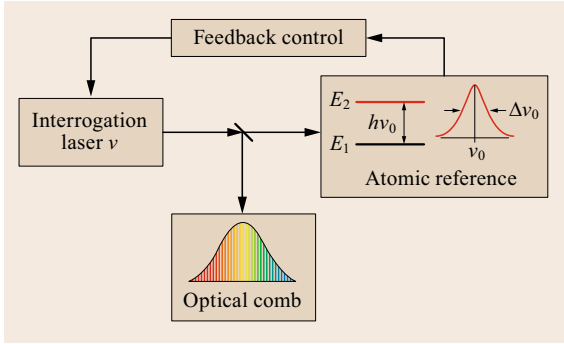

**Fig. 5.19** Diagram of optical clock

The two technologies that are critical to optical clock progress are the optical comb and laser frequency stabilization. The optical comb (also known as the frequency comb) enables the coherent translation from optical frequencies to microwave frequencies where timing information is usually used, transferred and analyzed. This is a huge step for optical clocks, since previous chains linking optical to microwave frequencies required man-years of highly skilled work and large amounts of equipment to build and maintain. The second critical technology is laser frequency stabilization. To take full advantage of the optical line quality factor, the clock laser, which is now the local oscillator for this clock, must have a frequency uncertainty on the order of 1 Hz or less. This is difficult to achieve but offers great potential for future development of clock technology.

## 5.3 Space-Qualified Atomic Standards

The development of space-qualified atomic clocks has its origin in the navigation satellite concepts of the late 1960s and early 1970s. The Transit Doppler navigation system [5.37] first demonstrated the potential of worldwide high-accuracy navigation by satellite. These early navigation satellites were in a low altitude orbits, which provided sufficiently strong signals for users to calculate their position from the observed Doppler shift. The oscillator, or clock, had to be stable enough to permit a good frequency measurement over the period of time the satellites were in view. If the oscillator had a frequency change within that interval the frequency measurement would be in error creating a position error as well.

The advanced navigation satellite system designs, such as the Naval Research Laboratory (NRL) TIMATION (time navigation) concept and ultimately the Global Positioning System (GPS) were based on passive ranging to provide continuous accurate navigation to their users [5.38]. Development of space-qualified clocks for GPS was focused on predictable stability over time intervals of typically a day. From NRL work in the first phase of the GPS program (Block I) a space clock development program was formed to

develop space-qualified clocks for the NAVSTAR satellites [5.39]. To meet the system error requirements, projects in rubidium, cesium and hydrogen maser units were initiated. Improvements to the rubidium and cesium units used in the Block I demonstration satellite constellation were required to support the producibility, reliability and performance needs of the operational satellites (Block II/IIA) and alternative industrial sources for these units were required to be developed. The Block II/IIA GPS satellites contained two space cesium clocks and two rubidium clocks. Subsequent blocks of satellites, the replacement Block IIR and improved Block IIR-M contained three rubidium clocks and Block IIF contains two space rubidium and one space cesium clock. The next Block III satellites are to contain three rubidium clocks.

Developments of space-qualified atomic clocks have also been conducted for the Russian Federation GLONASS (global navigation satellite system), the European Galileo system, and the Chinese BeiDou navigation satellite system. Each GLONASS and GLONASS-M satellite hosts Russian three Cs-beam frequency standards [5.40], whereas the latest generation of GLONASS-K1 satellites is equipped with both cesium and rubidium clocks [5.41]. The Galileo satellites make use of passive hydrogen masers as their primary clocks in addition to conventional Rb gas cell frequency standards [5.42]. China, finally had a development project into space rubidium clocks since the initial deployment of BeiDou [5.43, 44] and is also investigating use of hydrogen masers for their global navigation systems [5.45].

Overviews of spaceborne atomic frequency standards and their use in the individual global and regional navigation satellite systems are given in [5.46] and [5.47]. The specific design aspects that distinguish spaceborne clocks from their terrestrial counterparts (such as environmental robustness and utmost reliability) are further discussed in [5.48].

### 5.3.1 Space Rubidium Atomic Clocks

The first atomic clocks in orbiting satellites were flown on board the Navigation Technology Satellite one (NTS-1) [5.49]. This satellite contained two quartz crystal clocks, developed under the TIMATION program, and two experimental rubidium clocks based on the FRK unit built by Efratom of Munich [5.50]. These rubidium clocks were commercial clocks modified as an experiment to survive the launch and thermal environment of space. Both rubidium units were encased in a large radiation shield to reduce the effects of radiation on the clock electronics. The performance of the NTS-1 rubidium clocks is shown in Fig. 5.20 in comparisons with the NTS-1 quartz oscillators and a cesium frequency standard flown later on the NTS-2 spacecraft. Despite a notable frequency drift at time exceeding several hours, these units provided the proof-of-concept necessary for use of rubidium clocks as primary units in the first NAVSTAR developmental satellites.

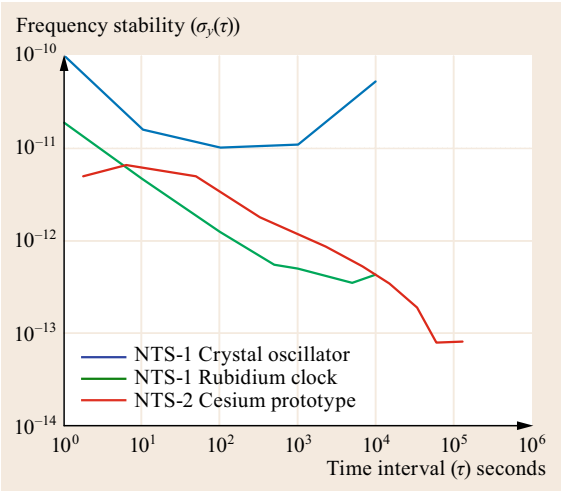

**Fig. 5.20** Performance of NTS space clocks

The rubidium atomic clocks used in the early Block I GPS satellites were built by Rockwell International based on the FRK design of Efratom [5.51]. These units were a combination of an electronics design rebuilt for use in space by the Anaheim Division of Rockwell International and the physics portion built by Efratom. Fig. 5.21 shows the qualification unit of this design.

The early performance of the GPS units had a number of difficulties but they provided sufficient performance to support continued development. Nevertheless, the atomic clock of choice – and what was perceived to be the best clock for the final operational system (GPS Block II) – became the space-qualified cesium beam clock (Sect. 5.3.2), since it was a primary standard and did not exhibit the significant drift characteristic typical of rubidium. During the development of the GPS operational system in the 1980s alternative space-qualified atomic clocks were developed as part of the operational program of deployment [5.39]. The alternative source for space-qualified rubidium clocks was a design originally from EG&G, who became Perkin Elmer Optoelectronics and are currently known as Excelitas [5.52]. That company produced two prototype units that went on to become the atomic clock of choice for the GPS system during the Block IIR satellite deployment. Developments for GPS satellites focused on performance, improvements in the clock's state-of-health diagnostics, ground testability, and reduction of environmental sensitivities.

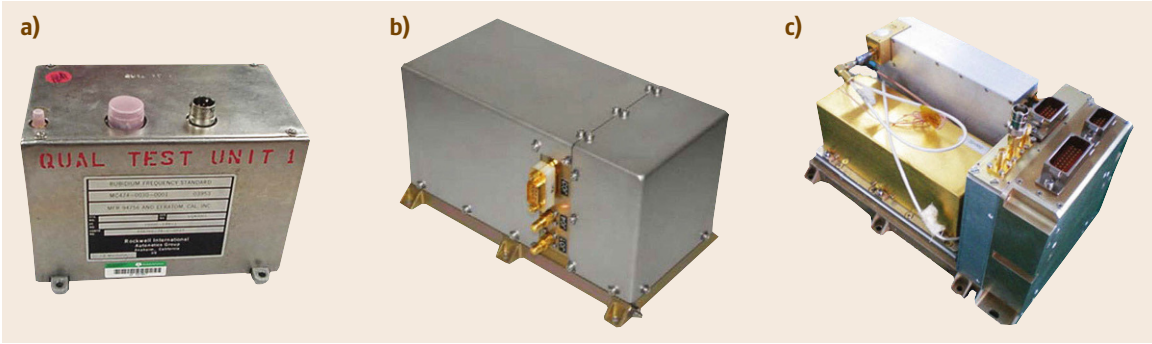

**Fig. 5.21a–c** Space-qualified rubidium clocks for GNSS Satellites: a qualification model for the early GPS satellites **(a)** (image courtesy of NRL), the RAFS developed by TEMEX/Spectratime for Galileo **(b)** (image courtesy of Spectratime), and the inside view of a second generation BeiDou rubidium clock **(c)** (after [5.44])

The latest version of Excelitas rubidium frequency standards used on board the GPS Block IIF satellites [5.53] as well as the *Michibiki* satellite of the Japanese quasi-zenith satellite system (QZSS) offer roughly a factor-of-two improvement in noise level and offer a stability of about $\sigma_y(\tau) = 1 \cdot 10^{-12}\,\mathrm{s}^{1/2}/\tau^{1/2}$. This is mainly achieved through the use of a xenon buffer gas and an advanced filter for the rubidium spectral lines that increase the overall quality factor [5.54]. Both the Block IIR and Block IIF operational rubidium clocks have demonstrated outstanding inflight performance as discussed further in Sect. 5.3.6.

Even though several BERYL Rubidium clocks [5.55] where flown on GLONASS precursor satellites [5.46], the Russian navigation has focused on the exclusive use of cesium beam frequency standards for more than 30 years (Sect. 5.3.2). Only recently, rubidium clocks have been introduced as alternative atomic frequency standards in the GLONASS-K series [5.41]. However, no flight results have become available up to the end of 2015.

Rubidum atomic frequency standards (RAFS) for the European Galileo program were originally developed under Swiss management by Spectratime (formerly Temex Neuchatel Time) along with Astrium, Germany, who did the space-qualified electronics [5.56]. The clocks exhibit representative stabilities of $\sigma_y(\tau) = 2\text{–}4 \cdot 10^{-12}\,\mathrm{s}^{1/2}/\tau^{1/2}$ and were flight tested in the GIOVE-A and -B satellites [5.57] prior to their selection and incorporation into the operational Galileo satellites. A sample of the Galileo RAFS is shown in Fig. 5.21. Complementary to the Galileo program, a variant using a Swiss electronic package has also been developed for use as backup clocks within the Chinese BeiDou constellation [5.47, 56]. Furthermore, the Specatratime Rubidium clocks are employed as primary frequency standards for the Indian Regional Navigation Satellite System (IRNSS; now known as NavIc for Navigation with Indian Constellation).

Along with the buildup of their national navigation satellite systems, various types of space-qualified rubidium clocks have also been developed in China. These indigenous RAFS exhibit a reported stability of about $5 \cdot 10^{-12}\,\mathrm{s}^{1/2}/\tau^{1/2}$ and presently serve as primary onboard clocks for the regional BeiDou navigation system. A recent RAFS model developed by the Beijing Institute of Radio Metrology and Measurement is shown in Fig. 5.21.

### 5.3.2 Space-Qualified Cesium Beam Clocks

The first prototype cesium clocks evaluated in orbit for GNSS were contained in NTS-2, which was the precursor of the NAVSTAR Block I satellites [5.38, 39, 58]. Two prototype cesium units were flown in NTS-2 and provided the space qualification of the cesium tube necessary for continued development. The cesium tube qualified in NTS-2 developed by Frequency and Time Systems Inc. (FTS) is shown in Fig. 5.22 and was the same tube used in the operational Block II/IIA GPS satellites. Performance of the NTS-2 cesium units in orbit is also shown in Fig. 5.20.

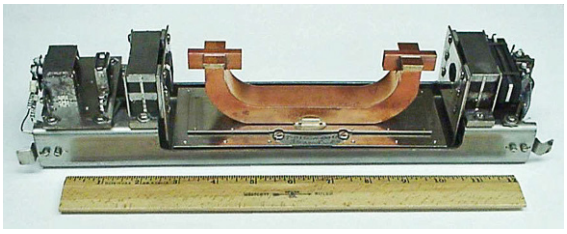

**Fig. 5.22** Cesium beam tube without external shields and vacuum container showing the Ramsey cavity, the cesium reservoir on the right and detector assembly on the left. Image courtesy of NRL

During the next development step, engineering models of a refined design were built and tested. In cooperation with the US Defense Nuclear Agency, complete radiation testing was performed to determine the design parameters necessary for a radiation-hardened unit. The unit design and development with FTS continued through the preproduction model (PPM) stage. Six of these PPMs were built and provided to the prime satellite contractor Rockwell International (RI) for use in the early NAVSTAR satellites. The first PPM was launched in NAVSTAR 4 and the last would have been launched in NAVSTAR 7. This cesium design became the one employed in the Block II and IIA operational GPS satellites. These satellites had two cesium and two rubidium clocks in each satellite.

The next generation of cesium clocks for space were developed and deployed in the GPS Block IIF satellites [5.53]. These clocks employ a similar thermal cesium beam tube to that used in the earlier GPS satellites, but use digital electronics rather than the analog electronics used previously. The complete unit of the digital cesium beam frequency standard (DCFBS) for GPS Block IIF is shown in Fig. 5.23. It achieves a representative stability of $1 \cdot 10^{-12}\,\mathrm{s}^{1/2}/\tau^{1/2}$, and is mainly used as backup clock on those satellites. Its inflight performance is further described in Sect. 5.3.6.

Aside from GPS, cesium beam atomic clocks are also used extensively within the Russian GLONASS constellation, where they have served as the primary source of time and frequency information on most satellites launched so far. Satellites of the first generation GLONASS satellites were equipped with three GEM clocks [5.55] built by the Russian Institute of Radio Navigation and Time (RIRT), formerly Leningrad Scientific Research Radiotechnical Institute (LSRRI), in St. Petersburg. Only one clock is active at a time, while the others are kept in cold redundancy [5.40]. Even though the GLONASS clocks were operated in a sealed compartment at ambient pressure and temperature, their limited survivability posed a major constraint to the overall lifetime of those satellites [5.60].

**Fig. 5.23** GPS Block IIF digital cesium beam frequency standard (DCFBS) from Symmetricom (after [5.59]). Reproduced with permission of MicroSemi

Satellites of the subsequent GLONASS-M series, which still makes up the majority of the current constellation, are equipped with MALAKHIT clocks that are likewise built by RIRT. Following [5.55, 61], the two clock types exhibit Allan deviations of about $1.5 \cdot 10^{-10}\,\mathrm{s}^{1/2}/\tau^{1/2}$ and $3 \cdot 10^{-11}\,\mathrm{s}^{1/2}/\tau^{1/2}$ at timescales of 100 s to one day. More recent developments have resulted in a performance improvement by a factor of 2–3 as well as a notably reduced mass of the GLONASS onboard frequency standards [5.62].

### 5.3.3 Space-Qualified Hydrogen Maser Clocks

The use of hydrogen masers for the ground stations and eventually in spacecraft was considered for GPS before the beginning of the program. Efforts at that time were based on adapting the active hydrogen maser design developed by the Smithsonian Astrophysical Observatory (SAO). SAO developed a series of active hydrogen masers for the Very Long Baseline Interferometry program that were capable of being operated in ground stations at remote sites. From that design, SAO built a space-qualified hydrogen maser for the National Aeronautics and Space Administration's (NASA) Gravity Probe One unit to investigate the gravitational relativistic effects on a precise clock. The probe was launched in the mid-1970s in a vertical ballistic trajectory to maximize the relativistic effects on the atomic clock [5.63]. The successful flight qualification and operation in the 2.5 h launch profile demonstrated the potential for operating such a clock in orbiting spacecraft. However, this particular active hydrogen maser design was rather large to consider incorporating into an orbiting satellite.

Reduction in the size of such a space clock was considered essential, so compact passive physics unit designs were investigated by NRL for GPS [5.64]. Various passive maser designs were investigated, both of the physics unit as well as electronics designs for cavity stabilization and interrogation. Several experimental units were built incorporating design alternatives for evaluation and the most successful approach was the Hughes Q-enhanced design incorporating a small magnetron cavity [5.65, 66]. This compact passive hydrogen maser design reduced the overall size of the device to roughly the size of a GPS space-qualified cesium clock.

Figure 5.24 shows the physics unit of the final version of the Hughes design.

The Galileo program also developed a small passive hydrogen maser (PHM) clock for operational satellites [5.67–69]. The development was jointly performed by Spectratime, Switzerland, and Galileo Avionica, Italy, who where in charge of the physics package and the electronics package, respectively. The maser cavities used in these devices are of similar design to that of the Q-enhanced maser design discussed above. They are a magnetron cavity design using a metal cavity machined to hold the hydrogen containment bulb with three arms that provide the capacitive loading on the cavity. The microwave cavity is thermally controlled to exhibit variations at the level of a few milli-Kelvin for baseplate temperature changes of about ±5 K. The Galileo PHM achieves a typical performance of $1 \cdot 10^{-12}\,\mathrm{s}^{1/2}/\tau^{1/2}$ over timescales of 1–10 000 s, which marks a notable performance increase over the Galileo RAFSs and makes it one of the best clocks ever used in navigation satellites. On the other hand, the mass of about 18 kg is notably larger than that of the rubidium clock. A flight-qualified space passive hydrogen maser ready for thermal vacuum testing is shown in Fig. 5.25. The PHMs for the Galileo program were flight tested on board the GIOVE-B technology demonstration satellite [5.57] and are now in routine use on board the operational Galileo satellites.

In parallel to the Galileo PHM developments, Observatoire de Neuchâtel and Spectratime pursued the development of a space-qualified, active hydrogen maser for use within the Atomic Clock Ensemble in Space (ACES [5.28]). The Space H-Maser (SHM) uses a sapphire loaded microwave cavity and achieves an Allan deviation down to $5 \cdot 10^{-15}$ at a timescale of 100 s [5.70, 71]. The larger mass (35 kg) and power consumption (77 W) of the active maser did not allow its consideration for the present Galileo system. Nevertheless, its use on ACES will provide further evidence for the potential of high-performance clocks in future navigation systems.

### 5.3.4 Space Linear Ion Trap System (LITS)

The Jet Propulsion Laboratory Time and Frequency Group have developed a new technology standard known as the linear ion trap standard (LITS) [5.72]. Operational versions of these units are being deployed in the NASA Deep Space Network as replacements for the large active hydrogen masers currently in use. A spacecraft version of these units has been investigated and offers the potential of a very small size and power clock with potentially high stability. The physics package is small but since it is a passive device a high quality local oscillator is needed to gain the full potential of these devices. The potential performance gain using a modest performance local oscillator and the adaptability to digital implementation of the electronics could be a major step in spacecraft clocks [5.73]. NASA is currently developing a space-qualified version of this device for demonstration in a space environment [5.74].

### 5.3.5 Satellite Onboard Timing Subsystems

Aside from the atomic frequency standard, navigation satellite systems commonly employ some form of frequency distribution unit as part of their timing subsystem. Following [5.75], this unit may serve up to three purposes:

- Selection of one out of multiple clocks as the main source for the time and frequency generation

- Conversion of the native clock frequency to the base frequency for the navigation signal generation, and finally
- Performance of fine frequency adjustments to keep deviations of the onboard time from the GNSS time scale within specified limits.

In advanced timing system implementations, the above functions are combined with a monitor that compares the active clock against a reference to identify potential anomalies such as occasional bad points or outliers, phase jumps and frequency steps. All of these anomalous effects may happen singly, in combination, suddenly, or over a period of time. Serious situations related to satellite clock anomalies can be avoided by detection of these anomalies on board rather than through detection by tracking data on the ground. The clock's behavior can be better monitored on board in real time without additional noise or errors added by the communication link. However, multiple operating frequency standards on board are necessary to accomplish this result.

A well-known example of a timing subsystem taking care of the above functions is the Time Keeping System (TKS) of the GPS Block IIR satellites [5.76–78]. The TKS was originally designed to provide a common interface to different types of atomic clocks as well as determine the differences between the onboard atomic clocks and the output voltage-controlled crystal oscillator (VCXO). The system was configured to provide an interface for three atomic clocks, any one of which, when operating, was compared with a redundant VCXO by a phase comparator running at 600 MHz (Fig. 5.26). The VCXO produces the final signal but is adjusted or disciplined to the atomic clock's output. This intercomparison produces a measure of the onboard atomic clock's performance but it is ambiguous as to whether it occurs in the atomic clock or in the VCXO. Either one can affect the resultant comparison. At least three clocks would be necessary to be intercompared in order to produce an unambiguous determination of which clock produced the unacceptable performance [5.5].

In a similar fashion to GPS, the Galileo satellites utilize an onboard system called the clock monitoring and comparison unit (CMCU) [5.79–81] to monitor a standby clock with the clock driving the satellite transmitter (Fig. 5.27). Each Galileo satellite is equipped with two rubidium atomic frequency standards as well

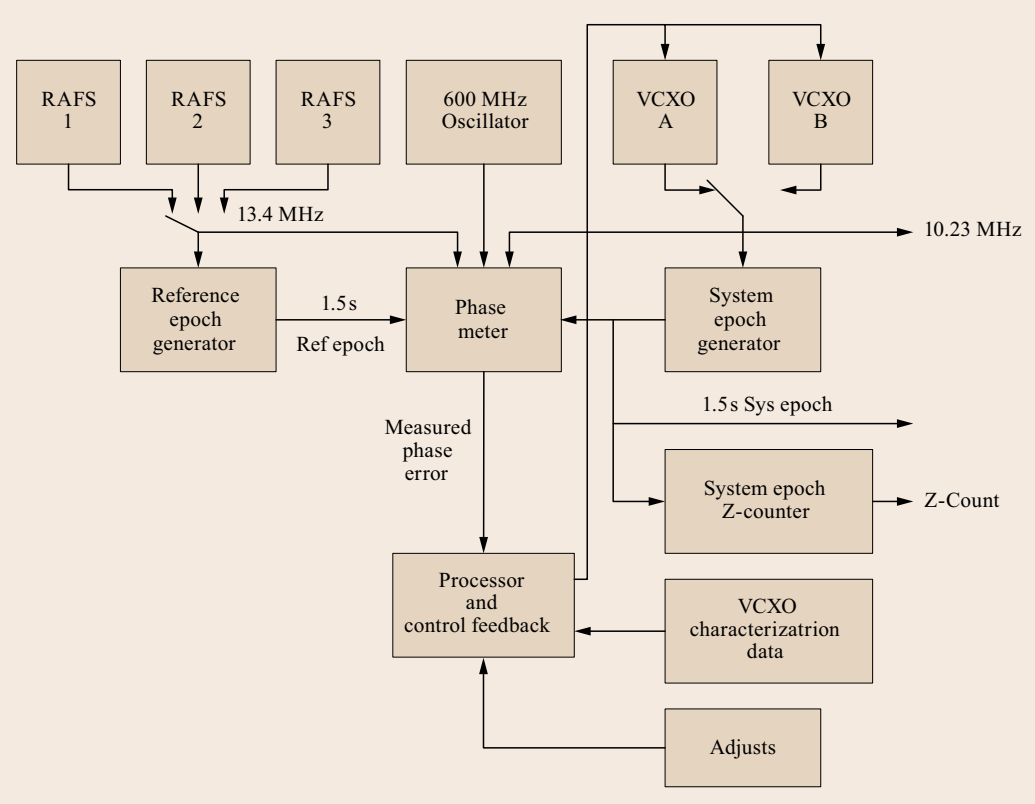

**Fig. 5.26** Block diagram of Block IIR satellite Time Keeping System

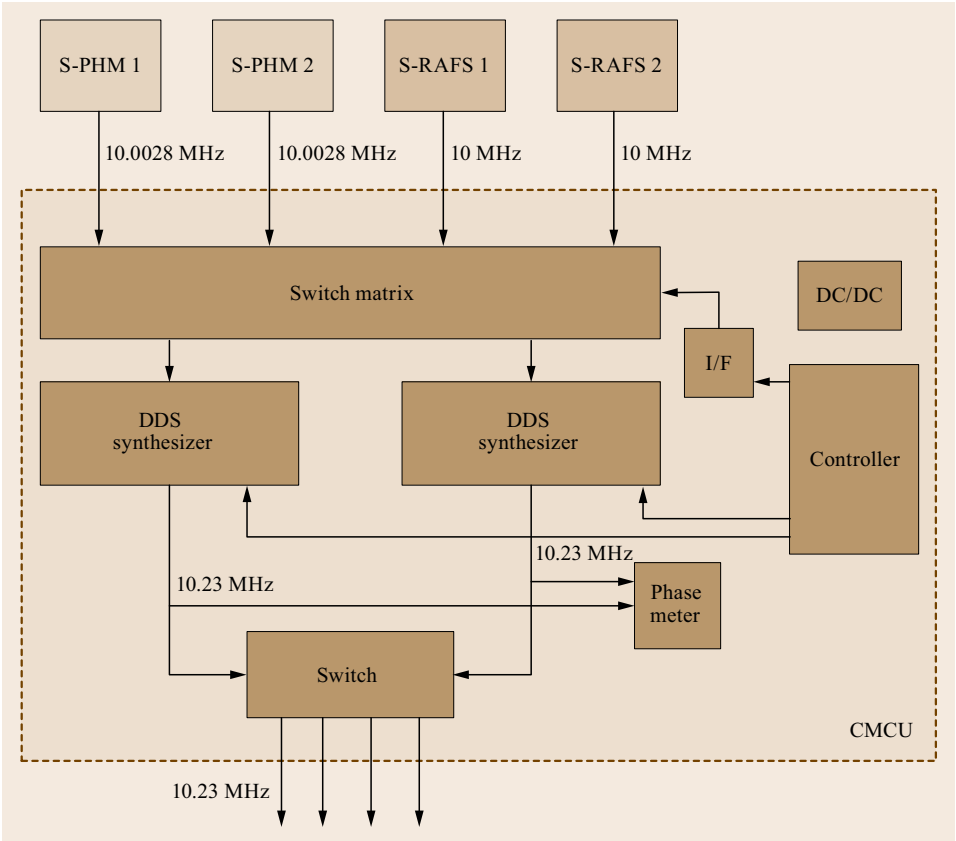

**Fig. 5.27** Diagram of the Galileo clock monitoring and comparison unit

as two passive hydrogen masers. At any time, two of these four clocks are active while the other two serve as cold redundancy. Using a switching matrix, the signals of the two active clocks are connected to two synthesizers that shift the native clock frequency of 10 MHz for the RAFSs and 10.0028 MHz for the PHM by roughly 230 kHz to obtain the 10.23 MHz core frequency for the navigation signal. The synthesizers can be digitally controlled and enable adjustments of the output frequency in steps of less than $10^{-15}$ [5.81]. Even though only one synthesizer is selected to serve as master time reference, both outputs are continuously monitored through a phase meter. By continuously comparing the master clock with an operating standby clock, a switching transient and a loss of knowledge of the satellite time is avoided in case an immediate switch between both clocks needs to be made.

The onboard systems in use today are still mostly dependent upon the performance of a single clock to produce the desired performance. If clocks could be compared on board or with the signals from neighboring satellites provided satellite cross-links or signals from the other satellites could be made available, their outputs could be monitored to be less susceptible to interruption or anomaly but also to produce a somewhat more stable and accurate signal. This onboard comparison capability could provide an immediate detection of anomalies in the operational clock and if properly instrumented possibly even the navigation payload. The resulting status could be inserted into the navigation message for direct broadcast to the users in case of anomaly and to the ground monitoring stations, thereby providing a real-time alerting capability to the system. Data associated with the comparative indication could also be telemetered to the control segment for diagnostic and remedial actions. The current GNSSs do not perform a comparison between the onboard clocks sufficient for determination of clock anomalies. Instead they rely on ground monitoring for detection and correction of such anomalies. A more sophisticated measurement system would be necessary to support a technique for automatic detection and correction on board.

### 5.3.6 On-Orbit Performance of Space Atomic Clocks

The performance of atomic clocks on board the GNSS satellites is critical to the ultimate accuracy achievable

by the system. Today's satellite navigation systems operate primarily in a passive mode, where the satellites are tracked by a set of of monitoring stations. From these observations the system parameters, i. e., satellite ephemerides and clock correction values, are predicted ahead. The navigation information computed at the system master station is then uploaded into the satellites for transmission to the users over time [5.82]. Consequently, the ability to evaluate the clock performance in orbit and to accurately predict the system parameters is required. Effects contributing to the clock observations must be carefully modeled or eliminated, so that the observed and predicted satellite clock information will be as accurate as possible [5.83, 84].

Similar to GNSS-based positioning, the monitoring of GNSS satellite clocks makes use of pseudorange and carrier-phase observations. Both of these reflect measurements of the difference between the signal receive and transmit times relative to the local receiver and transmitter clocks. As indicated by the terminology, pseudoranges (and likewise the carrier-phase observations) do not represent a pure measurement of the distance $\rho$, but include contributions of the respective clock offsets relative to a common system timescale. As discussed in more detail in Chap. 19, the pseudorange $p_i$ and carrier-phase observations $\varphi_i$ on the $i$-th frequency ($i = 1, 2, \ldots$) can be modeled as

$$\begin{aligned} p_i &= \rho + c(dt_\mathrm{r} - dt^\mathrm{s}) + I_i + T + e_i \\ \varphi_i &= \rho + c(dt_\mathrm{r} - dt^\mathrm{s}) - I_i + T + A + \varepsilon_i \,, \end{aligned} \tag{5.25}$$

where $c$ is the vacuum speed of light, $\rho$ is the distance between the satellite antenna and the user receiver's antenna, $dt_\mathrm{r}$ is the clock synchronization offset of the user receiver's time, $dt^\mathrm{s}$ is the clock synchronization offset of the satellite's time at the time of transmission, $I_i$ is the frequency dependent propagation delay due to the ionosphere and $T$ is the delay due to the neutral atmosphere, mostly the troposphere. The measurements errors $e_i$ and $\varepsilon_i$ exhibit standard deviation at the decimeter and millimeter level, respectively, for pseudorange and carrier-phase observations. Even though carrier-phase measurements exhibit an extremely low noise, they also include an ambiguity $A$, which comprises both integer multiples of the wavelength and fractional-cycle phase biases. During uninterrupted tracking of a satellite signal the ambiguity is constant thus offering highly precise measurements of the range change and clock offset variations over time.

The various delays and errors associated with the observations are discussed in depth in Chap. 19. However, once the observations are corrected for instrumentation, equipment effects (antenna offsets and the like), propagation effects, geometric effects or delays, and satellite position relative to the receiving equipment are all compensated, the residual differences

$$\begin{aligned} cdt^\mathrm{s} - cdt_\mathrm{r} &= (\rho + I_i + T) - p_i + e_i \\ cdt^\mathrm{s} - cdt_\mathrm{r} - A &= (\rho - I_i + T) - \varphi_i + \varepsilon_i \end{aligned} \tag{5.26}$$

between the measurements and the modeled geometric range and propagation delays are basically a compari-

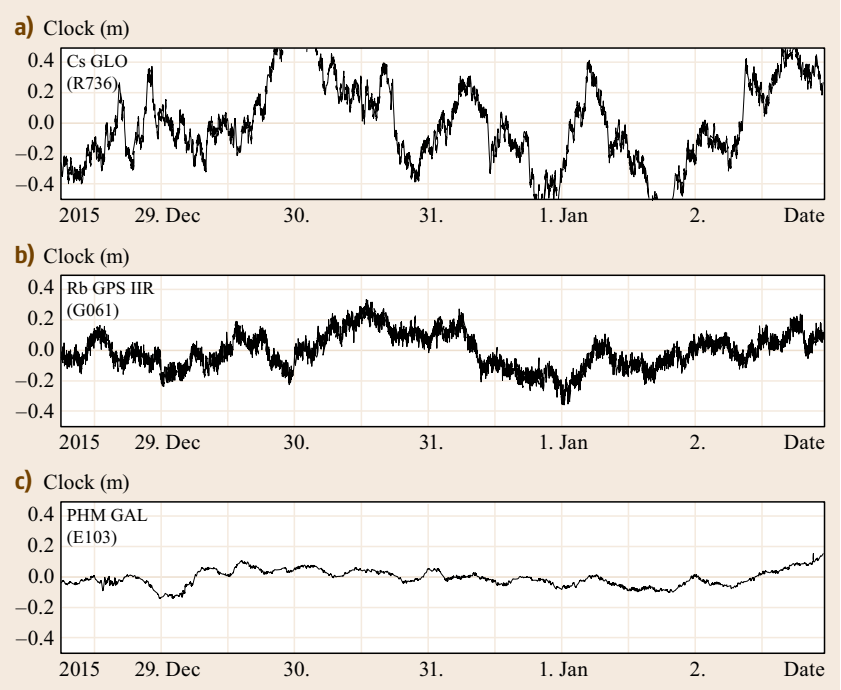

**Fig. 5.28a–c** Time series of observed clock offsets ($cdt^\mathrm{s} - cdt_\mathrm{r}$) for selected GNSS onboard frequency standards: GLONASS cesium clock **(a)**, GPS Block IIR rubidium clock **(b)**, and Galileo passive hydrogen maser **(c)**. All values are referred to a highly stable ground clock (active hydrogen maser) and have been detrended with a second-order polynomial. Values in brackets denote the space vehicle number of the respective GNSS satellites. Based on data from a multi-GNSS orbit and clock solution [5.85] of GeoForschungsZentrum (GFZ), Potsdam

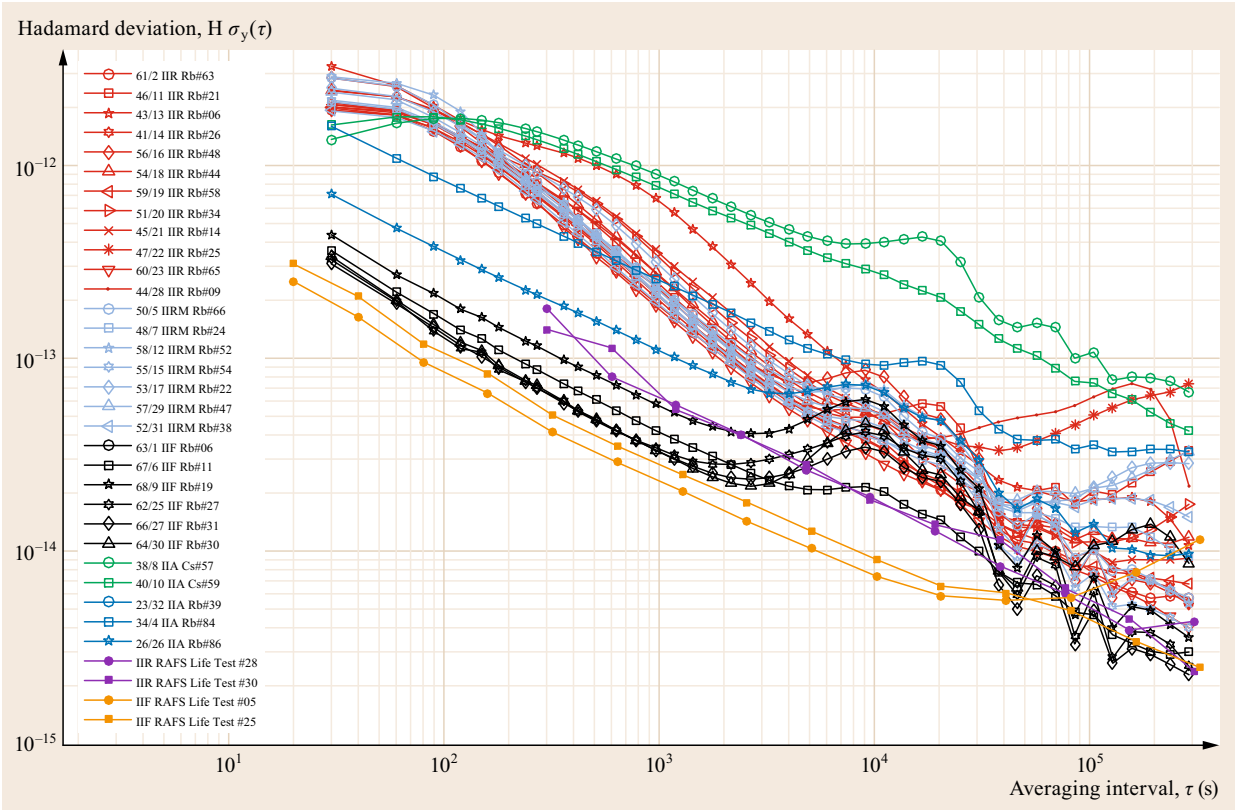

**Fig. 5.29** On-orbit performance of GPS satellite clocks (Oct.–Dec. 2014). Individual satellites are identified by their space vehicle number (SVN)/pseudorandom noise (PRN) number. In addition the Block type and the active clock are indicated

son of two clock outputs just as they would be measured in a laboratory evaluation of two clocks. Examples of observed satellite clock offsets relative to a ground reference are shown in Fig. 5.28 for different GNSS satellites. The time series clearly reveal the different short- and long-term stability of individual types of atomic frequency standards.

Characterizing the satellite clocks' performance and predicting their performance ahead is dependent upon the ability to separate all other errors from the measurement so that only clock errors remain. This function is performed for the GNSSs by their respective tracking networks to support their operation. For GPS the network consists of the GPS Ground Segment tracking stations (Chap. 7) combined with additional stations operated by the National Geospatial-Intelligence Agency (NGA). This network supports the real-time operation of the GPS as well as providing the data for producing precise ephemerides for all the GPS satellites. In their support to the science community, the International GNSS Service (IGS; see Chap. 33) performs a similar function to provide highly accurate GNSS orbit products. The IGS data products have significantly reduced errors over that expected by normal navigation users. Details of the IGS product generation and the processes used to estimate satellite orbits, atmospheric parameters, site coordinates and Earth rotation parameters from a globally distributed network of monitoring stations are discussed in Chap. 34.

Clock offsets estimated from a global monitoring network as part of the precise orbit and clock determination process form a primary means for the inflight performance assessment of atomic frequency standards. In accord with the typical data rates and data arcs used in such adjustment processes, they mostly provide information on the clock stability at timescales of about 5 min to 1 day. For use at short timescales, the method is less suitable though, due to the high computational effort required for high-rate clock solutions. As an alternative, the *one-way carrier-phase* technique (OWCP) has been proposed in [5.86]. It makes use of carrier-phase observations from a single monitoring station connected to a highly stable reference clock (typically an active hydrogen maser). Based on (5.26) the difference of the onboard and ground clock is evaluated using a coarse orbit model such as broadcast ephemerides.

Subsequently, the resulting time series is detrended using a low-order polynomial to remove the impact of the carrier phase ambiguity and residual orbit errors as well as uncompensated atmospheric delays. Subject to a short data arc (up to a few hundred seconds) and the absence of large ionospheric variations, the method can even be applied with single-frequency observations rather than a more noisy dual-frequency combination.

Practical results and a comparison of the OWCP method with other clock estimates have, for example, been reported in [5.87–89]. The unique potential of this method to study the onboard clock stability at subsecond timescales has been demonstrated in [5.90] using GNSS receivers with data rates of 50 Hz and beyond. A special variant of the OWCP method has, furthermore, been studied in [5.91]. It makes use of the triangulation concept [5.92] for a statistical characterization of the clock noise, by processing data from three satellites simultaneously. This method does not require a highly stable ground clock, but relies on equal noise properties of all involved satellite clocks.

The space-qualified atomic clocks in the GPS operational satellites have stability requirements ranging from $2 \cdot 10^{-13}$ /day for cesium and $1 \cdot 10^{-14}$ /day for the rubidium on the later satellites. On-orbit performance has provided better than expected stabilities as demonstrated in Fig. 5.29. This figure provides the frequency stabilities of the GPS constellation clocks as measured by the Hadamard deviation calculated using the International GNSS Service (IGS) final clock products over the month of November 2013. For comparison with the on-orbit clock performance, Fig. 5.29 also shows the data from two Block IIF rubidium units under long-term test by the NRL. As the plots show, on-orbit performance of the Block IIF units is near that of the environmentally controlled ground units, at least over the short term.

Over longer averaging intervals the performance is degraded in comparison by apparent fixed period

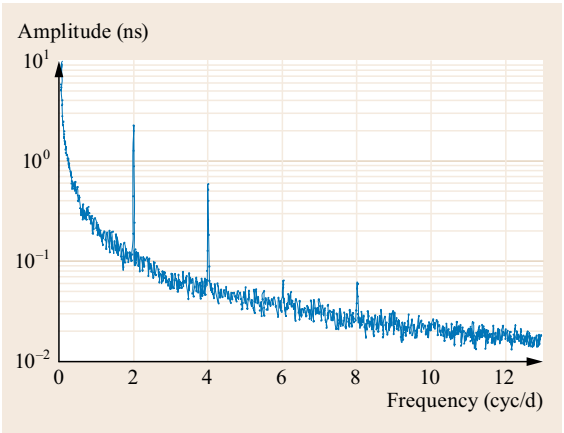

**Fig. 5.30** Averaged amplitude spectrum of GPS constellation clocks (after [5.93])

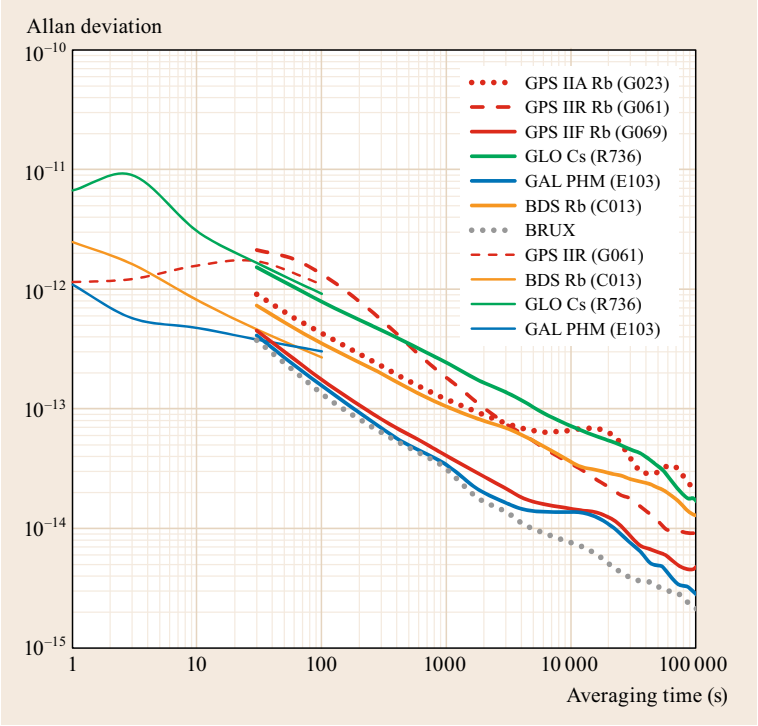

**Fig. 5.31** Comparison of atomic clocks performances for current GNSS satellites. *Bold lines* provide Allan deviations for timescales of 30 s to 100 000 s based on data from the clock product of GeoForschungsZentrum (GFZ), Potsdam [5.85] for a one-week data arc in Jan. 2016. A *dotted gray* line provides the corresponding values for a hydrogen maser at the IGS GNSS station in Brussels. For comparison, *thin lines* show clock stability values over short timescales (1–100 s) as derived in [5.90] from a OWCP analysis

harmonic variations attributable to the satellite timing signal [5.93, 94]. The strongest of these harmonic variations occur nominally at 2.003 and 4.006 cycles per solar day with amplitudes of more than 2 ns for some GPS satellites. The Hadamard deviation statistic has a broad frequency response to pure harmonics so the harmonic variations are seen more distinctly using frequency domain techniques, as shown in Fig. 5.30. These data used individual satellite data spectra calculated by applying a standard periodogram with Blackman–Harris windowing to approximately 150 days of IGS final clock data for each satellite referenced to IGS time. The clock data for each satellite were detrended by fitting and removing a second-order polynomial prior to calculating its periodogram. The averaged spectrum was then obtained by averaging the individual satellite spectra at each Fourier frequency. Evidence is increasingly strong that the origin of the variations is likely to be thermal sensitivity, possibly of the associated electronics or of the units themselves.

A comparison of GPS atomic frequency standards with those of other navigation satellite systems in shown in Fig. 5.31 for timescales ranging from 1 s to more than a day. Stabilities for the various clock types differ by up to a factor of ten and are generally better for rubidium clock and hydrogen masers than for the currently employed cesium beam clocks. A superior performance can, in particular, be noted for the GPS IIF RAFS and the Galileo PHM, which exhibit stability values close to the observational limit over a wide range of timescales. While the Allan deviation follows the expected linear trend in the double-logarithmic representation for most clocks and satellites, bumps of varying amplitude can frequently be recognized at timescales near one half of the orbital period. These may be caused by thermal variations in the onboard equipment as discussed above, but can also be related to radial orbit errors induced by, for example, an incomplete modeling of solar radiation pressure forces [5.95]. On the other hand, ADEV bumps observed at timescales less than 1000 s for some types of GNSS satellites can often be attributed to the function of the respective timekeeping system [5.78].

## 5.4 Relativistic Effects on Clocks

The technologies of clocks, timekeeping, and GNSS have long advanced to a state where the precision of the measurements is on the order of nanoseconds and where such performance is necessary for satellite-based global navigation. To achieve this level of precision and accuracy, corrections imposed by relativity must be taken into account in addition to errors in the measurement systems, instrumental errors on board a satellite and atmospheric propagation delays. The development of GPS first brought a system into application, in which the principles of the special and general theories of relativity are not merely a matter of scientific interest, but have become an engineering necessity.

To understand the relationship between Coordinated Universal Time (UTC) reference timescale, its dependence on the International Atomic Time (TAI), their relation to the rotation of the Earth, as well as the time maintained and used by individual GNSSs, the relativistic relationship of timekeeping in and around the Earth is necessary [5.96]. In a relativistic formulation it is also necessary to have a clear understanding of the relationship of space-time reference systems in that framework. These relationships have been defined primarily by resolutions of the various international scientific organizations. The most important of these resolutions are:

1. International Astronomical Union (IAU) Resolution A4 (1991) defining the Geocentric Celestial Reference System (GCRS), the Barycentric Celestial Reference System (BCRS) and their time coordinates. IAU Resolution B1 (2000) further refines the BCRS definition.
2. International Union of Geodesy and Geophysics (IUGG) Resolution 2 (2007; see [5.96, Annex C]) defining the Geocentric Terrestrial Reference System (GTRS), along with the International Terrestrial Reference System (ITRS).

The nomenclature used here follows the IAU/IUGG framework in that the GCRS is known as the Earth-Centered Inertial (ECI) coordinate system, the GTRS (in practice, the ITRS) is known as the Earth-Centered Earth-Fixed (ECEF) coordinate system, and the BCRS is the barycentric coordinate system.

### 5.4.1 Relativistic Terms

GPS provided the initial theoretical model for relativistic synchronization and time comparison for GNSS development and operation as well as a laboratory for the validation of relativistic algorithms. However, the effects of relativity on precise orbiting vice orbit clocks

and the systems operating them should be understood in the context of global timekeeping. Relativistic formalism and relationships are based on observations and measurements between different frames of reference. Consequently an understanding of the different frames of reference and how they are realized in actual use is needed. This section will discuss a description of the relativistic effects on orbiting and Earth bound clocks and the implications for GNSS and other satellite-based time and position determination systems. This discussion is a prelude to understanding the issues of global timekeeping and GNSS timekeeping systems which are directly analogous.

GNSS internal timescales provide a basis for maintaining system internal synchronization and precision measurements between the elements of the system. The GNSS time is based on time maintained by sets of atomic clocks that are effectively generating versions of atomic time. They are linked to timekeeping centers so they can provide the most versatile and effective means of disseminating precise global time available.

The definition of some key relativistic terms and their meaning follows:

*Proper time* $\tau_p$ is the actual reading of a clock or the local time in the clock's own frame of reference.

*Coordinate time* $t$ is the independent variable in the equations of motion of material bodies and in the equations of propagation of electromagnetic waves. It is a mathematical coordinate in the four-dimensional space-time of the coordinate system. For a given event, the coordinate time has the same value everywhere. Coordinate times are not measured; rather, they are computed from the proper times of clocks.

*Space-time interval*. The relation between coordinate time and proper time depends on the clock's position and state of motion in its gravitational environment and is derived by integration of the space-time interval. In the comparison of the proper times of two clocks, the coordinate time is ultimately eliminated. Thus the relativistic transfer of time between clocks is independent of the coordinate system. The coordinate system may be chosen arbitrarily on the basis of convenience.

In general, the space-time interval $ds$ is described by

$$\begin{aligned} ds^2 &= g_{\mu\nu} dx^\mu dx^\nu \\ &= g_{00}c^2dt^2 + 2g_{0j}c\,dt\,dx^j + g_{ij}dx^i dx^j \,, \end{aligned} \tag{5.27}$$

where $g_{\mu\nu}$ are the components of the metric. In the notation used here a Greek index assumes the range 0, 1, 2, 3 and a Latin index assumes the range 1, 2, 3. A repeated index implies summation on that index. The metric depends upon the gravitational potentials, angular velocity and linear acceleration of the reference frame. Upon a transformation of the coordinates, the space-time interval remains invariant. Therefore the metric $g_{\mu\nu}$ transforms as a second-order covariant tensor.

The general expression for the relationship between proper time $\tau_p$ and the coordinates of the chosen coordinate system, comprising the coordinate time $x^0 \equiv ct$ and the spatial coordinates $x^i$, is given by

$$\begin{aligned} ds^2 &= g_{00}c^2dt^2 + 2g_{0j}c\,dt\,dx^j + g_{ij}dx^i dx^j \\ &= -c^2 d\tau_p^2 \,. \end{aligned} \tag{5.28}$$

Therefore $dt = d\tau_p$ for a clock at rest in an inertial frame of reference, for which $dx^i = 0$ and $-g_{00} = 1$, $g_{0j} = 0$, and $g_{ij} = \delta_{ij}$. The elapsed coordinate time corresponding to the measured proper time as registered by a clock along a path between points A and B is

$$\begin{aligned} \Delta t = \pm \int_A^B \frac{1}{\sqrt{-g_{00}}} \sqrt{1 + \frac{1}{c^2}\left(g_{ij} + \frac{g_{0i}g_{0j}}{-g_{00}}\right)\frac{dx^i}{d\tau_p}\frac{dx^j}{d\tau_p}}\,\mathrm{d}\tau_p \\ + \frac{1}{c}\int_A^B \frac{g_{0j}}{-g_{00}}\frac{dx^j}{d\tau_p}\mathrm{d}\tau_p \,. \end{aligned} \tag{5.29}$$

For an electromagnetic signal, the space-time interval is

$$ds^2 = g_{00}c^2dt^2 + 2g_{0j}c\,dt\,dx^j + g_{ij}dx^i dx^j = 0 \,. \tag{5.30}$$

The speed of light is $c$ in every inertial frame of reference. The elapsed coordinate time of propagation along a path between points A and B is

$$\begin{aligned} \Delta t = \pm \int_A^B \frac{1}{\sqrt{-g_{00}}} \sqrt{1 + \frac{1}{c^2}\left(g_{ij} + \frac{g_{0i}g_{0j}}{-g_{00}}\right) dx^i dx^j} \\ + \frac{1}{c}\int_A^B \frac{g_{0j}}{-g_{00}}\mathrm{d}x^j \,, \end{aligned} \tag{5.31}$$

where the expression in parenthesis

$$\gamma_{ij} \equiv g_{ij} + \frac{g_{0i}g_{0j}}{-g_{00}}$$

represents the metric of three-dimensional space and

$$d\rho = \sqrt{\gamma_{ij}dx^i dx^j}$$

represents the increment of three-dimensional distance.

### 5.4.2 Coordinate Timescales

For practical purposes, different types of coordinate times are distinguished:

*Geocentric Coordinate Time (TCG)* is the coordinate time in a coordinate system with origin at the Earth's center (ECI or ECEF).

*Terrestrial Time (TT)* is the coordinate time that is rescaled from TCG so that it has approximately the same rate as the proper time of a clock at rest on the geoid. The geoid is the surface of constant gravity potential, which is closely approximated by mean sea level. The relationship between TCG and TT is defined such that

$$\frac{d(\mathrm{TT})}{d(\mathrm{TCG})} \equiv 1 - L_\mathrm{G} \,,$$

where

$$L_\mathrm{G} \equiv 6.969290134 \cdot 10^{-10} \approx 60.2\,\mu\mathrm{s/d}$$

as discussed below. The value of $L_\mathrm{G}$ is a defined constant. Consequently,

$$\begin{aligned}\mathrm{TCG} - \mathrm{TT} &= L_\mathrm{G}(\mathrm{TCG} - \mathrm{TCG}_0) \\ &= \frac{L_\mathrm{G}}{1 - L_\mathrm{G}}(\mathrm{TT} - \mathrm{TT}_0) \,,\end{aligned}$$

where $\mathrm{TCG}_0$ and $\mathrm{TT}_0$ correspond to JD 2 443 144.5 TAI (1977 Jan. 1, 0 h). The practical realization of TT is

$$\mathrm{TT} = \mathrm{TAI} + 32.184\,\mathrm{s} \,. \tag{5.32}$$

*Barycentric Coordinate Time (TCB)* is the coordinate time in a coordinate system with origin at the solar system barycenter. The coordinate time difference between TCB and TCG is a transformation that depends on both time and position. This timescale is important to be used when the satellite is outside Earth orbit and the influence of the Solar System needs to be taken into account.

### 5.4.3 Geocentric Coordinate Systems

The following section will discuss the transformation between the proper time of an ideal clock (one that exactly realizes the SI second) and coordinate time in a geocentric coordinate systems.

#### Earth-Centered Inertial Coordinate System

The coordinate time associated with an Earth-centered inertial (ECI) coordinate system is TCG. Through terms of order $1/c^2$, the components of the metric tensor in this coordinate system are

$$\begin{aligned} -g_{00} &= 1 - \frac{2U}{c^2} \,, \\ g_{0j} &= 0 \,, \\ g_{ij} &= \left(1 + \frac{2U}{c^2}\right)\delta_{ij} \,, \end{aligned} \tag{5.33}$$

where $U$ is the gravitational potential. The elapsed TCG in the ECI coordinate system corresponding to the elapsed proper time as registered by a clock moving along a path between points A and B with velocity $v$ is given by

$$\Delta t = \int_\mathrm{A}^\mathrm{B} \left(1 + \frac{1}{c^2}U + \frac{1}{2c^2}v^2\right) \mathrm{d}\tau_\mathrm{p} \,. \tag{5.34}$$

The Earth's potential $U$ at radial distance $r$, geocentric latitude $\phi$, and longitude $\lambda$ may be expressed as an expansion in spherical harmonics

$$\begin{aligned} U(r,\phi,\lambda) &= \frac{\mathrm{GM}_\oplus}{r}\left[1 + \sum_{n=2}^{\infty}\sum_{m=0}^{n}\left(\frac{\mathrm{R}_\oplus}{r}\right)^n \right. \\ &\left. \times P_{nm}(\sin\phi)(C_{nm}\cos m\lambda + S_{nm}\sin m\lambda)\right] \end{aligned} \tag{5.35}$$

with coefficients $C_{nm}$ and $S_{nm}$. Here, $\mathrm{GM}_\oplus$ is the gravitational coefficient of the Earth and $\mathrm{R}_\oplus$ its equatorial radius. Furthermore, the factors $P_{nm}$ denote the associated Legendre functions of degree $n$ and order $m$.

For practical applications it is sufficient to include only the Earth oblateness correction and approximate the gravitational potential as

$$\begin{aligned} U &= \frac{\mathrm{GM}_\oplus}{r} \\ &\quad + J_2\frac{\mathrm{GM}_\oplus}{r}\left(\frac{\mathrm{R}_\oplus}{r}\right)^2 \frac{1}{2}\left(1 - 3\sin^2\phi\right) \,, \end{aligned} \tag{5.36}$$

where $J_2 = -C_{2,0} \approx 1.08 \cdot 10^{-3}$ is the leading zonal gravity coefficient.

Even for a clock at rest on the surface of the rotating Earth, it is necessary to account for its velocity $\boldsymbol{v} = \boldsymbol{\omega} \times \boldsymbol{r}$ in the ECI coordinate system, where $\boldsymbol{\omega}$ is the angular velocity of the Earth and $\boldsymbol{r}$ is the position of the clock. Thus TCG elapsed as the clock records proper time $\Delta\tau_\mathrm{p}$

is

$$\Delta t = \int_A^B \left(1 + \frac{1}{c^2}U + \frac{1}{2c^2}||\boldsymbol{\omega}\times\boldsymbol{r}||^2\right) = \int_A^B \left(1 + \frac{1}{c^2}W\right) \mathrm{d}\tau_\mathrm{p}\,, \tag{5.37}$$

where

$$W = U + \frac{1}{2}||\boldsymbol{\omega}\times\boldsymbol{r}||^2 = U + \frac{1}{2}\omega^2 r^2 \cos^2\phi \tag{5.38}$$

is the gravity potential.

As the gravity potential $W_0$ over the surface of the geoid is constant, it may be evaluated on the equator and is approximately given by

$$W_0 \approx \frac{GM_\oplus}{R_\oplus}\left(1 + \frac{1}{2}J_2\right) + \frac{1}{2}\omega^2 {R_\oplus}^2\,. \tag{5.39}$$

The current best estimate of $W_0$ is $6.2636856\cdot 10^7\,\mathrm{m}^2/\mathrm{s}^2$.

According to (5.37), the TCG in the ECI coordinate system that corresponds to the proper time $\Delta\tau_{\mathrm{p}0}$ measured by a clock at rest on the geoid is

$$\Delta t \equiv \mathrm{TCG} = \left(1 + \frac{W_0}{c^2}\right)\Delta\tau_{\mathrm{p}0} \approx (1 + L_\mathrm{G})\Delta\tau_{\mathrm{p}0}\,, \tag{5.40}$$

where $L_\mathrm{G} \equiv 6.969290134\cdot 10^{-10}$. By convention, the value of $L_\mathrm{G}$ is a defined constant. It represents the best available value of $W_0/c^2$ at the time of its definition in 2000 [5.96].

TT is obtained by rescaling TCG by the factor $1 - L_\mathrm{G}$. Thus

$$\Delta t' \equiv \mathrm{TT} = (1 - L_\mathrm{G})\mathrm{TCG}\,. \tag{5.41}$$

It follows that

$$\mathrm{TT} = (1 - L_\mathrm{G})(1 + L_\mathrm{G})\Delta\tau_{\mathrm{p}0} \approx \Delta\tau_{\mathrm{p}0}$$

to within a few parts in $10^{18}$.

For a clock on an Earth-orbiting satellite, the orbit may be regarded as Keplerian (unperturbed) in the first approximation (Chap. 3). The potential at distance $r$ from the Earth's center is approximately $U = GM_\oplus/r$. Therefore the increment of TCG is

$$\Delta t = \int_A^B \left(1 + \frac{1}{c^2}\frac{GM_\oplus}{r} + \frac{1}{2c^2}v^2\right)\mathrm{d}\tau_\mathrm{p}. \tag{5.42}$$

The variation of the satellite velocity $v$ with distance $r$ is determined from the conservation of the specific energy

$$\varepsilon = \frac{1}{2}v^2 - U = \frac{1}{2}v^2 - \frac{GM_\oplus}{r}\,, \tag{5.43}$$

which amounts to

$$\varepsilon = -\frac{GM_\oplus}{2a} \tag{5.44}$$

for an orbit of semimajor axis $a$. Therefore, to this order of approximation, the elapsed coordinate time is

$$\Delta t = \int_A^B \left(1 - \frac{1}{c^2}\frac{GM_\oplus}{2a} + \frac{1}{c^2}\frac{2GM_\oplus}{r}\right)\mathrm{d}\tau_\mathrm{p} = \left(1 - \frac{1}{c^2}\frac{GM_\oplus}{2a}\right)\Delta\tau_\mathrm{p} + \frac{2GM_\oplus}{c^2}\int_{t_0}^{t}\frac{1}{r}\mathrm{d}t\,. \tag{5.45}$$

In the last integral $\mathrm{d}\tau_\mathrm{p}$ has been replaced by $\mathrm{d}t$ as this term is a relativistic correction of order $1/c^2$.

For a Keplerian orbit the radial distance is given by

$$r = a(1 - e\cos E)\,,$$

where $e$ is the orbital eccentricity and $E$ is the eccentric anomaly. The eccentric anomaly is determined from the mean anomaly by Kepler's equation

$$M \equiv n\Delta t = E - e\sin E\,,$$

where

$$n \equiv \frac{2\pi}{T} = \sqrt{\frac{GM_\oplus}{a^3}}$$

is the mean motion and $T$ is the orbital period (Chap. 3). Therefore, the TCG elapsed as the clock records proper time $\Delta\tau_\mathrm{p}$ is approximately

$$\Delta t = \int_A^B \left(1 - \frac{1}{c^2}\frac{GM_\oplus}{2a} + \frac{1}{c^2}\frac{2GM_\oplus}{r}\right)\mathrm{d}\tau_\mathrm{p} = \left(1 + \frac{3}{2}\frac{1}{c^2}\frac{GM_\oplus}{a}\right)\Delta\tau_\mathrm{p} + \frac{2}{c^2}\sqrt{GM_\oplus a}\cdot e\sin E\,.$$

The second term is a periodic correction due to the orbital eccentricity that causes a residual variation in distance and velocity given by

$$\Delta t_{\mathrm{ecc}} = \frac{2}{c^2}\sqrt{GM_\oplus a}\cdot e\sin E = \frac{2}{c^2}(\boldsymbol{v}\cdot\boldsymbol{r})\,. \qquad (5.46)$$

To compare the proper time of a clock on a satellite with the proper time of a clock at rest on the geoid, it is necessary to convert from TCG to TT. By (5.41) and (5.42), the result is (TT)

$$\begin{aligned}\Delta t' &= (1-L_{\mathrm{G}})\Delta t\\ &= \int_{\mathrm{A}}^{\mathrm{B}}\left(1+\frac{1}{c^2}(U-W_0)+\frac{1}{2}\frac{1}{c^2}v^2\right)\mathrm{d}\tau_{\mathrm{p}}\,.\end{aligned}$$

Since $\Delta t' \approx \Delta\tau_{\mathrm{p0}}$, the interval of proper time recorded by a clock at rest on the geoid, which corresponds to the interval of proper time recorded by a clock on the satellite, is therefore given by

$$\begin{aligned}\Delta\tau_{\mathrm{p0}} = &\left(1+\frac{3}{2}\frac{1}{c^2}\frac{GM_\oplus}{a}-\frac{1}{c^2}W_0\right)\Delta\tau_{\mathrm{p}}\\ &+\frac{2}{c^2}\sqrt{GM_\oplus a}\cdot e\sin E\,. \qquad (5.47)\end{aligned}$$

It comprises a rate difference at the level of few parts in $10^{10}$ for common GNSS satellites as well as the eccentricity dependent periodic part with representative amplitudes of 10–100 ns. Both contributions and their practical implications for navigation satellite systems are further discussed in Sect. 5.4.5.

At the subnanosecond level of precision, it is necessary to take into account the orbital perturbations due to the harmonics of the Earth's gravitational potential, the tidal effects of the Moon and the Sun, as well as solar radiation pressure. Leading contributions result from the $J_2$ perturbation of the satellite position and velocity. Following [5.97], these give rise to a supplementary correction

$$\begin{aligned}\delta\Delta\tau_{\mathrm{p0}} = &\frac{7}{2}\frac{GM_\oplus R_\oplus^2}{a^3c^2}J_2\left(1-\frac{3}{2}\sin^2 i\right)\Delta\tau_{\mathrm{p}}\\ &-\frac{3}{2}\frac{R_\oplus^2}{a^2c^2}J_2\sqrt{GM_\oplus a}\sin^2 i\sin 2u \qquad (5.48)\end{aligned}$$

that needs to be considered on top of (5.47). Here, $i$ denotes the inclination of the satellite orbit while $u$ is the argument of latitude. Besides a drift correction, the $J_2$ contribution comprises a harmonic term of about 0.1 ns amplitude with a twice-per-revolution periodicity.

To fully account for the $J_2$ perturbation in the potential of (5.36), it is necessary to perform a numerical integration of the orbit and a numerical integration of (5.42). The tidal effects of the Moon and the Sun and solar radiation pressure should also be considered. For low-Earth orbits, both the zonal and tesseral gravitational harmonics are important and the usual eccentricity correction of (5.46) is no longer accurate. In this case, it is likewise preferable to integrate the orbit and integrate (5.42) numerically including the higher-order harmonics of the Earth's gravitational potential.

### Earth-Centered Earth-Fixed Coordinate System

Through terms of order $1/c^2$, the metric tensor components in the rotating Earth-centered Earth-fixed (ECEF) coordinate system are given by

$$\begin{aligned}-g_{00} &= 1-\frac{2U}{c^2}-\frac{||\boldsymbol{\omega}\times\boldsymbol{r}||^2}{c^2}\\ &= 1-\frac{2W}{c^2}\\ g_{0j} &= \frac{(\boldsymbol{\omega}\times\boldsymbol{r})_j}{c}\\ g_{ij} &= \delta_{ij}\,. \qquad (5.49)\end{aligned}$$

Using coordinate time TT, the elapsed coordinate time is

$$\begin{aligned}\Delta t' = &\int_{\mathrm{A}}^{\mathrm{B}}\left(1-\frac{1}{c^2}gh+\frac{1}{2}\frac{1}{c^2}(v')^2\right)\mathrm{d}\tau_{\mathrm{p}}\\ &+\frac{1}{c^2}\int_{\mathrm{A}}^{\mathrm{B}}(\boldsymbol{\omega}\times\boldsymbol{r})\cdot\boldsymbol{v}'\mathrm{d}\tau_{\mathrm{p}}\,, \qquad (5.50)\end{aligned}$$

where $h$ is the height of the clock above the geoid, $g$ is the local acceleration of gravity, $v'$ is the velocity of the clock relative to the geoid, and $\boldsymbol{r}$ and $\boldsymbol{v}'$ are the position and velocity vectors of the clock in the ECEF frame. It is assumed that $h$ is small. For high accuracy, the variation of $g$ with latitude and elevation should also be taken into account.

The second integral of (5.50) is the Sagnac effect for a transported clock. This effect may be expressed as

$$\begin{aligned}\Delta t_{\mathrm{Sagnac}} &= \frac{1}{c^2}\int_{\mathrm{A}}^{\mathrm{B}}(\boldsymbol{\omega}\times\boldsymbol{r})\cdot\boldsymbol{v}'\mathrm{d}\tau_{\mathrm{p}}\\ &= \frac{1}{c^2}\int_{\mathrm{A}}^{\mathrm{B}}(\omega R_\oplus\cos\phi)(v'\cos\theta)\mathrm{d}\tau_{\mathrm{p}}\\ &= \frac{\omega R_\oplus^2}{c^2}\int_{\mathrm{A}}^{\mathrm{B}}\cos^2\phi\,\mathrm{d}\lambda = \frac{2\omega A}{c^2}\,, \qquad (5.51)\end{aligned}$$

where $\phi$ is the latitude, $\lambda$ is the longitude, $v' \cos\theta$ is the eastward component of the velocity, and $A$ is the projection onto the equatorial plane of the area swept out by the position vector with respect to the center of the Earth (positive for the eastward direction and negative for the westward direction).

### 5.4.4 Propagation of Signals

This section deals with the computation of the coordinate time of propagation of signals when the transmitter and receiver positions are both given as expressed in the ECI, ECEF, and barycentric coordinate systems.

These equations apply in all cases. In particular, they must be used when setting the parameters of clocks on satellites that are steered to clocks on the Earth.

#### Propagation in ECI Coordinate System

When considering computation in an ECI coordinate system, the coordinate time of propagation (TCG) may be considered as the sum of a geometric part and a gravitational part. The geometric part is

$$\Delta t \approx \frac{1}{c} \int_{\text{path}} \sqrt{g_{ij} dx^i dx^j} = \frac{\rho}{c} , \tag{5.52}$$

where $g_{ij} \approx \delta_{ij}$ and $\rho$ is the geometric path length of the signal path.

If the signal is transmitted at coordinate time $t_T$ and is received at coordinate time $t_R$, the TCG of propagation over the path is

$$\begin{aligned} \Delta t = \frac{\rho}{c} &= \frac{1}{c} |\boldsymbol{r}_R(t_R) - \boldsymbol{r}_T(t_T)| \\ &\approx \frac{1}{c} |\Delta \boldsymbol{r} + \boldsymbol{v}_R(t_R - t_T)| \\ &\approx \frac{1}{c} |\Delta \boldsymbol{r}| + \frac{1}{c^2} \Delta(\boldsymbol{r} \cdot \boldsymbol{v}_R) , \end{aligned} \tag{5.53}$$

where the transmitter has position $\boldsymbol{r}_T$ and the receiver has position $\boldsymbol{r}_R$ and velocity $\boldsymbol{v}_R$ and where $\Delta \boldsymbol{r} \equiv \boldsymbol{r}_R(t_T) - \boldsymbol{r}_T(t_T)$ is the difference between the position of the receiver and the transmitter at the coordinate time of transmission $t_T$. The correction to the coordinate time due to the receiver velocity is

$$\Delta t_{\text{vel}} \approx \frac{\Delta \boldsymbol{r} \cdot \boldsymbol{v}_R}{c^2} . \tag{5.54}$$

Note that additional terms of order $1/c^3$ may amount to several picoseconds, depending on the configuration.

To consider the effect of the gravitational potential on an electromagnetic signal, it is necessary to include the potential in both the spatial and temporal parts of the metric. The components of the metric are

$$\begin{aligned} -g_{00} &= 1 - \frac{2U}{c^2} , \\ g_{0j} &= 0 , \\ g_{ij} &= \left(1 + \frac{2U}{c^2}\right) \delta_{ij} . \end{aligned} \tag{5.55}$$

Therefore, the elapsed TCG is

$$\begin{aligned} \Delta t &\approx \frac{1}{c} \int_{\text{path}} \sqrt{\frac{g_{ij}}{-g_{00}} dx^i dx^j} \\ &\approx \frac{1}{c} \left(1 + \frac{2U}{c^2}\right) \sqrt{\delta_{ij} dx^i dx^j} \\ &= \frac{\rho}{c} + \frac{1}{c^3} \int_{\text{path}} 2U \mathrm{d}\rho . \end{aligned} \tag{5.56}$$

The gravitational time delay is

$$\Delta t_{\text{delay}} = \frac{2GM_\oplus}{c^3} \ln\left(\frac{R + r + \rho}{R + r - \rho}\right) , \tag{5.57}$$

where $R$ and $r$ are the distances from the geocenter to the transmitter and receiver, respectively.

The gravitational delay typically amounts to a few tens of picoseconds for a path between a satellite and Earth. The total TCG is the sum of the terms in equations (5.53) and (5.57).

The coordinate time of propagation (TT) is

$$\begin{aligned} \Delta t' &= (1 - L_G) \Delta t \\ &= \frac{\rho}{c} - L_G \frac{\rho}{c} + \frac{2GM_\oplus}{c^3} \ln\left(\frac{R + r + \rho}{R + r - \rho}\right) . \end{aligned} \tag{5.58}$$

This is the time interval that would be measured by a clock on the geoid. For example, a signal sent from a geostationary satellite with orbital radius 42 164 km to a clock on the equator at the same longitude would have a path delay of −27 ps. For a GPS satellite at an elevation angle of 40°, the second and third terms nearly cancel so that the path delay is −3 ps.

#### Propagation in ECEF Coordinate System

When considering signal propagation in an ECEF coordinate system, the geometric part of the TCG is

$$\Delta t = \frac{1}{c} \int_{\text{path}} \sqrt{g_{ij} dx^i dx^j} + \frac{1}{c} \int_{\text{path}} g_{0j} \mathrm{d}x^j . \tag{5.59}$$

The metric components are

$$\begin{aligned} -g_{00} &\approx 1 \,, \\ g_{0j} &= \frac{(\boldsymbol{\omega}\times\boldsymbol{r})_j}{c} \,, \\ g_{ij} &\approx \delta_{ij} \,, \end{aligned} \tag{5.60}$$

where $\boldsymbol{r}$ is the position vector of a point on the signal path. The coordinate time (TT) is $\Delta t' = (1-L_G)\Delta t$.

The first term of (5.59) is $\rho'/c$, where $\rho'$ is the Euclidean path length in the ECEF coordinate system. If the transmitter has position $\boldsymbol{r}_T$ and the receiver has position $\boldsymbol{r}_R$ and velocity $\boldsymbol{v}'_R$, then

$$\begin{aligned} \frac{\rho'}{c} &= \frac{1}{c}|\boldsymbol{r}_R(t_R) - \boldsymbol{r}_T(t_T)| \\ &\approx \frac{1}{c}|\Delta\boldsymbol{r} + \boldsymbol{v}'_R(t_R - t_T)| \\ &\approx \frac{1}{c}|\Delta\boldsymbol{r}| + \frac{1}{c^2}\Delta\boldsymbol{r}\cdot\boldsymbol{v}'_R \,, \end{aligned} \tag{5.61}$$

where $\Delta\boldsymbol{r} \equiv \boldsymbol{r}_R(t_T) - \boldsymbol{r}_T(t_T)$.

The second term of (5.59) is the Sagnac effect. Therefore,

$$\begin{aligned} \Delta t_{\text{Sagnac}} &= \frac{1}{c^2}\int_A^B (\boldsymbol{\omega}\times\boldsymbol{r})\cdot\boldsymbol{v}'\,\mathrm{d}\tau_p \\ &= \frac{1}{c^2}\int_A^B (\boldsymbol{\omega}\times\boldsymbol{r})\cdot\mathrm{d}\boldsymbol{r} \\ &= \frac{1}{c^2}\int_A^B \boldsymbol{\omega}\cdot(\boldsymbol{r}\times\mathrm{d}\boldsymbol{r}) \\ &= 2\frac{1}{c^2}\int_A^B \omega\cdot\mathrm{d}A = \frac{2\omega A}{c^2} \,, \end{aligned} \tag{5.62}$$

where $A$ is the projection onto the equatorial plane of the area formed by the center of rotation and the endpoints of the signal path. The gravitational delay must also be considered to compute the total time of propagation.

### 5.4.5 Relativistic Offset for GNSS Satellite Clocks

As noted before, the Global Positioning System as well as all other GNSSs must incorporate relativistic effects in their normal operation. They provide a means of performing time and position measurements with satellite clocks on a practical scale and a validation of the accuracy and consistency of the algorithms is used in such measurements across a broad area of applications.

For measurements with a precision at the nanosecond level, there are three relativistic effects that must be taken into account. First, there is the effect of time dilation. The velocity of a moving clock causes it to appear to run slow relative to a clock on the Earth. GPS satellites revolve around the Earth with an orbital period of 11.967 h and a velocity of 3.874 km/s. Thus, on account of its velocity, a GPS satellite clock appears to run slow by 7 μs/d. Second, there is the effect of gravitational redshift. At an altitude of 20 184 km the difference in gravitational potential causes the satellite clock to appear to run fast by 45 μs/d. In addition, the effects contributed by the velocity of rotation and gravitational potential of the rotating geoid must be included. The net effect of time dilation and gravitational redshift is that the satellite clock appears to run fast by approximately 38 μs/d when compared to a similar clock on the Earth's surface, which is an enormous rate difference for a clock with a precision of a few nanoseconds. To compensate for this large secular effect, the GPS clock is given a fractional rate offset prior to launch of $-4.465\cdot10^{-10}$ from its nominal frequency of exactly 10.23 MHz, so that on average it appears to run at the same rate as a clock on the ground. The actual frequency of the satellite clock prior to launch is thus 10.22999999543 MHz. Similar considerations apply for the other navigation satellite systems, even though the apparent frequency is different for each constellation due to the specific orbital altitude and velocity of the various satellites.

Although the GPS orbits are nominally circular, there is always some residual eccentricity. The eccentricity causes the orbit to be slightly elliptical. Thus the velocity and gravitational potential vary slightly over one revolution and, although the principal secular effect is compensated by a rate offset, there remains a small residual variation that is proportional to the eccentricity. For example, with an orbital eccentricity of 0.02, there is a relativistic sinusoidal variation in the apparent clock time having an amplitude of 46 ns at the orbital period. By convention [5.98], the eccentricity-dependent periodic relativistic effect is removed in precise clock products of all GNSSs produced by the IGS and other providers, to obtain an essentially linear variation of the reported clock offset. With the exception of GLONASS [5.99], the same holds for broadcast clock offset values transmitted by the various GNSSs as part of their navigation messages [5.100–104]. This correction must therefore be calculated and taken into account in the user's receiver.

The third relativistic effect is associated with the universality of the speed of light. Thus the displacement of the receiver relative to an inertial frame during the time of flight of the signal must be included. In the Earth's rotating frame of reference, this property is called the Earth rotation correction or Sagnac effect. For a receiver at rest on the rotating geoid observing a GPS satellite, the maximum correction is 133 ns.

GPS has served as a laboratory for doing physics at the one-to-ten nanosecond level. The consistent application of relativity to GPS Time and position measurements has been demonstrated by the operational precision of the system and by numerous experiments designed to test these individual effects over a wide range of conditions.

A more robust treatment of relativity will be required for clock modeling and orbit determination in future GNSS generations that are looking for greater accuracy. At the subnanosecond level, relativistic effects must be included that are not modeled in the present system. One of the most important comes from the contribution to the redshift from the gravitational potential harmonic due to Earth oblateness [5.97]. There is a secular effect of approximately 0.5 ns/day and a periodic effect at half the orbit period with amplitude of 0.04 ns (corresponding to about 1 cm). While partly masked by thermal clock or bias variations, this effect has become discernible with the high precision provided by modern rubidium or hydrogen maser clocks of new GNSS satellites [5.88]. At the few picosecond level, it is also necessary to consider the tidal potentials of the Sun and Moon and the Earth's gravitation has an effect on the speed of propagation of light itself. That is, the gravitational potential causes the speed of propagation to depart slightly from the value of $c$.

## 5.5 International Timescales

The development of atomic clocks and their use in GNSS has made precise and accurate clock measurements and comparisons available globally. One of the first applications of this technology was in the comparison and generation of global timescales. Since these clocks generate *atomic time*, their use in GNSS is linked to global timekeeping of atomic time and the accuracy of this timekeeping is now such that the principles of relativity need to be taken into account.

Atomic time has become the basis of all physically realized timescales. A version of atomic time has been maintained continuously in various laboratories since 1955 although not formally adopted as an international timescale until 1971. Prior to the creation of the Bureau International de l'Heure (BIH) in 1920 at the Paris Observatory, timescales were based wholly upon astronomical observations and were not internationally agreed. The unit of time of the timescale in use was the second and it was likewise based on the astronomical observation of the length of a day.

With advent and operation of cesium atomic standards in the 1950s, and broadcast systems such as Long Range Navigation (LORAN) enabling accurate international comparison of these standards, these led to the initial form of Atomic Time (AT). The formation of International Atomic Time (TAI) was recommended by the International Astronomical Union (IAU) in 1967, the International Union of Radio Science (URSI) in 1969 and the International Radio Consultative Committee (CCIR) of the International Telecommunication Union (ITU) in 1970.

The 14th General Conference on Weights and Measures (CGPM) approved the establishment of TAI in 1971 as the relativistic coordinate time scale whose unit interval is the second of the International System of Units (SI) as realized on the rotating geoid. This established the SI second as the standard for the unit of time based on the hyperfine frequency of cesium 133 [5.105, 106].

### 5.5.1 International Atomic Time (TAI)

The International Atomic Time (TAI) is the metrologic timescale maintained by the Bureau des Poids et Measure (BIPM) since timekeeping responsibility was transferred to the BIPM from the BIH in 1988 [5.24, 107]. It is established as the basis of atomic clock comparison data supplied to the BIPM by participating timekeeping centers and laboratories and is generated by a particular algorithm for treating the data known as ALGOS [5.108].

TAI is defined as a coordinate timescale in a geocentric reference frame with the SI second as the scale unit realized on the rotating geoid. The fact that TAI is a coordinate timescale was determined by the Consultative Committee for the Definition of the Second in 1980 and the necessary framework for evaluating the relativistic terms in the establishment of TAI have been presented in Sect. 5.4.

The accuracy of TAI is a primary consideration in maintaining the SI second and providing a reliable reference scale in the long term [5.109]. The optimization

of the long-term stability is done at the expense of short-term accessibility. The calculation of TAI uses data over an extended period. Clock-comparison data are sent to the BIPM every ten days on days with the modified Julian date (MJD) ending in 9. Blocks of data covering 60 days are used in the calculation of the scale.

A period of 60 days was chosen to place the effective integration time of the scale at the transition between the flicker floor and the random walk frequency modulation of cesium clocks. Stability would therefore not be improved by a longer integration time. The period of 60 days is enough to smooth out the noise contributed by the time links (GNSS and other comparison techniques) and the white frequency modulation noise of the clocks. The monthly BIPM Circular T then alternates between provisional, based on only 30 days of data, and the definite, based on the full 60 days of data.

The determination of TAI [5.110] is then performed in three steps:

1. Calculation (using a post-processing, iterative procedure) of an intermediate scale, known as Echelle Atomique Libre (EAL) or Free Atomic Scale, using the clock comparison data and ALGOS
2. The evaluation of the duration of the scale unit of EAL using data from primary frequency standards and an optimum filter
3. The production of TAI from EAL by applying, if necessary, a correction to the scale interval of EAL to give a value as close as possible to the SI second. Correcting of the scale unit is known as *steering* and is done infrequently.

At a time $t$, the free atomic time scale EAL is defined in terms of the readings $h_i(t)$ of the group of $N$ clocks, $H_i$, contributed by the various timing centers, expressed as

$$\mathrm{EAL}(t) = \frac{\sum_{i=1}^{N} p_i [h_i(t) + h_i'(t)]}{\sum_{i=1}^{N} p_i} \,. \tag{5.63}$$

Here, $p_i$ is the statistical weight assigned to clock $H_i$ and $h_i'(t)$ is a time correction designed to ensure time and frequency continuity of the scale when either the weighting of individual clocks or the total number of clocks is changed [5.108, 111].

This expression cannot be used directly because the measured quantities that provide the basic data cannot be the readings of individual clocks but are comparisons between pairs of clocks. Such is the nature of timekeeping and clock measurements. At time $t$, the slowly varying differences $\zeta_{ij}(t)$ between clocks $H_i$ and $H_j$ are written as $\zeta_{ij}(t) = h_i(t) - h_j(t)$.

The output of EAL is $N$ values of the differences $x_i(t)$ defined by $x_i(t) = \mathrm{EAL}(t) - h_i(t)$, where $x_i$ are the differences between the individual clocks and the time defined by EAL. The difference can then be expressed as $x_i(t) - x_j(t) = -\zeta_{ij}(t)$, and (5.63) can be transformed into

$$\sum_{i=1}^{N} p_i x_i(t) = \sum_{i=1}^{N} p_i h_i'(t) \,. \tag{5.64}$$

In practice comparative data from the nonredundant system of $N-1$ time links between the timing centers is employed to solve for these last two expressions.

The weight assigned to each clock is calculated in such a way as to favor the long-term stability of the resulting scale. This also minimizes the annual fluctuations and frequency drift that the predominately commercial frequency standards maintained at the timing centers with respect to the primary timescale frequency standards. An important feature of the ALGOS algorithm is the fact that the evaluation of the weight of the clock, although based upon data covering a whole year, takes into account the 60 days of data for which EAL is being specifically computed. It is thus possible to judge clocks on their actual performance during the interval of time during which EAL is being established. It is also possible to take into account of any abnormal behavior observed in an individual clock by adjusting its weight, if necessary to zero. This has proved useful on many occasions.

The weight is normally based on the variance $\sigma_i^2(6,\tau)$ of mean rate with respect to EAL calculated over two-monthly samples [5.108]. This variance, instead of the usual pair variance, was chosen because it gives greater reduction in the weight of clocks showing a frequency drift. The weights are obtained directly from

$$p_i = \frac{1000}{\sigma_i^2(6,\tau)} \,, \tag{5.65}$$

with $\sigma_i$ expressed in nanoseconds per day, provided that over the current period of 60 days no abnormal behavior is apparent. In the case of abnormal behavior a weight of zero is assigned. A maximum weight of 100 is assigned to the 15% or so of clocks having $\sigma_i(6,\tau) \le 3.16\,\mathrm{ns/d}$. The maximum weight is chosen to ensure that the scale is heavily biased in favor of the best clocks without allowing any one to become predominant, no clock having a contribution greater than about 2%.

The time correction term

$$h_i'(t) = a_i(t_0) + B_{ip}(t)(t - t_0) \tag{5.66}$$

is made up of two components, where $a_i(t_0)$ is simply the time differences between the clock $H_i$ and EAL at a time $t_0$, which is the time at the beginning of the 60-day period, and $B_{ip}(t)$ is the predicted difference in rate between $H_i$ and EAL for the period between $t_0$ and $t$. The rate of clock $H_i$, for example, is defined by

$$\text{rate} = \frac{a_i(t_0 - t) - a_i(t_0)}{t - t_0} \,. \tag{5.67}$$

The prediction of $B_{ip}(t)$ is obtained by a one-step linear prediction based upon the previous value. This is justified by the fact that the period of 60 days is such that the predominant clock noise is random walk for which the most probable estimate for the value over the next period is simply that over the immediate preceding period. Having established the best estimate of EAL the transformation to TAI is made by the decision whether or not the rate of EAL differs sufficiently from the rate of the best primary standards to warrant a correction or *steering*. From 1984 to 1989, no steering was necessary and thus during this period TAI was in fact simply EAL with a constant frequency offset. Since then, several frequency changes of five parts in $10^{15}$ each have been found necessary.

Finally, the output of these calculations is presented in the monthly *Circular T* published by the BIPM and distributed to participating timing centers. This circular is alternately provisional or definitive depending upon whether it is issued in the middle or at the end of a 60-day calculation period.

### 5.5.2 Coordinated Universal Time (UTC)

The initial form of atomic time attempted prior to 1972 was to keep close agreement to astronomical time by adjusting both the frequency offset and fractional step adjustments of time broadcasts of atomic time signals with the Earth's rotation. Close coupling to the Earth's rotation was considered necessary to aid celestial navigation, however that system of adjustment was very difficult to coordinate between broadcast stations and provide a uniform accurate reference time. The present UTC system was adapted so that an approximation to the epoch of universal time (UT1), a version of universal time (sometimes called mean solar time) that is determined by the transit time of stars corrected for seasonal variations, and the interval of the SI second would be provided by a single scale. The history and development of these timescales is discussed in [5.112].

The current definition of Coordinated Universal Time (UTC) was developed by the Consultative Committee for International Radiocommunication (CCIR; now known as International Telecommunications Union Radiocommunication sector, ITU-R) [5.110]. It was a compromise solution to the international timescale between using TAI and continuing international time based on the rotation of the Earth. It is a stepped atomic time scale based on the rate of TAI adjusted by the addition or deletion of integer seconds, known as leap seconds, to maintain the time within 0.9 s of Universal Time (UT1), UTC is used to coordinate the reference time kept by the timing centers. The specific definition is maintained by ITU-R Recommendation TF.460.6 [5.110, 113]. Since UTC was adopted its use has grown considerably within the radio and telecommunications community.

UTC is specifically defined as $\text{TAI} - \text{UTC} = n$, an integer number of seconds, and $|\text{UT1} - \text{UTC}| < 0.9\,\text{s}$. In 2014, UTC is behind TAI by 35 seconds. The integer number of seconds' difference is adjusted by the use of *leap seconds* (either positive or negative) to maintain the relationship of UTC to UT1. For other uses dependent upon coordination with Earth orientation the difference can be further refined by the additional term DUT1 recommended to be broadcast for further adjustment of UTC. DUT1 is the *predicted* difference, UT1–UTC in integral multiples of 0.1 s. A user of UT1 can then adjust the accuracy to $< 0.1$ s. The decision of when to insert a leap second is determined by the variable change in the rotation rate of the Earth. The International Earth Rotation and Reference Service (IERS) monitors the rotation rate of the Earth along with the other Earth orientation parameters including the predicted value of DUT1. They determine the need to adjust UTC and advise the BIPM when to insert or delete the second.

As the needs of GNSS operations, broadcasting and timekeeping services require the generation and transmission of a *real-time* or immediate timescale and UTC itself is based on the rate of TAI which is a post-processed metrologic timescale, a real-time version was needed. This real-time version also needed to be produced from the same clocks and oscillators that produce the timekeeping data for TAI. To provide a real-time timescale timing centers produce a real-time representation of UTC and identify it by using the nomenclature UTC(k) where $k$ is the timing center. UTC without the qualifying parentheses and $k$ nomenclature would then identify the timescale referenced as the final international value determined by the BIPM. The centers maintaining a realization of UTC relating to the major GNSS and their values of UTC(k) are shown in Fig. 5.32.

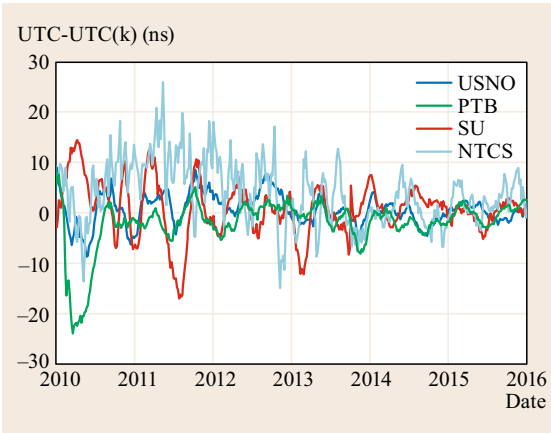

**Fig. 5.32** Values of UTC(k) realizations of UTC maintained by associated GNSS timing centers (after [5.114])

These qualifications are made in ITU-R Recommendation TF.536 on Time-Scale Notation [5.115]. The final determination of UTC does not have a physical output and is available after a delay of two to four weeks in the form of an offset from the representation maintained by a participating laboratory. The value for both TAI and UTC are disseminated by the BIPM via the monthly publication of *Circular T*. The offset of TAI and UTC with respect to participating observatories or laboratories is given in terms of TAI or UTC minus UTC(k). For example, UTC (USNO) is the delivered real-time prediction of UTC as maintained by US Naval Observatory.

UTC is recognized as the basis of global timekeeping and telecommunications use and is the only timescale that is physically realized and disseminated. The CCIR in 1978 and the World Administrative Radio Conference (Geneva) in 1979 recommended that UTC should be used to designate the time in all international telecommunication activities. The ITU *Radio Regulations* define UTC as the timescale based on the SI second, specified in Recommendation ITU-R TF.460, and notes that UTC may be regarded as the general equivalent of mean solar time at the Greenwich meridian. The global reference for GNSS and satellite time and frequency applications is UTC. Its use in GNSS and managing with its discontinuous nature will be discussed in the following sections.

## 5.6 GNSS Timescales

In order to achieve synchronicity within a GNSS a stable common time reference must be globally available for the supporting ground segment to provide precise observations of the satellites for computation of the data products needed to operate the system and support the many users. This time reference is most commonly achieved in today's GNSSs through generation of its own real-time internal timescale in each system. Classically, reference time for a system was provided by establishing a specific master clock whose signals were transmitted or distributed as the reference time for all system measurements. For a system of global extent this master clock approach is difficult. It is virtually the same problem as global timekeeping but on a real-time basis.

The approach developed to address this problem is to generate an internal timescale in real time that is in effect a virtual system timescale made from the measurements of the clocks within the system. The system timescale is therefore not physically realized by an actual clock output within the system. This virtual time reference is possible since the GNSS must be supported by a global network of tracking sites to track and provide data to a centralized site in real time. Here, *real-time* means that as the observational data is collected the system data is incrementally generated for the system. The computation of the satellite ephemerides and other navigation-related data, including the clock parameters of the satellites and ground supporting network, may be determined against a weighted average of the clock observed values.

The internal system reference timescale, GPS Time (GPST) for example, is produced in this manner. The process is similar to that of the international timescale being a weighted ensemble average of the physical clocks contributing to the operation of the system. Whereas the product of the international timescale is the publication of the offsets of the contributing time centers after the fact, a GNSS must have a real-time determination of the time within the system as the basis of system position and timing measurements. Consequently, the technique adopted has been the generation of a real-time weighed ensemble of the system's internal clocks that results in a time reference that is only physically realized by the clock output of the system's user receivers. The significant difference between the international timescale and the internal time reference is not just the real-time condition but the fact that the system time reference must deal with clocks of different characteristics. Classical ensembling for timescales deals with the same kind or similar clocks. With dissimilar types the combination of their stochastic characteristics has more complex computational difficulties.

An alternative approach to generating an internal system time reference is the more classical approach of considering the time reference to be independent of the system. Computationally the system's parameters would then consider time to be an independent value. The satellite and ground clocks could be monitored and maintained independently of the internal system operations through direct measurements of each clock, satellite or ground, using techniques such as two-way satellite time and frequency transfer (TWSTFT). This two-way technique is more commonly employed with communication satellites to compare clocks at ground sites but could be employed within a GNSS [5.116]. However, maintaining the clocks independently would lose the computational correlations with the other system parameters such as the satellite ephemerides since the precision and accuracy of the system measurements to the reference issue still needs to be minimized.

Consequently, within an internal time reference, observations are gathered passively and processed by the use of models, environmental measurements and other means of compensation of relevant observation effects necessary to relate the clocks to one another. A clock error model and timescale algorithm is then applied to the clock differences to produce estimates of the error of each clock relative to a stable virtual system timescale. Offset corrections of each satellite relative to its reference are then transmitted from each satellite in the form of predictions of the clock relative to System Time (ST) as part of its navigation message, along with the epoch of the prediction parameters so that offsets may be determined by the receiver software relative to the current epoch.

Variations of this approach are utilized by all of the major GNSSs, including GPS, GLONASS, Galileo, and BeiDou. Additional predicted corrections that relate the GNSS timescale to that of other systems and to UTC maintained by the timekeeping center associated with the particular system are also transmitted in the satellite system messages. Note that the GNSS ground segment upload interval for predicted navigation data to be transmitted by the satellites is primarily determined by the intrinsic stability of the satellite clocks. The more stable the satellite clock the less frequent an upload of the predicted clock corrections is necessary. For example, GPS satellites navigation uploads and clock prediction corrections in the 2015 time period are nominally once per day.

Table 5.2 summarizes the current relationship between each of the main quartet of GNSS times and UTC as well as the system's strategy for maintaining time. All system times except GLONASS Time are continuous timescales that do not apply leap seconds as are currently applied to UTC.

GNSS receivers that are capable of simultaneously tracking satellites from multiple GNSSs are increasingly available. Because each system provides corrections relative to its own internal ST the user of multi-GNSS signals must either sacrifice the additional degrees of freedom necessary to estimate the offsets between each GNSS ST or, where available, utilize any cross-GNSS offsets that are may be included in the navigation messages.

In the case of GPST, each GPS satellite carries multiple atomic clocks, however only one is used to generate the satellite transmissions at a time. The satellite clocks and monitor station clocks contribute to the statistical formation of the continuous system time known as GPS Time [5.117, 118], which is specified to be within 1 µs of UTC(USNO) modulo leap seconds since leap seconds are not inserted in GPS Time. GPST provides a time reference typically at a precision of better than 25 ns. However, depending upon the receiving equipment used in practice the precision can be 20 ns or better.

The epoch of GPST is midnight of January 5/6, 1980 UTC. Therefore, GPST is behind TAI by a constant value of 19 s. As of the beginning of 2016, GPST is ahead of UTC by 17 s which changes every time a leap second is applied to UTC. GPST is optimized for the navigation service, which requires short-term stability and uniform global distribution. For timing ap-

**Table 5.2** GNSS Times versus UTC for the main quartet of GNSSs. Each offset is separated into the whole number of seconds and its subsecond component $C_i$. Furthermore, $n = \text{TAI} - \text{UTC}$ denotes the integer second offset between International Atomic Time and Coordinated Universal Time (e.g., $n = 36$ s starting on 1 July 2015)

| | | |
|---|---|---|
| UTC – GPST | $0\,\text{h} - n + 19\,\text{s} + C_0$ | GPS Time (GPST) is steered to UTC(USNO), $C_0$ is required to be less than 1 µs but is typically less than 20 ns |
| UTC – GLST | $-3\,\text{h} + 0\,\text{s} + C_1$ | GLONASST (GLONASS Time) is steered to UTC(SU) including leap seconds. $C_1$ is required to be less than 1 ms. Note that GLONASST is offset from UTC by −3 hours corresponding to the offset of Moscow local time from the Greenwich meridian. |
| UTC – GST | $0\,\text{h} - n + 19\,\text{s} + C_2$ | Galileo Time (GST) is steered to a set of European Union UTC(k) realization and $C_2$ is nominally less than 50 ns. |
| UTC – BDT | $0\,\text{h} - n + 33\,\text{s} + C_3$ | BeiDou Time (BDT) is steered to UTC(NTSC) and $C_3$ is specified to be maintained less than 100 ns. |

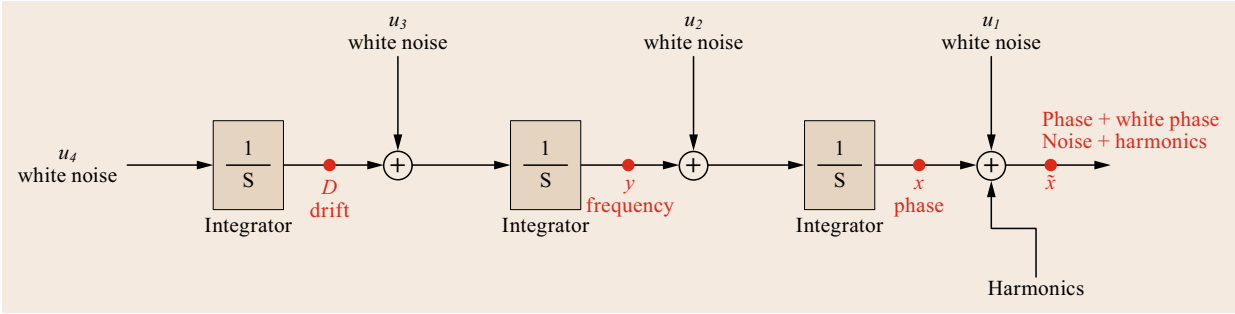

**Fig. 5.33** IGS v2.0 Clock Model

plications that require a source of UTC, the real-time predicted offset of UTC (as realized at USNO) with respect to GPS Time is available from the GPS broadcast navigation message [5.100].

Like GPS, Galileo has adopted a uniform system time (GST) that does not contain leap seconds [5.101]. The starting epoch for GST is 00:00 on 22 August 1999 UTC (midnight between 21 and 22 August 1999). At this starting epoch GST was set to be ahead of UTC by 13 seconds so as to be consistent with GPST. The epoch for the Chinese BeiDou navigation satellite system time (BDT) is 00:00 on 1 January 2006 UTC and is related to UTC through UTC(NTSC) [5.102].

A primary requirement for a satellite navigation system is a uniformly precise system of time so that the navigation service is not interrupted by adjusting clocks. Such has not been the case with the Russian GLONASS satellite navigation system, which uses UTC(SU) offset by three hours as its system time [5.99].

The International GNSS Service (IGS; Chap. 33) established by the geodetic community also determines their own observational timescale, known as IGS Time (IGST) for coherency of the measurement data collected globally by numerous agencies and sites. Its formation is similar to GPST [5.119, 120]. The clock model used in the second version of IGST implemented in 2011 [5.121] uses a basic four-state model for all the clocks, which is illustrated in Fig. 5.33.

The base model contains a deterministic phase $x$, the phase derivative (frequency) $y$, and the second derivative $D$ of phase (drift) each with an independent random walk component. An additional phase state $\tilde{x}$ is included to model a pure white phase noise and to couple it to any harmonic states. In accord with the observed clock behavior discussed in Sect. 5.3.6 four additional state parameters $a_{\omega_1}$, $b_{\omega_1}$, $a_{\omega_2}$ and $b_{\omega_2}$ are used to model up to two (once- and twice-per-revolution) harmonics that can appear in the satellite observations.

*Acknowledgments.* The authors would like to thank Dr. Joseph White, a colleague at the US Naval Research Laboratory, as well as Dr. Bob Nelson. Publication restrictions did not permit including Dr. White or Dr. Nelson in the authorship though many of the sections on individual atomic frequency standards and relativity were either contributed or edited by them.

# 6. Atmospheric Signal Propagation

Thomas Hobiger, Norbert Jakowski

Global navigation satellite system (GNSS) satellites emit signals that propagate as electromagnetic waves through space to the receivers which are located on or near the Earth's surface or on other satellites. Thereby, electromagnetic waves travel through the ionosphere and the neutral atmosphere (troposphere) which causes signals to be delayed, damped, and refracted as the refractivity index of the propagation media is not equal to one. In this chapter, the nature and effects of GNSS signal propagation in both the troposphere and the ionosphere, aref examined. After a brief review of the fundamentals of electromagnetic waves their propagation in refractive media, the effects of the neutral atmosphere are discussed. In addition, empirical correction models as well as the state-of-the-art atmosphere delay estimation approaches are presented. Effects related to signal propagation through the ionosphere are dealt in a dedicated section by describing the error contribution of the first up to third-order terms in the refractive index and ray path bending. After discussing diffraction and scattering phenomena due to ionospheric irregularities, mitigation techniques for different types of applications are presented.

## 6.1 Electromagnetic Wave Propagation

For a long period in the history of natural sciences, light was considered as the only part of the electromagnetic spectrum. Study of light has been conducted in ancient cultures and continued until the sixteenth and seventeenth centuries when the discussion about the nature of light, whether it can be described as a wave or as a particle, arose. It took another century, before electromagnetic waves other than light were studied. In 1800, William Herschel discovered infrared light and soon Johann Ritter noticed an effect which was later described as ultraviolet radiation. In 1845, Faraday discovered the polarization of light in dependence of the strength of a magnetic field and in the 1860s, James Maxwell developed four partial differential equations for the electromagnetic field. Maxwell soon realized that two of his equations predicted the existence and behavior of waves in the field. Furthermore, he noticed that such waves travel at a speed which was about the known speed of light. Maxwell's theory survived the groundbreaking discoveries of the next two centuries and his equations still represent one of the most elegant ways to express the fundamentals of electricity and magnetism. Based on these mathematical formulations, one can derive wave propagation characteristics that are valid for all wavelengths, which belong to the electromagnetic spectrum.

### 6.1.1 Maxwell Equations

Maxwell's equations in their classical form (e.g., [6.1]) can be expressed as

$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t} , \tag{6.1}$$

$$\nabla \times \boldsymbol{H} = \boldsymbol{J} + \frac{\partial \boldsymbol{D}}{\partial t} , \tag{6.2}$$

$$\nabla \cdot \boldsymbol{D} = \rho , \tag{6.3}$$

$$\nabla \cdot \boldsymbol{B} = 0 , \tag{6.4}$$

where the quantities $\boldsymbol{E}$ and $\boldsymbol{H}$ are the electric and magnetic field vectors, respectively. $\boldsymbol{D}$ and $\boldsymbol{B}$ denote the electric and magnetic flux densities, respectively, $\boldsymbol{J}$ represents the electric current density and $\rho$ is the volume charge density. Thereby, the $\nabla$ operator is defined in a 3-D Cartesian coordinate system $\mathbb{R}^3$, which is spanned by the orthogonal unit vectors $\{\boldsymbol{e}_x, \boldsymbol{e}_y, \boldsymbol{e}_z\}$ as

$$\nabla = \boldsymbol{e}_x \frac{\partial}{\partial x} + \boldsymbol{e}_y \frac{\partial}{\partial y} + \boldsymbol{e}_z \frac{\partial}{\partial z} . \tag{6.5}$$

In addition, $\cdot$ and $\times$ denote the inner and outer vector products, respectively. Together with the constitutive relations

$$\boldsymbol{D} = \varepsilon \boldsymbol{E} , \tag{6.6}$$

$$\boldsymbol{B} = \mu \boldsymbol{H} , \tag{6.7}$$

one can understand how electric and magnetic fields are generated and altered by each other and by charges and currents. The permittivity $\varepsilon$ and permeability $\mu$ are related to the electric ($\chi$) and magnetic ($\chi_\mathrm{m}$) susceptibilities of the material by

$$\varepsilon = \varepsilon_0 (1 + \chi) , \tag{6.8}$$

$$\mu = \mu_0 (1 + \chi_\mathrm{m}) , \tag{6.9}$$

where $\varepsilon_0$ and $\mu_0$ are the corresponding values in vacuum. Solving the classical Maxwell equations requires sophisticated methods and in many cases results in a numerical solution of the coupled partial derivative equations. However, if certain properties about the medium through which the electromagnetic waves propagate are known, simplification of above equations can be made and propagation characteristics can be derived more easily. This applies in particular for trans-troposphere and trans-ionosphere electromagnetic wave propagation.

### 6.1.2 Electromagnetic Wave Propagation in the Troposphere

Electromagnetic waves that are transmitted from GNSS satellites pass the ionosphere first, before entering the neutral atmosphere, in particular, the troposphere. In both media, electromagnetic signals are delayed and refracted, which causes an excess path delay that needs to be corrected in order to realize accurate positioning and timing applications. In order to find a solution for the wave propagation in the troposphere (Sect. 6.2), one can assume an isotropic, nonconducting and neutral medium. Thus, $\boldsymbol{J} = \boldsymbol{0}$ and $\rho = 0$ can be applied to (6.2) and (6.3), respectively. As shown by, for example, [6.2], one can derive the wave equations for the electric and magnetic field as

$$\nabla^2 \boldsymbol{E} = \mu\varepsilon \frac{\partial^2 \boldsymbol{E}}{\partial t^2} = \frac{n^2}{c^2} \frac{\partial^2 \boldsymbol{E}}{\partial t^2} , \tag{6.10}$$

$$\nabla^2 \boldsymbol{B} = \mu\varepsilon \frac{\partial^2 \boldsymbol{B}}{\partial t^2} = \frac{n^2}{c^2} \frac{\partial^2 \boldsymbol{B}}{\partial t^2} , \tag{6.11}$$

where

$$c = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} \tag{6.12}$$

is the speed of light in vacuum and

$$n = \sqrt{\frac{\varepsilon\mu}{\varepsilon_0 \mu_0}} \tag{6.13}$$

introduces the concept of the refractivity index. Thus, the knowledge of the refractivity index at any given location along the wave path allows to derive the propagation characteristics, in particular delay and damping of the electromagnetic wave. Before explaining these two phenomena exceeded on the electromagnetic wave, one needs to recall that the refractivity index $n$ is close to one. Thus, many publications introduce the so-called refractivity

$$N = (n - 1) \cdot 10^6 , \tag{6.14}$$

which avoids the usage of numbers that distinguish only very little from unity. Since the refractivity index $n$ is a complex number, refractivity $N$ consists of a real and an imaginary part. According to, for example, [6.3], $N$ can be expressed as

$$N = N_0 + N'(f) + \mathrm{j}N''(f) , \tag{6.15}$$

where the second and third terms reflect the frequency dependence of the refractivity and $\mathrm{j} = \sqrt{-1}$ denotes the imaginary unit. Since variations of $N$ over one wavelength are negligible for the troposphere in any of the GNSS bands, propagation effects of real and imaginary parts of $N$ can be dealt with separately. The real part of the refractivity, that is, $(N_0 + N'(f))$

causes electromagnetic waves to be refracted and delayed. Thus, a good model of this propagation behavior, respectively, the possibility to estimate such delays within post-processing will be a crucial issue for high accurate positioning applications. As described in [6.4], one can model the real part of the refractivity by

$$N = \sum_i \left( A_i(f)\rho_i + B_i(f)\frac{\rho_i}{T} \right), \tag{6.16}$$

where $\rho_i$ is the density of the $i$-th atmospheric gas, $T$ denotes the absolute temperature, and $A_i$ and $B_i$ are constants which are usually determined from experiments. If the composition and distribution of atmospheric gases were known with sufficient accuracy, one might be able to derive an empirical model for $N$ which can be used to deal with troposphere path delays in post-processing of GNSS data. This approach will be picked up and discussed further in Sect. 6.2.2.

The third remaining term in (6.15), that is, $N''(f)$, belongs to the imaginary part of the complex refractivity and is the reason for signal damping, also called attenuation or absorption. In general, $N''(f)$ can be related to the so-called absorption coefficient $\alpha(f)$ by

$$\alpha(f) = 1 \cdot 10^6 \frac{4\pi f N''(f)}{c}. \tag{6.17}$$

Based on this relation, it is possible to compute the receiving power $P$ of a signal which has been sent from transmitter Tr, propagates through the atmosphere along the path $S$ and captured at the receiver Rcv. In doing so, one obtains

$$P = P_0 \exp\left( \underbrace{-\int_{\mathrm{Tr}}^{\mathrm{Rcv}} \alpha(f)\mathrm{d}s}_{\kappa(S,f)} \right), \tag{6.18}$$

where $P_0$ denotes the received signal power in a lossless medium. Although absorption does not directly impact phase and group delay measurements, it has an impact on the quality of the GNSS measurements. Satellite signals tracked at low elevation angles have long propagation paths trough the atmosphere, which increases the opacity $\kappa(S,f)$, that is, the integral in (6.18), and thus attenuates the signals stronger than observations taken in the zenith direction.

### 6.1.3 Electromagnetic Wave Propagation in the Ionosphere

In order to solve the Maxwell equations for electromagnetic waves in the ionosphere, it is necessary to have more information about the physical properties of the medium, especially since $\boldsymbol{J}$ is not equal to zero. In general, a magnetic plasma, like the ionosphere, is an anisotropic and birefringent medium, which requires the usage of tensor notation for the conductivity $\tilde{\boldsymbol{\sigma}}$ and the dielectric coefficient $\tilde{\boldsymbol{\varepsilon}}$. Following the derivation from [6.5] one defines:

- The plasma frequency for electrons

$$f_\mathrm{p}^2 = \frac{e^2 n_\mathrm{e}}{4\pi^2 m_\mathrm{e} \varepsilon_0}. \tag{6.19}$$

- The electron gyro (or synchrotron) frequency

$$\boldsymbol{f}_\mathrm{g} = \frac{e}{2\pi m_\mathrm{e}} \boldsymbol{B}_\oplus. \tag{6.20}$$

- And the collision frequency of the electrons $\nu$.

Where $e$ and $m_\mathrm{e}$ are the charge and mass of the electron, respectively, $n_\mathrm{e}$ is the free electron density, $\boldsymbol{B}_\oplus$ is Earth's magnetic field vector, and $\varepsilon_0$ is the vacuum permeability defined already in the prior section. This leads to the abbreviations

$$X = \frac{f_\mathrm{p}^2}{f^2}, \quad Y = \frac{f_\mathrm{g}}{f}, \quad Z = \frac{\nu}{f}, \tag{6.21}$$

or

$$\tilde{X} = \frac{X}{1 + \mathrm{j}Z}, \quad \tilde{Y} = \frac{Y}{1 + \mathrm{j}Z}. \tag{6.22}$$

These yield the conductivity tensor $\tilde{\boldsymbol{\sigma}}$ (in a Cartesian coordinate system when the $z$-axis is assumed to be in the direction of $\boldsymbol{B}_\oplus$)

$$\tilde{\boldsymbol{\sigma}} = 2\pi f \varepsilon_0 \mathrm{j} \begin{pmatrix} \frac{\tilde{X}}{1-\tilde{Y}^2} & \frac{\mathrm{j}\tilde{X}\tilde{Y}}{1-\tilde{Y}^2} & 0 \\ -\frac{\mathrm{j}\tilde{X}\tilde{Y}}{1-\tilde{Y}^2} & \frac{\tilde{X}}{1-\tilde{Y}^2} & 0 \\ 0 & 0 & \tilde{X} \end{pmatrix}. \tag{6.23}$$

Moreover, the plasma can be treated neutral if the length of scale is bigger than the Debye length [6.6]. Together with Ohm's law

$$\boldsymbol{i} = \tilde{\boldsymbol{\sigma}} \boldsymbol{E}, \tag{6.24}$$

where $\boldsymbol{i}$ is the current density, one finds the dielectric tensor. This can be expressed as

$$\tilde{\boldsymbol{\varepsilon}} = \begin{pmatrix} 1-\frac{\tilde{X}}{1-\tilde{Y}^2} & \frac{\mathrm{j}\tilde{X}\tilde{Y}}{1-\tilde{Y}^2} & 0 \\ -\frac{\mathrm{j}\tilde{X}\tilde{Y}}{1-\tilde{Y}^2} & 1-\frac{\tilde{X}}{1-\tilde{Y}^2} & 0 \\ 0 & 0 & 1-\tilde{X} \end{pmatrix} . \tag{6.25}$$

Applying the dielectric tensor to Maxwell's equations and carrying out a few mathematical transformations one finds the expression

$$\boldsymbol{n} \times (\boldsymbol{n} \times \boldsymbol{E}) = -\tilde{\boldsymbol{\varepsilon}} \boldsymbol{E} \, , \tag{6.26}$$

where the refractivity index vector $\boldsymbol{n} = (c/f)\boldsymbol{k}$ has been assigned to the wave vector $\boldsymbol{k}$. As discussed in detail in [6.6] the Appleton–Hartree equation

$$n^2 = 1 - \frac{\tilde{X}(1-\tilde{X})}{1-\tilde{X}-\frac{\tilde{Y}_\mathrm{T}^2}{2} \pm \sqrt{\frac{\tilde{Y}_\mathrm{T}^4}{4} + \tilde{Y}_\mathrm{L}^2(1-\tilde{X})^2}} \tag{6.27}$$

serves as a solution for (6.26). Two new expressions were introduced in (6.27) by splitting $\tilde{Y}$ into two components. The longitudinal component $\tilde{Y}_\mathrm{L} = \tilde{Y}\cos\Theta$ and the transversal component $\tilde{Y}_\mathrm{T} = \tilde{Y}\sin\Theta$ account for the angle between the propagation direction and Earth's magnetic field. Again, the refractivity index is a complex quantity and the following properties of a magnetic plasma, such as the ionosphere, can be found:

- *Dispersive*: The index of refraction depends on the used frequency and it can be shown that the group velocity differs from phase velocity.
- *Absorptive*: The index of refraction is a complex number and the imaginary part, called extinction coefficient, describes the energy absorption. This process is dissipative as wave energy is converted into heat through collision processes.
- *Birefringent*: The index of refraction has two distinct values, which suggests the possibility of two ray paths; each one characterized by different phase and group velocities.
- *Anisotropic*: Each of the two indices of refraction is a separate function of the orientation of the normal to the surface of constant wave phase with respect to the background (uniform) magnetic field.

One of the biggest challenges for any system operating in the radio-frequency band is the determination of the propagation velocity of its signal. If such waves propagate through vacuum, the traveled distance would just be the product of speed of light in vacuum with the propagation time between sender and receiver. When signals travel through a magnetic plasma like the ionosphere, phase propagation speed accelerates and group velocity is slowed down.

## 6.2 Troposphere

Although the terms *atmosphere* and *troposphere* appear to be interchangeably, there exists a clear definition (Sect. 6.2.1) which suggests that the usage of the latter expression is more suitable when dealing with GNSS signal propagation effects. In general, the troposphere is the lowest portion of the Earth's atmosphere where approximately 80% of the atmosphere's mass and 99% of its water vapor and aerosols can be found. Since these constituents and their distribution are of great importance for GNSS signal propagation, in most cases the term *troposphere* is used to describe signal delays, attenuation, and scintillation effects. However, one should keep in mind that about 25% of the *tropospheric delay* is caused by gases which are located above the troposphere, in particular gases in the tropopause and the stratosphere.

### 6.2.1 Characteristics of the Troposphere

The word troposphere originates from the Greek expression *tropos* which can be translated as *change*. This reflects the fact that turbulent mixing plays an important role in the troposphere's structure and behavior. Most of the phenomena we associate with day-to-day weather occur in the troposphere. In general, the troposphere starts at the Earth's surface and can reach to a height of 20 km above sea level at maximum. However, in most regions of the world the troposphere reaches only up to roughly 10 km (Fig. 6.1). The prominent feature of this domain is that the temperature generally decreases with altitude at a constant lapse rate of −7 to −5 K/km of altitude. At higher latitudes in winter and at nighttime, a temperature inversion layer in a height between 0.5 and 2 km could exist before the constant lapse rate of the troposphere starts. The boundary between the top of the troposphere and the stratosphere is called the tropopause, which is a region of approximately constant or less varying temperature in a height between 8 and 12 km (Fig. 6.1).

According to the World Meteorological Organization, the tropopause is defined as the lowest level at which the lapse rate decreases to 2 K/km or less, pro-

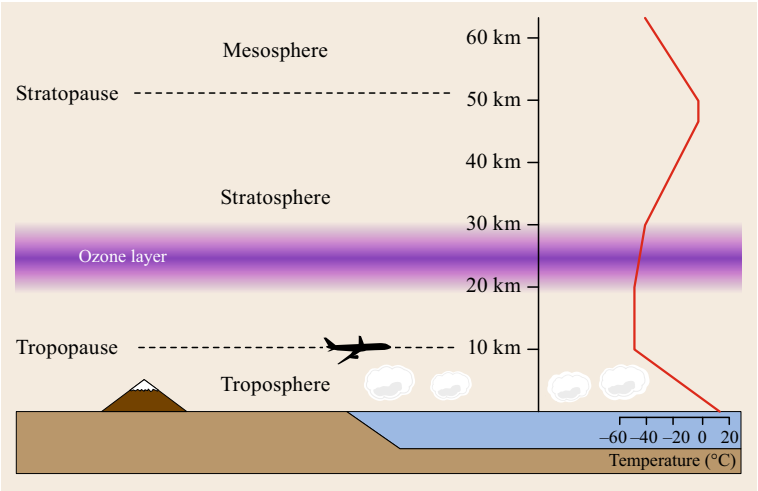

**Fig. 6.1** The troposphere is the lowest layer of Earth's atmosphere where weather happens and most of the clouds can be found. The layer up is the stratosphere, followed by the mesosphere. Distinction between the layers is made with vertical temperature lapse rates (see *curve* on the right side) as discussed in Sect. 6.2.1

vided that the average lapse rate between this level and all higher levels within 2 km does not exceed 2 K/km. The height of the tropopause depends on latitude, season, and whether it is day or night. Near the equator, the tropopause is about 20 km above the sea level. In winter near the poles the tropopause is much lower at about 7 km height. In the lower stratosphere, the rate of change of temperature gradually reverses to a positive temperature lapse rate of about 1–2 K/km. Such a slow, nonuniform increase exists through the whole height range of the stratosphere up to a height of roughly 50 km. At this altitude, which is called stratopause, the lapse rate reverses again and temperature will be around 0 °C. The region above the stratopause is called mesosphere that is characterized by a negative temperature lapse rate causing the temperature to drop to approximately −90 °C at a height of 90 km, where the mesopause marks the end of this atmospheric domain (Fig. 6.1). Knowing that the atmospheric pressure in the mesosphere is relatively small (0.02–1 hPa) and its behavior strongly follows the barometric formula (Sect. 6.2.3), one can understand that the small propagation delay contribution of the mesosphere can be neglected or well modeled if needed.

As shown in the next section, the wet and dry constituents of the atmosphere affect the propagation delay of GNSS signals in different ways. Pressure profiles of water vapor differ much from dry pressure, which follows a more deterministic behavior. Moreover, water vapor is confined to the troposphere, below about 10 km and most of it is found below 4 km. Other than the dry air components, the spatial and temporal distribution of water vapor is highly variable, which makes it difficult to explain phenomena related to this constituent with an empirical or climatological model. As discussed later in Sect. 6.2.4, GNSS post-processing allows to measure integrated water vapor by estimating its contribution together with the other unknown parameters.

On the other hand, dry atmosphere constituents are only varying little over temporal and spatial scales of hours and kilometers, respectively. Table 6.1 lists the molar weights and percentage on the total volume of the most prominent dry air constituents. Thus, propagation effects exerted from the dry air part can be well modeled and compensated with the help of empirical models. Besides wet and dry air, the atmosphere also contains aerosols (water droplets, ice crystals, salt grains, and dust particles). However, since they do not impact on GNSS signal propagation such constituents are not further discussed here.

**Table 6.1** Composition of the *clean dry* air in the standard US model throughout the troposphere. $N_2$, $O_2$, and Ar represent 99.96% of the total volume and its composition is is quite homogeneous and constant. $CO_2$ is the only constituent which vary at ground level between day and night by up to a factor of 2

| Constituent | Molecular mass (kg/kmol) | Percentage in total volume |
|---|---|---|
| $N_2$ | 28.013 | 78.084 |
| $O_2$ | 32.000 | 20.946 |
| Ar | 39.948 | 0.934 |
| $CO_2$ | 44.010 | 0.033 |

### 6.2.2 Tropospheric Refraction

As discussed in the prior section, the abundance of dry atmosphere constituents is remarkably homogeneous and constant. Moreover, the *wet part* of the atmosphere, that is, water vapor, is the only constituent which has a significant dipole moment that can influence the propagation of electromagnetic waves. Since contributions from liquid water droplets do not exceed millimeter order, they can be ignored for GNSS measurements and one can re-write (6.16) as the sum of three main constituents, that is,

$$N(f) = k_1(f)\frac{p_\mathrm{d}}{T}Z_\mathrm{d}^{-1} + k_2(f)\frac{p_\mathrm{w}}{T}Z_\mathrm{w}^{-1} + k_3(f)\frac{p_\mathrm{w}}{T^2}Z_\mathrm{w}^{-1} \tag{6.28}$$

as described in [6.7]. Thereby, the pressure of dry air $p_\mathrm{d}$ controls the first contribution and wet air pressure $p_\mathrm{w}$ governs the second and third contribution. In doing so, the compressibility factors for dry $Z_\mathrm{d}$ and wet $Z_\mathrm{w}$ air describe how these constituents differ from an ideal gas. Although (6.28) is still frequency dependent, one should keep in mind that by neglecting liquid water vapor, one has implicitly restricted the applicability to the electromagnetic propagation in the lower microwave spectrum. The compressibility factor $Z_i$, is the ratio of the molar volume $V_{\mathrm{m},i}$ of a gas $i$ to the molar volume of an ideal gas $\hat{V}_{\mathrm{m},i}$ at the same temperature $T$ and pressure $p$. This relation can be expressed as

$$Z_i = \frac{V_{\mathrm{m},i}}{\hat{V}_{\mathrm{m},i}} = \frac{pV_{\mathrm{m},i}}{RT} = \frac{pM_i}{\rho_i RT}\,, \tag{6.29}$$

where $R$ is the universal gas constant, $M_i$ is the molar mass of the $i$-th constituent, and $\rho_i$ the corresponding density. The usage of empirically determined values makes it is possible to derive a model for the incompressibilities, which depend only on temperature and the pressure. In doing so, [6.8] obtains

$$Z_\mathrm{d}^{-1} = 1 + p_\mathrm{d}\left[57.97\cdot 10^{-8}\left(1+\frac{0.52}{T}\right) - 9.4611\cdot 10^{-4}\,\frac{T_\mathrm{c}}{T^2}\right] \tag{6.30}$$

and

$$Z_\mathrm{w}^{-1} = 1 + 1650\,\frac{p_\mathrm{w}}{T^3}\,(1 - 0.0131\,T_\mathrm{c} + 1.75\cdot 10^{-4}\,T_\mathrm{c}^2 + 1.44\cdot 10^{-6}\,T_\mathrm{c}^3)\,, \tag{6.31}$$

where $T_\mathrm{c}$ is the temperature in degree Celsius, whereas $T$ is the absolute temperature in Kelvin. If the coefficients $k_i(f)$ are known with sufficient accuracy, one can derive wet and dry refractivity models which only depend on temperature, pressure and water vapor content.

In the following, only electromagnetic propagation effects in a frequency range below 40 GHz will be considered. Since all microwave-based space-geodetic techniques, including GNSS, operate in this frequency domain, a set of three coefficients, $k_1$, $k_2$, and $k_3$, without explicit frequency dependence will be sufficient to link between temperature, pressure, and water vapor pressure and total refractivity. Thus, (6.28) simplifies to

$$N = k_1\frac{p_\mathrm{d}}{T}Z_\mathrm{d}^{-1} + k_2\frac{p_\mathrm{w}}{T}Z_\mathrm{w}^{-1} + k_3\frac{p_\mathrm{w}}{T^2}Z_\mathrm{w}^{-1}\,. \tag{6.32}$$

Various measurements in laboratories and other studies have been carried out to determine accurate coefficients for the $k_\mathrm{i}$ values. A thorough discussion of the history of these measurements and the best average values according to [6.9] can be found in [6.10]. Table 6.2 lists these values, which should be used for GNSS processing and for conversion between nonhydrostatic delay and integrated water vapor.

The first term in (6.32) is sometimes referred as dry refractivity, whereas the second and third are called wet refractivity. However, in most of the literature another distinction is made, which expresses (6.32) under consideration of the relation (6.29) as

$$N = \underbrace{k_1\frac{R}{M_\mathrm{d}}\rho}_{N_\mathrm{h}} + \underbrace{k_2'\frac{p_\mathrm{w}}{T}Z_\mathrm{w}^{-1} + k_3\frac{p_\mathrm{w}}{T^2}Z_\mathrm{w}^{-1}}_{N_\mathrm{w}}\,, \tag{6.33}$$

where

$$k_2' = k_2 - k_1\frac{M_\mathrm{w}}{M_\mathrm{d}}\,. \tag{6.34}$$

Here, $N_\mathrm{h}$ is called hydrostatic refractivity and the sum of the latter two terms in (6.33) is called nonhydrostatic or wet refractivity. The introduction of mean molar masses of dry air, $M_\mathrm{d}$, and wet air, $M_\mathrm{w}$, enable the usage of the factor $k_2'$ for a better representation of (6.33). This way of expressing the refractivity budget has the advantage that the hydrostatic refractivity depends only on the total density of the air, which can be easily deduced from ground-based pressure measurements (Sect. 6.2.3). On the other side, the nonhydrostatic (or wet) part can be

**Table 6.2** Suggested values of the refractivity coefficients and their uncertainty (after [6.9])

| Coeff. | Value | Unit |
|---|---|---|
| $k_1$ | $77.6890 \pm 0.015$ | K/hPa |
| $k_2$ | $71.2952 \pm 10$ | K/hPa |
| $k_3$ | $375\,463 \pm 3000$ | $\mathrm{K}^2$/hPa |

related to temperature and water vapor pressure, a concept which allows the determination of highly variable water vapor variations by means of GNSS as described in Chap. 38.

Although a tiny frequency dependence of the refractivity exists in theory, simulations can show that such an influence on troposphere delays is below 0.2 mm for all elevation angles. Thus, the troposphere can be treated as a nondispersive medium, that is, $\mathrm{d}N/\mathrm{d}f = 0$. This feature simplifies the derivation of easy-to-apply troposphere propagation models, troposphere delay effects are identical for group- and phase delay observations. However, it also implies that troposphere excess delays cannot be removed by dual- or multifrequency measurements like in the case of trans-ionospheric propagation (Sect. 6.3.5). Therefore, it is necessary to estimate troposphere delays by a sophisticated functional model within the parameter adjustment process. In doing so, it is important to understand how to relate between refractivity $N$, respectively, index of refractivity $n$ and the troposphere signal delay. According to Fermat's principle, the path taken by an electromagnetic wave minimizes the total delay between the transmitter T and the receiver R. In doing so, the ratio between propagation time and speed of light (in vacuum) is called electric path length $L$ and can be expressed as

$$L = \int_{\mathrm{R}}^{\mathrm{T}} n(s)\mathrm{d}s\,, \tag{6.35}$$

where $\mathrm{d}s$ is an infinitesimal distance along the true ray path. In case of vacuum propagation, the index of refractivity equals one and the straight line which connects T and R becomes the ray-path. This straight line length $\overline{\mathrm{TR}}$ is called geometric distance $G$. As for the troposphere, $n > 1$ causes electromagnetic waves to propagate slower than in vacuum and continuous refraction causes the ray-path to be bent in according to Fermat's principle. Thus, one can determine the troposphere delay $\Delta L$ as

$$\Delta L = \int_{\mathrm{R}}^{\mathrm{T}} n(s)\mathrm{d}s - G\,. \tag{6.36}$$

If we recall the definition of refractivity (6.14), this equation can be reformulated as

$$\Delta L = 10^{-6}\int_{\mathrm{R}}^{\mathrm{T}} N(s)\mathrm{d}s + S - G\,, \tag{6.37}$$

where $S = \int_{\mathrm{R}}^{\mathrm{T}} \mathrm{d}s$ is the geometric length of the true (bended) propagation path. Together with (6.33) it is now possible to write

$$\Delta L = 10^{-6}\left(\int_{\mathrm{R}}^{\mathrm{T}} N_{\mathrm{h}}(s)\mathrm{d}s + \int_{\mathrm{R}}^{\mathrm{T}} N_{\mathrm{w}}(s)\mathrm{d}s\right) + \underbrace{S-G}_{\Delta_{\mathrm{g}}}\,, \tag{6.38}$$

which makes it clear that the total troposphere delay can be interpreted as the sum of three contributions. The first part is called hydrostatic delay

$$\Delta L_{\mathrm{h}} = 10^{-6}\int_{\mathrm{R}}^{\mathrm{T}} N_{\mathrm{h}}(s)\mathrm{d}s \tag{6.39}$$

and the second contribution is referred to as wet delay

$$\Delta L_{\mathrm{w}} = 10^{-6}\int_{\mathrm{R}}^{\mathrm{T}} N_{\mathrm{w}}(s)\mathrm{d}s\,. \tag{6.40}$$

Other than $\Delta L_{\mathrm{h}}$ and $\Delta L_{\mathrm{w}}$, which consider that electromagnetic waves are slowed down in the atmosphere, the last contribution $\Delta_{\mathrm{g}}$ originates from the bending effect, which causes signals to travel a longer path than the straight connection between T and R. For practical reasons when dealing with mapping functions (Sect. 6.2.3), $\Delta_{\mathrm{g}}$ is included in the hydrostatic part.

Since GNSS observations are taken at any arbitrary azimuth and elevation angle, one needs to know the hydrostatic and wet delay contributions at each of these observing directions in order to be able to remove the troposphere excess delay which biases the observations. However, as shown in Sect. 6.2.4, one is able to estimate troposphere parameters when assuming a relation between zenith troposphere delays and those observed at arbitrary elevations and the azimuth directions. Therefore, it is useful to introduce the zenith hydrostatic delay (ZHD)

$$\mathrm{ZHD} = 10^{-6}\int_{h_0}^{h_\infty} N_{\mathrm{h}}(z)\mathrm{d}z \tag{6.41}$$

and the zenith wet delay (ZWD)

$$\mathrm{ZWD} = 10^{-6}\int_{h_0}^{h_\infty} N_{\mathrm{w}}(z)\mathrm{d}z\,. \tag{6.42}$$

In doing so, vertical integration needs to be carried out from height $h_0$ to the upper height of the atmosphere $h_\infty$. As shown in the next section, empirical zenith delay models can be rather easily established due to the strong vertical alignment of the atmosphere.

### 6.2.3 Empirical Models of the Troposphere

Recalling (6.33), it is obvious that the hydrostatic delay depends only on the total density of the air. Following the idea of a hydrostatic equilibrium, a motionless fluid has zero net force on it and thus the sum of the forces in a given direction must be opposed by an equal sum of forces in the opposite direction. This hydrostatic balance can be expressed in a 1-D (vertical) case as

$$\frac{\partial p}{\partial z} + \rho(z) g(z) = 0 \,, \tag{6.43}$$

where $g(z)$ is the total gravity acceleration at a given height $z$. Integrating vertically provides the pressure $p_0$ at a given (geopotential) height $h_0$ by

$$p_0 = \int_{h_0}^{\infty} \rho(z) g(z) \mathrm{d}z = g_{\mathrm{eff}} \int_{h_0}^{\infty} \rho(z) \mathrm{d}z \,, \tag{6.44}$$

where the effective gravity $g_{\mathrm{eff}}$

$$g_{\mathrm{eff}} = \frac{\int_{h_0}^{\infty} \rho(z) g(z) \mathrm{d}z}{\int_{h_0}^{\infty} \rho(z) \mathrm{d}z} \tag{6.45}$$

was introduced. In doing so, $g_{\mathrm{eff}}$ is the gravity acceleration, which is representative for an atmosphere with density variation $\rho(z)$. As gravity is monotonically decreasing with height, one can interpret $g_{\mathrm{eff}}$ as the gravity acceleration at the centroid height $h_{\mathrm{c}}$ of the atmospheric column, that is,

$$h_{\mathrm{c}} = \frac{\int_{h_0}^{\infty} \rho(z) z \mathrm{d}z}{\int_{h_0}^{\infty} \rho(z) \mathrm{d}z} \,. \tag{6.46}$$

According to [6.11], the approximation

$$h_{\mathrm{c}} = (0.9\, h_0 + 7300\,\mathrm{m}) \tag{6.47}$$

holds for all latitudes and seasons with an uncertainty of about ±400 m. Thus, one can compute $h_{\mathrm{c}}$ and use this value to derive the effective gravity acceleration $g_{\mathrm{eff}}$ for any given location.

#### Pressure and Temperature Information

Almost all empirical models that are able to model troposphere delays for the analysis of GNSS data require, the user to input pressure values at the locations where the observations have been taken. Thus, unless a pressure sensor is installed at the site the user is left with the problem to obtain accurate pressure information, which can be used for the computation of hydrostatic and wet delay models. *Berg* [6.12] derived the simple empirical model

$$p = 1013.25\,\mathrm{hPa}\,(1 - 2.25 \cdot 10^{-5}\,\mathrm{m}^{-1}\, h)^{5.225} \,, \tag{6.48}$$

which provides pressure values for a given orthometric [6.13] height $h$. *Hopfield* [6.14] presented another, more sophisticated model for computing empirically pressure at a given height $h$. His approach considers a temperature lapse rate $\alpha = 4.5\,\mathrm{K/m}$ and reads as

$$p = 1013.25\,\mathrm{hPa} \left( \frac{T_{\mathrm{k}} - \alpha h}{T_{\mathrm{k}}} \right)^{\frac{g}{R_{\mathrm{d}}\alpha}} \,, \tag{6.49}$$

where $T_{\mathrm{k}} = 293.16\,\mathrm{K}$, that is, 20 °C, was assumed to be the temperature at the sea level. Together with the value for the mean gravity acceleration $g = 9.7867\,\mathrm{ms}^{-2}$ and the dry air gas constant $R_{\mathrm{d}} = 0.287\,\mathrm{kJ/K/kg}$ users are able to derive pressure in the case that no in-situ measurements were available at the ground site. However, with millimeter accurate GNSS observations, such models turned out to be insufficient for post-processing. Thus, users either need to extract accurate pressure values from numerical weather models (NWMs) or rely on more sophisticated empirical models for the computation of such values. For the latter choice, a variety of models have been presented recently, which are capable to provide accurate pressure information that does not bias or degrade the GNSS solutions. UNB3m [6.15], global pressure and temperature (GPT [6.16]), and GPT2 [6.17] are the most prominent models. The latter one is also recommended by the current conventions [6.18] of the International Earth Rotation and Reference Systems Service (IERS).

UNB3m was the first empirical model that could be used to obtain a good guess of meteorologic parameters in the case that no meteo sensor is available at a GNSS site. This model not only provides pressure and temperature and relative humidity, but also outputs other meteorologic information that might be useful for GNSS processing. However, as UNB3m was mainly derived from US standard atmosphere [6.19] data the model did not represent temporal variations other than those modeled by an annual signal. This drawback was partially overcome by the introduction of the GPT, which represents the meteorologic quantities in the form of spherical harmonic coefficients of degree and order 9. Although temporal variations are still limited to an annual term, the major advantage of GPT is the data source on which the coefficients were fitted. Other than UNB3m, GPT uses numerical weather model data to determine the empirical model coefficients. Thus, GPT had been suggested in the IERS conventions [6.18] for processing of space geodetic data before it was replaced by its successor, that is, GPT2. Like GPT, GPT2 is derived from numerical weather model data. However, spherical harmonics are replaced with gridded coefficients, semiannual terms are included and a more sophisticated up- and down-continuation algo-

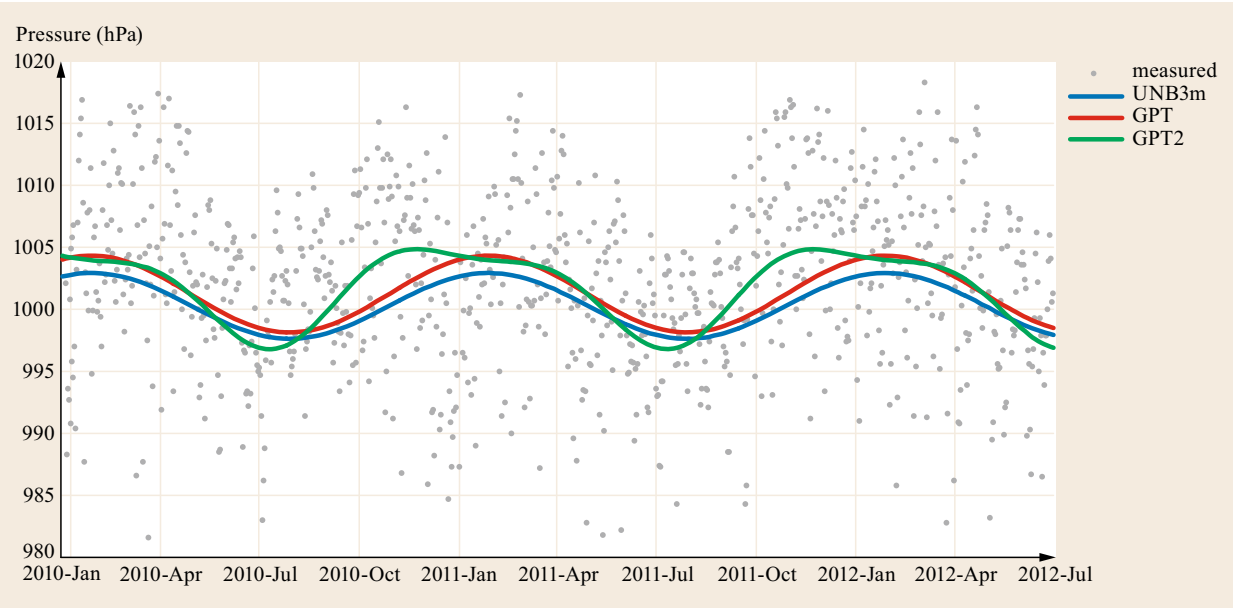

**Fig. 6.2** Daily pressure values (*dots*) at 12 h local time (i. e., 3 h UT) at Koganei, Tokyo, Japan, are plotted together with the pressure predictions from the UNB3m (*blue*), GPT (*red*), and GPT2 (*green*) models

rithm is being used to obtain temperature and pressure at the user's station. A comparison of modeled pressure values with predictions from three different pressure models is shown in Fig. 6.2.

### The Saastamoinen Hydrostatic Delay Model

Since hydrostatic delays are solely dependent on pressure, one can derive an accurate model for this part of the atmosphere delay quite easily. Considering (6.44) and replacing the vertical integration over the total air density in (6.33) yield

$$\mathrm{ZHD} = 10^{-6} k_1 \frac{R\, p_0}{M_\mathrm{d}\, g_\mathrm{eff}} \,, \tag{6.50}$$

which allows to relate the hydrostatic zenith delay directly to ground pressure $p_0$. In doing so, one needs to have an accurate empirical model for $g_\mathrm{eff}$ as defined in (6.45). References [6.11, 20] describe how to find such a relation based on a standard gravity model. They suggest using

$$g_\mathrm{eff} = 9.7840\,\mathrm{m/s^2}\,\kappa(\varphi, h_0) \tag{6.51}$$

with

$$\kappa(\varphi, h_0) = 1 - 0.00266\,\cos(2\varphi) - 0.28\cdot 10^{-6}\,\mathrm{m^{-1}}\,h_0 \,, \tag{6.52}$$

where $\varphi$ is the latitude of the site and $h_0$ has to be the geopotential height of the receiver (6.44).

### Wet Delay Models

Other than the hydrostatic delay contribution, wet delays are less accurately predictable from ground-based sensor data. Due to the high spatial and temporal variability of water vapor, one can only derive a model with limited capability to predict the ZWD

$$\mathrm{ZWD} = 10^{-6}\left(\int_{z_0}^{z_\infty}\left(k_2'\frac{p_\mathrm{w}}{T}Z_\mathrm{w}^{-1}\right)\mathrm{d}z + \int_{z_0}^{z_\infty}\left(k_3\frac{p_\mathrm{w}}{T^2}Z_\mathrm{w}^{-1}\right)\mathrm{d}z\right). \tag{6.53}$$

at a given site. According to [6.10], the first term is about 60 times smaller than the second one in (6.53). Various models for ZWD have been proposed for space geodetic applications. For example, *Saastamoinen* [6.11] focused on the ideal gas law and developed the simple formula

$$\mathrm{ZWD} = 0.0022768\,(1255 + 0.05\,T_\mathrm{s})\frac{p_\mathrm{ws}}{T_\mathrm{s}} \,, \tag{6.54}$$

which provides a reasonable estimate of the wet delay contribution when temperature $T_\mathrm{s}$ and water vapor pressure $p_\mathrm{ws}$ are measured at the site. *Hopfield* [6.14] followed another approach, leading to the basic relation

$$\mathrm{ZWD} = \frac{10^{-6}}{5} N_\mathrm{w}(h_\mathrm{s}) h_\mathrm{w} \,, \tag{6.55}$$

where $N_w(h_s)h_w$ is the wet air refractivity at the site (at height $h_s$) and $h_w = 11\,000$ m is the assumed height of the tropopause under which water vapor can be found. Besides various other models, the suggestion from [6.21] is also worth to be mentioned here as it suggests the simple linear relation

$$\mathrm{ZWD} \approx 0.217 \frac{p_w}{T} , \tag{6.56}$$

which can be used as a good approximation for a-priori ZWDs. As discussed in [6.10], one can derive from this model an approximation based on ground meteo data, that is,

$$\mathrm{ZWD} \approx 748 \frac{p_{ws}}{T_s^2} . \tag{6.57}$$

For applications with even less accuracy requirements on ZWD, one can use the rule of thumb estimate

$$\mathrm{ZWD} \approx \frac{p_{ws}}{100} \tag{6.58}$$

when the surface water vapor pressure $p_{ws}$ is given in units of hPa. All empirical models for wet delay prediction (6.91)–(6.96) have in common that they rely solely on surface or site dependent data. Such models will give reasonable estimates of ZWD for standard meteorologic conditions, but fail to predict ZWDs with centimeter accuracy for weather situations that deviate from such an assumption. Given the rather low accuracy of such models, ZWDs are usually estimated whenever enough satellites are tracked in order to separate this delay contribution from station coordinates and clock parameters. For applications that target lower accuracy, the wet delay contribution might be either neglected or approximated by one of the models listed above.

### 6.2.4 Troposphere Delay Estimation

Empirical troposphere models which were discussed in the prior section have been only defined for the zenith direction. Thus, one needs to have a good mathematical model which relates between zenith troposphere delays and the actual delay at a given elevation angle. In addition, if the accuracy requirements of a GNSS application do not permit to apply empirical troposphere delay corrections, one needs to estimate such excess delay together with the other unknown parameters. Both issues can be dealt with when introducing the concept of mapping function, which are discussed here.

#### Separation of Parameters

GNSS observations, that is, code and carrier phase measurements, are affected by troposphere delays in the same way. Other than ionosphere delays, which can be canceled out (at first-order) by dual-frequency measurements (Sect. 6.3.5), propagation through the neutral atmosphere (troposphere) does not cause dispersive delays on GNSS measurements. Although various approaches for modeling troposphere delays have been discussed in the prior sections, it is important to recall that all these models are available in the zenith direction. Thus, if troposphere excess delays should be corrected by such models only, one needs to have a mathematical approach that relates between a delay in the zenith direction ($\tau(E = 90°)$) and the one observed at a given elevation angle ($\tau(E)$). Defining a so-called mapping function (Sect. 6.2.4)

$$M(E) \approx \frac{\tau(E)}{\tau(E = 90°)} , \tag{6.59}$$

which approximates the fraction on the right with sufficient accuracy, allows to apply a-priori zenith troposphere corrections for GNSS observations at arbitrary elevation angles. However, since such models, in particular those for the wet troposphere delays, are limited in their accuracy, one needs to chose another approach to remove troposphere delays when realizing highly precise applications by means of GNSS. Thus, instead of only correcting troposphere delays by a-priori models, one can estimate troposphere excess delays by making use of the mapping function approach. Assuming that mapping functions for hydrostatic ($M_h(E)$) and wet ($M_w(E)$) are provided in a convenient form, one can apply the following two-step processing strategy:

1. Since hydrostatic zenith troposphere delays can be computed with high accuracy, one can use, for example, the Saastamoinen model (Sect. 6.2.3) for deriving ZHD at a given GNSS site. Together with a proper mapping function ($M_h(E)$), this information can be transformed into slant troposphere delays at any elevation angle. Such delays can be applied as corrections in post-processing, respectively, in the parameter adjustment process. Since hydrostatic delays are the dominating contributor to the troposphere delay budget, more than 85% of any total troposphere delay can be accounted for by this approach.
2. The remaining troposphere delays, which are thought to be attributable to wet delays need to be estimated within the parameter adjustment process. This is usually realized by adding a time-dependent representation of ZWD as additional parameters which are estimated together with the other unknown parameters. In order to separate wet troposphere delay from the other parameters, one takes

advantage from the mapping function approach which introduces an elevation dependent scaling factor, that is, $M_w(E)$, for each observation.

The mapping function $M(E)$ follows $\approx 1/\sin(E)$ in first-order and thus provides a unique partial derivative for least squares extended Kalman filter or other adjustment methods. Figure 6.3 discusses parameters, that is, station position, clock, and troposphere, which can be separated together due to different elevation dependent behavior. Thus, when estimating troposphere parameters together with the other unknowns, one should make sure that a sufficient number of observations at different elevation angles are taken in order to properly separate the different physical signals.

### Mapping Functions

The simplest form of any mapping function can be obtained through the rather crude assumption of a plane earth together with a horizontally stratified atmosphere where no variations of the refractivity occur within a layer. Ignoring bending effects, the path delay will then simply be proportional to the propagation path length in each layer and the mapping function will be identical to the cosecant function, that is,

$$M(E) = \csc E = \frac{1}{\sin E} \,. \tag{6.60}$$

This simple approximation works surprisingly well, having an error of about 1% (corresponding to approximately 2 cm for the zenith component of total delay at a sea level site) for an elevation angle of 20°. However, in order to improve the positioning results and take into account observations from lower elevations, such a simple mapping function approximation does not work well for applications with a higher demand on accuracy. Obviously, the cosecant mapping function can be improved by introducing a spherical earth instead of a plane model. In order to have a slightly better treatment of the hydrostatic and wet components separately, *Chao* [6.22] derived the following expressions that also depend on the elevation angle only

$$M_h(E) = \frac{1}{\sin E + \left(\frac{0.00143}{\tan E + 0.0445}\right)} \tag{6.61}$$

and

$$M_w(E) = \frac{1}{\sin E + \left(\frac{0.00035}{\tan E + 0.017}\right)} \,. \tag{6.62}$$

They were recommended to be used down to elevation angles of approximately 15°. There are also other models suggested by *Chao* [6.22] with similar accuracy [6.23, 24]. Further improvements can be made by using models for the pressure, temperature, and humidity profiles. Several different versions of such mapping functions were developed and published in [6.14, 25–28]. The advantage with this type of mapping function is that the result is a closed-form solution where the input parameters are surface meteorology and parameters describing the characteristics of the pressure, temperature, and humidity profiles.

In general, it is important to mention that hydrostatic mapping function does not only model the ratio between slant and ZHDs, but also account for the extra delay caused by signal bending in the atmosphere. This convention ensures that wet mapping functions, deliver only the wet component of the troposphere delay, when being applied in parameter adjustment.

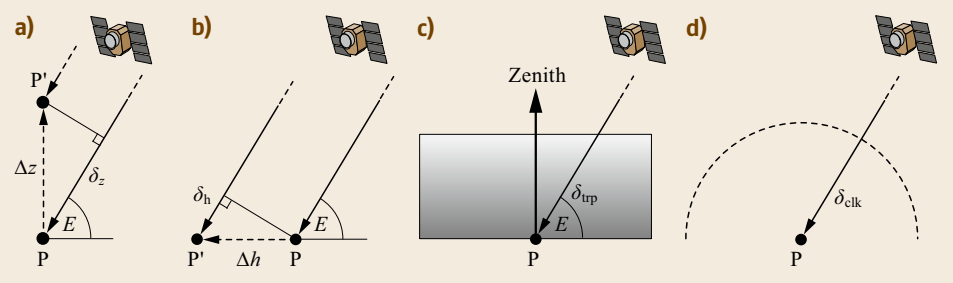

**Fig. 6.3a–d** Elevation dependency of different target parameters. **(a)** A change in the vertical $\Delta z$ leads to an extra delay path which can be expressed as $\delta_z(E) = \Delta z \sin(E)$. **(b)** A change in the horizontal component $\Delta h$ causes a delay of $\delta_h(E) = \Delta h \cos(\varepsilon)$ (Note: Here a two-dimensional (2-D)-case, with the horizontal displacement aligned toward the satellite, is being depicted for better readability. For a three-dimensional (3-D) case one needs to add the azimuth dependency for the two components.) **(c)** Troposphere delays depend on the mapping function, which in first-order can be approximated by $\delta_{trp}(E) \sim \delta_{trp}(E = 90°)\, 1/\sin(E)$. **(d)** A clock offset appears to be isotropic, that is, independent from the elevation angle

### Mapping Functions of the Continued Fraction Form

The use of the continued fraction form for the mapping function was suggested by *Marini* [6.29] and reads as

$$M(E) = \frac{1}{\sin E + \frac{a}{\sin E + \frac{b}{\sin E + \frac{c}{\sin E + \ldots}}}} \,. \tag{6.63}$$

Based on ray-tracing through standard atmospheres models various authors determined the coefficients $a$, $b$, and $c$ as functions of pressure, water vapor pressure, and temperature on the Earth surface, or from temperature gradients and the height of the troposphere. The MTT (Mapping Temperature Test) mapping function [6.30] can be seen as an extension of this mathematical approach, but is modified so that the value of the mapping function is one in the zenith direction. It is formulated as

$$M(E) = \frac{1 + \left[\frac{a}{(1+b/(1+c))}\right]}{\sin E + \left[\frac{a}{\sin E + (b/(\sin E + c))}\right]} \,. \tag{6.64}$$

The parameters $a$, $b$, and $c$ depend here on ground surface temperature, the station latitude, and the orthometric height of the station, respectively. We note that the only parameter that needs to be measured is the temperature at the ground. The values of the empirical parameters are also derived here through ray tracing, not using a standard atmospheres model but a set of radiosonde data. A potential problem (or difficulty) with the Harvard–Smithsonian Center of Astrophysics (CfA-2.2, [6.20]), the Ifadis, and the MTT mapping functions is that they all use ground surface observations of meteorological parameters. Temperature inversions often introduce errors in these mapping functions where a too low surface temperature implies an underestimation of the temperature at higher altitudes. We also note that in addition to the work involved to obtain surface observations there is always the risk that poor instrumentation can introduce gross measurement errors. These potential measurement errors are often ignored in the analysis carried out in order to compare the accuracy of different mapping functions. This was the main motivation for *Niell* to formulate the Niell mapping function (NMF) [6.31]. The advantage of the NMF is that its parameters do not need any observations of ground meteorology. It is sufficient to know the time of the year, the latitude, and the height of the site. One may suspect that the NMF could be less accurate at extreme sites since it cannot be tuned to local weather conditions by means of surface observations. We have, however, not seen any such findings reported up until now. The NMF was, for example, tested on data from Chajnantor, a very dry site at a height of 5 km in Chile, with good results [6.32].

### Mapping Functions Based on NWP Model Results

The ultimate mapping function is of course only possible to obtain for a complete knowledge of the 3-D refractivity field in the atmosphere above the actual GNSS site. A method using data from either a climatological model or numerical weather prediction (NWP) analyses was developed and presented by *Rocken* et al. [6.33]. They refer to this method as *direct* mapping since its value at any specified elevation angle is obtained through a ray-tracing analysis based on vertical profiles of pressure, temperature, and humidity. In the study presented, one mapping function per day was computed and compared to ray-trace results from collocated radiosonde launches. Of course, this method can be developed further using the full 3-D-fields in order to also take possible azimuthal asymmetries into account. It will, however, mean that the number of ray-traces has to be significantly larger. *Niell* [6.34] developed the first mapping functions based on (6-hourly) data from NWM. An azimuthal symmetric mapping function for the hydrostatic delay was developed following the three term continued fraction form but with the additional parameter being the 200 hPa geopotential height obtained from NWM analysis. Since the hydrostatic mapping function is based on the height of the 200 hPa pressure level, it is called the isobaric mapping function (IMF). The IMF offered an improvement of approximately a factor of two compared to the NMF [6.34, 35]. The Vienna mapping functions (VMFs) [6.36] and VMF1 [6.37] have been developed along the same lines as the IMF but focusing on direct ray-tracing of the NWP reanalyses from the European Centre for Medium Range Weather Forecasting (ECMWF). The gridded and site-wise mapping function coefficients can be downloaded at [6.38]. The result from ray-tracing at an elevation angle of 3° is used to determine the value of the parameter $a$ in the NMF type of formula. They recommend the use of direct mapping functions rather than using the intermediate parameters, such as the geopotential height at the 200 hPa pressure level. The University of New Brunswick (UNB) [6.39] is also calculating VMF1 coefficients, using data from the NWM of the National Centers for Environmental Prediction (NCEP) and an NVM of the Canadian Meteorological Centre (CMC). They call it UNB-VMF1 and the parameters can be retrieved from [6.40]. Also the Deutsche GeoForschungsZentrum Potsdam (GFZ) is working on a realization of the VMF1 and other developments related to ray-tracing and mapping functions.

The global mapping functions (GMFs) [6.41] serve as a blind, or climatologic, counterpart to the VMF1. Recently, there was an update to GMF, called GPT2 [6.17], also providing improved blind pressure values at the sites. GMF and GPT2 are in the tradition of the mapping function [6.31].

In recent years, there has been considerable research on mapping functions, for example, the *adaptive mapping function* described in [6.42]. At some point, a clear separation between mapping functions and ray-tracing is no longer possible with the new developments. For any observation, the slant and the corresponding zenith delay can be determined by ray-tracing, the ratio being then called slant factor or mapping functions. The use of ray-tracing for tropospheric delay correction has, for example, been studied in [6.43–45].

#### Gradients

Mapping functions, as discussed in the prior section, work under the assumption of an azimuthal symmetric atmosphere around the GNSS site. However, due to local and regional climatic and weather conditions, atmosphere delays at a constant elevation angle will slightly vary with the azimuth direction. In order to account for such an effect, the so-called gradients need to be estimated together with the wet troposphere delays for utmost high precise positioning applications. Currently, two gradient mapping functions have been suggested to model the dependence on the azimuth angle $A$. *MacMillan* [6.46] proposes to use the simple form

$$M_{\mathrm{gr}}(A,E) = M_{\mathrm{h}}(E)\cot E\,(G_{\mathrm{N}}\cos A + G_{\mathrm{E}}\sin A) \tag{6.65}$$

for estimating the two horizontal gradients, that is, $G_{\mathrm{N}}$ in the north–south direction and $G_{\mathrm{E}}$ in the east–west direction. One has to use the hydrostatic mapping function $M_{\mathrm{h}}(E)$ as described in [6.35]. In [6.47], the gradient mapping function

$$M_{\mathrm{gr}}(A,E) = \frac{1}{\sin E\tan E + C}(G_{\mathrm{N}}\cos A + G_{\mathrm{E}}\sin A) \tag{6.66}$$

is suggested, which does not depend on another (hydrostatic) mapping function, but considers elevation dependency by its own model. *Chen* and *Herring* [6.47] suggest to use $C = 0.0031$ and $C = 0.0007$, if one estimates hydrostatic and wet gradients separately. However, such a separation is hardly used nowadays, and only total gradients are estimated within post-processing. In doing so, one should use $C = 0.0032$ as discussed in [6.30].

## 6.3 Ionospheric Effects on GNSS Signal Propagation

To understand transionospheric radio wave propagation and related effects on GNSS signals, we will briefly describe the main features of the ionosphere which are relevant for the subsequent discussion.

### 6.3.1 The Ionosphere

The ionosphere is the ionized part of the Earth's atmosphere, ranging from about 50 km up to about 1000 km height. Above the so-called transition region at around 1000 km height the ionized and co-rotating atmosphere is usually called plasmasphere or protonosphere reaching up to the plasmapause height at about 3–5 Earth radii in the equatorial plane. The term *plasmapause* characterizes the boundary to the outer magnetosphere. The ionospheric plasma is basically generated by solar radiation, which dissociates and ionizes neutral molecules and atoms. Since the energy of solar radiation in the visible (V) and infrared (IR) wavelength ranges is too low to ionize the neutral gas, they can reach the Earth's surface (Fig. 6.4).

The main constituents (i. e., O, $O_2$, N, $N_2$, NO) of the upper atmosphere are ionized by the solar radiation in the far and extreme ultraviolet (EUV) wavelength ranges ($\lambda < 130$ nm) as well as by high energetic solar x-rays. To a less extent, cosmic rays and energetic particles originating from the solar wind may also contribute to the ionospheric ionization. Consequently, the plasma is composed by a variety of different atomic and molecular ions interacting in a complex way by photochemical reactions. Basic processes can be described by the continuity and energy equations and equations of motion for the individual charged particles taking into account that the total number of ions is equal to the number of electrons in the ionospheric plasma indicating quasi-neutrality of the ionosphere. The fundamental continuity equation for the electrons is given by

$$\frac{\partial n_{\mathrm{e}}}{\partial t} = Q_{\mathrm{e}} - L_{\mathrm{e}} - \nabla\,(n_{\mathrm{e}}\,v_{\mathrm{e}})\,, \tag{6.67}$$

where $n_{\mathrm{e}}$ is the electron density, $t$ is the time, $Q_{\mathrm{e}}$ is the rate of electron production, $L_{\mathrm{e}}$ is the rate of electron loss, and $v_{\mathrm{e}}$ is the mean velocity of the electrons [6.6]. The divergence term stands for the net loss/gain of plasma due to transport processes. It is evident that density, composition, and temperature of the neutral gas

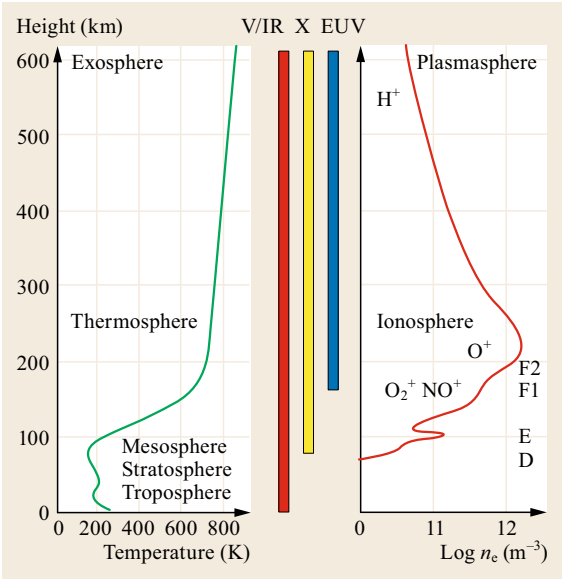

**Fig. 6.4** Vertical structure of the electron density of the ionosphere (*right*) in comparison with the neutral atmosphere temperature (*left*) and solar radiation penetration depths (*middle*)

have a severe impact on production, loss, and transport terms in the continuity equation.

The strong coupling of the ionosphere with the thermosphere is due to the fact that the plasma is a trace gas in the neutral gas with an ionization degree of about $10^{-3}$ at the F2 layer height. Thus, it becomes clear that thermospheric density affects all terms in the continuity equation (6.67). To give only a few examples: the higher the atomic oxygen density – the higher the photo-production; the higher the molecular densities – the higher the loss term. Transport processes due to diffusion and neutral winds depend also on thermospheric conditions. Thus, collisions between neutrals and charged particles as ions and electrons impact neutral winds by ion-drag. On the other hand, neutral winds may lift up the ionospheric plasma up and down along the geomagnetic field lines. Separation of electrons and ions by neutral winds may cause electric fields that are able to drive electric currents. Electric conductivity of magnetospheric origin may generate strong currents in the lower ionosphere where the electric conductivity maximizes around 100 km height (Fig. 6.4). Electric currents, on the other hand, may significantly heat the thermosphere, thus changing composition and temperature and finally all the constituents of the continuity equation. Composition changes, modifying the ratio between molecular and atomic constituents, have an essential impact on the ionization during ionospheric storms.

The complex dynamics of production, loss, and motion of the ionospheric plasma including strong coupling in particular with the thermosphere and magnetosphere lead to a typical vertical structure of the ionospheric electron density as shown in the *right* panel of Fig. 6.4.

The different ionospheric layers (named as D, E, F1, and F2 in order of increasing altitude) characterize regions where specific processes dominate. The E layer was named by E.V. Appleton (the physics Nobel prize winner in 1947) and designates the region where electrical conductivity and electric currents peak. The ionization at altitudes around 100 km is strongly impacted by high energetic particles and radiation such as x-rays accompanying solar flare eruptions which are associated with significant impact on terrestrial radio wave propagation.

The vertical electron density distribution can basically be described by *Chapman*'s theory [6.48]. Considering a horizontally stratified isothermal layer of a one-component gas, which is ionized by a monochromatic beam of solar radiation at an incidence angle $\chi$, the height dependence of the electron density $n_e$ is given by the Chapman layer function

$$n_e = N_0 \exp\left(\frac{1}{2}[1 - z - \sec\chi \exp(-z)]\right) \qquad (6.68)$$

with

$$z = \frac{h - h_0}{H} \,. \qquad (6.69)$$

Here, $N_0$ denotes the peak electron density of the layer, $h$ is the height above Earth's surface, $h_0$ the peak electron density height, and $H$ the pressure scale height of the neutral gas in the background. Although the aforementioned assumptions simplify the physics in (6.68), the Chapman layer formula describes the basic features of the vertical structure of the ionospheric electron density very well.

As has already been shown in Sect. 6.1, the electron density is the most important parameter characterizing the refractive index for radio waves in the ionosphere. This is also valid for the integral of the vertical electron density, which is called as total electron content (TEC) and counts all electrons in a columnar cylinder of unit area. The vertical total electron content (VTEC) is defined by

$$\mathrm{VTEC} = \int n_e \mathrm{d}h \,, \qquad (6.70)$$

whereas the often used slant total electron content (STEC) measured along a slant ray path $s$ is accordingly

defined by

$$\mathrm{STEC} = \int n_e \mathrm{d}s \,. \tag{6.71}$$

TEC is commonly measured in TEC units (1 TECU = $10^{16}$ electrons/m$^2$).

Since the ionizing solar radiation varies up to more than 50% within a typical 11 years solar cycle in particular at shorter wavelengths, the total ionospheric ionization, that is, VTEC, is strongly related to the solar cycle as illustrated in Fig. 6.5. The solar radio flux measured at 10.7 cm wavelength in Ottawa is a well-established index ($F_{10.7}$) of the solar activity due to its high correlation with the ionizing solar radiation in the EUV range.

Due to the strong coupling with the thermosphere and magnetosphere, which are also impacted by electromagnetic radiation and particles originating from the solar wind, the ionospheric behavior is very dynamic and closely related to space weather conditions as discussed in Chap. 39. Consequently, the impact on GNSS signal propagation depends significantly on space weather conditions. On the other hand, dual frequency GNSS measurements enable an effective monitoring of TEC and the ionospheric electron density distribution for studying solar terrestrial relationships.

### 6.3.2 Refraction of Transionospheric Radio Waves

To reach customers at the ground, signals of global navigation satellite systems (GNSS) must travel through the ionosphere. It is evident that the electromagnetic field of radio waves interacts with charged particles whose motion is controlled by the geomagnetic field. The degree of interaction is described by the refractive index $n$ which has been derived in the late 1920s and early 1930s by Appleton, Lassen, and Hartree by applying Maxwell's theory to the ionospheric plasma (Sect. 6.1). For further reading see [6.5, 49] and references therein.

When taking into account the real ionosphere, that is, considering the fact that due to the presence of the geomagnetic field the ionosphere is an anisotropic medium and collisions between neutrals and charged particles (ions and electrons) are allowed, the refractive index $n$ is given by the Appleton–Hartree formula [6.5, 49]. Since GNSS frequencies (L-band) are well above the collision frequencies, which are in the order of a few kHz, the complex formula can be simplified by neglecting collision terms. The refractive index $n$ is then given by the equation

$$n^2 = 1 - \frac{2X(1-X)}{2(1-X) - Y^2 \sin^2\Theta \pm \left[Y^4 \sin^4\Theta + 4(1-X)^2 Y^2 \cos^2\Theta\right]^{\frac{1}{2}}}\,, \tag{6.72}$$

where

$$X = \frac{f_p^2}{f^2}\,, \tag{6.73}$$

$$Y = \frac{f_g}{f}\,, \tag{6.74}$$

and $\Theta$ is the angle between the ray path and the geomagnetic field induction $B$ (Fig. 6.6), $f$ is the radio wave frequency, $f_p$ is the plasma frequency, and $f_g$ is the gyrofrequency of electrons that gyrate clockwise around the field lines in the field direction.

The plasma frequency $f_p$ is the resonance frequency of an electron gas of density $n_e$ excited by a radio wave

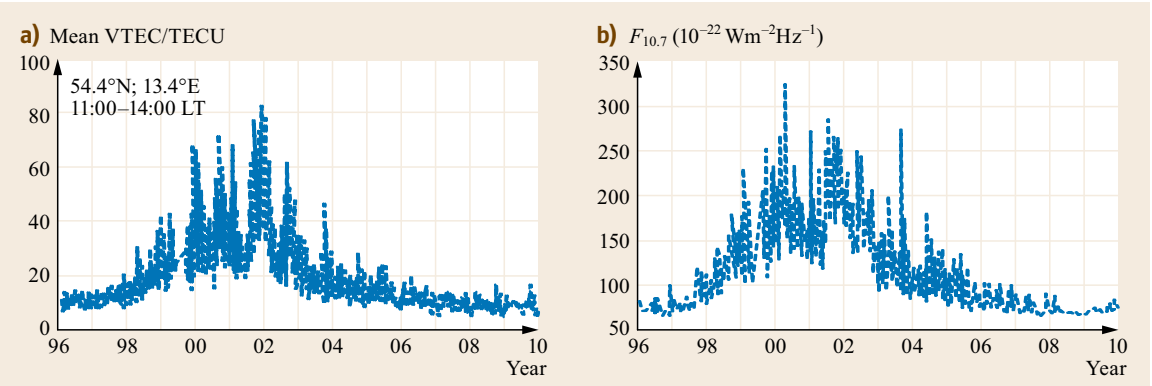

**Fig. 6.5a,b** GNSS-based TEC measurements obtained at 54.4°N and 13.4°E between 11:00 and 14:00 LT **(a)** in comparison with the solar radio flux index $F_{10.7}$ **(b)**

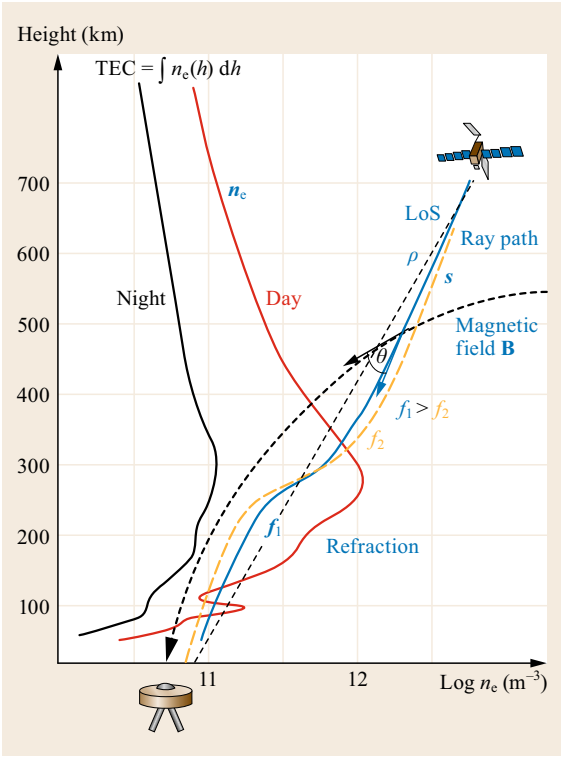

**Fig. 6.6** Scheme of transionospheric radio wave propagation at two frequencies $f_1$ and $f_2$ in the presence of the geomagnetic field $B$

and is given by

$$f_p^2 = \frac{n_e e^2}{4\pi^2 \varepsilon_0 m_e} , \tag{6.75}$$

where $e$ is the electron charge, $m_e$ is the electron mass, and $\varepsilon_0$ is the dielectric constant of vacuum.

The gyrofrequency $f_g$ denotes the frequency at which electrons gyrate around magnetic field lines in the ionosphere (clockwise in the field direction). The gyrofrequency is as a function of the geomagnetic field induction $B$ according to

$$f_g = \frac{e B}{2\pi m_e} . \tag{6.76}$$

The gyrofrequency is in the order of $\leqslant 1.4$ MHz near the Earth surface and decreases with radial distance $r$ from the center of the Earth by $1/r^3$. According to (6.72), the ionosphere is a dispersive and anisotropic propagation medium. Since the collision terms have been neglected, the absorption capability of the ionosphere is ignored in this high frequency approach. Absorption phenomena play a significant role in terrestrial radio communication; here they are completely ignored.

Due to the small size of the $X$ and $Y$ terms ($X \approx 10^{-5}$ and $Y \approx 10^{-3}$), the refractive index $n$ can be expanded in inverse powers of frequency. The expansion up to the fourth inverse powers of frequency gives

$$n = 1 - \frac{1}{2}X \pm \frac{1}{2}XY\cos\Theta - \frac{1}{4}X\left[\frac{1}{2}X + Y^2(1+\cos^2\Theta)\right] . \tag{6.77}$$

In terms of plasma, gyro, and wave frequencies, this equation can be written as

$$n = 1 - \left(\frac{f_p^2}{2f^2}\right) \pm \left(\frac{f_p^2 f_g}{2f^3}\cos\Theta\right) - \left(\frac{f_p^2}{8f^4}\left[\frac{f_p^2}{2} + f_g^2(1+\cos^2\Theta)\right]\right) , \tag{6.78}$$

where the terms in brackets denote the first-, second- and third-order refraction effects.

The double signs in (6.72), (6.77), and (6.78) indicate double refraction of a radio wave travelling through the nonisotropic plasma of the ionosphere. The anisotropy is due to the presence of the geomagnetic field which leads to a double refraction depending on the direction and strength of the geomagnetic field along the ray path. The upper (+) sign represents the ordinary wave (left-hand side circularly polarized) whereas the negative sign refers to the extraordinary wave (right-hand side circularly polarized) [6.50–52]. Equations (6.77) and (6.78) indicate that $n < 1$, that is, the phase velocity $v = c/n$ is greater than the speed of light in vacuum causing a phase advance.

If the wavelength $\lambda = c/f$ of a radio wave traveling through the ionosphere is much smaller than characteristic spatial scales of the ionosphere $S_I$ ($\lambda \ll S_I$), principles of geometrical optics can be applied.

This means that the propagation follows Fermat's law of fastest arrival, meaning that the phase integral or eikonal $L = \int n ds$ becomes a minimum [6.5].

Considering the ray path $s$ and the line-of-sight (LOS) $\rho$ as shown in Fig. 6.6, the optical path length can be rewritten as

$$s = \underbrace{\int \mathrm{d}s_0}_{\rho} + \underbrace{\int (n-1)\mathrm{d}s}_{\Delta s_\varphi} + \underbrace{\int \mathrm{d}s - \int \mathrm{d}s_0}_{\Delta s_B} . \tag{6.79}$$

Here, $\rho$ is the true range between the transmitting satellite and the ground receiver along the line-of-sight (Fig. 6.6), $\Delta s_\varphi$ stands for the range error terms measured by phase changes and $\Delta s_B$ is the optical ray path excess due to bending [6.53].

Whereas the true range $\rho$ shall be determined in positioning, ionosphere probing techniques utilize in particular the residual terms of phase measurements in $\Delta s_\varphi$, which contain the electron density along the ray path. Instead of ionospheric range errors $\Delta s_\varphi$ and $\Delta s_B$, the ionospheric time delay is defined as

$$t_{DI} = \frac{(\Delta s_\varphi + \Delta s_B)}{c} , \tag{6.80}$$

where $c$ is the velocity of light in vacuum.

When measuring the travel time of the code phase in GNSS praxis, we have to take into account the group refractive index of the radio signals [6.5, 6]. The group refractive index is defined by

$$n_{gr} = n + f\left(\frac{dn}{df}\right) . \tag{6.81}$$

Inserting (6.78) for $n$, we get

$$n_{gr} = 1 + \left(\frac{f_p^2}{2f^2}\right) \mp \left(\frac{f_p^2 f_g}{f^3}\cos\Theta\right) + \left(\frac{3f_p^2}{4f^4}\left[\frac{f_p^2}{2} + f_g^2(1+\cos^2\Theta)\right]\right) , \tag{6.82}$$

where the terms in brackets denote the first-, second-, and third-order group refraction effects.

To simplify the subsequent discussion of higher order effects, we define the ionospheric range errors for the carrier phase measurements $d_I$ and code measurements $d_{Igr}$ as follows

$$d_I = \int (1-n)ds , \tag{6.83}$$

$$d_{Igr} = \int (n-1)ds . \tag{6.84}$$

These terms represent the ionospheric range errors that have to be used in GNSS observation equations for the code $d_{Igr}$ and carrier $d_I$ phase measurements as discussed in Chap. 19. GNSS applications commonly use the first-order approach defined by (6.76) and (6.81) or by (6.77) and (6.82) according to

$$d_I^{(1)} = \int \frac{f_p^2}{2f^2} ds = \frac{K}{f^2}\int n_e ds , \tag{6.85}$$

with

$$K = \frac{e^2}{8\pi^2\varepsilon_0 m_e} \approx 40.309\,m^3 s^{-2} . \tag{6.86}$$

Neglecting higher order terms in (6.78) and (6.82), the first-order ionospheric effect can effectively be eliminated by a linear combination of dual-frequency measurements (Chap. 20). For precise GNSS measurements that require accuracy at centimeter level and below, the consideration of higher order effects and bending is needed.

Since global positioning system (GPS) signals are right hand polarized [6.54], we consider only the extraordinary wave (corresponding to the lower sign in (6.78) and (6.82)) in the subsequent discussion. Following [6.53], we get

$$d_I = d_I^{(1)} + d_I^{(2)} + d_I^{(3)} = \frac{p}{f^2} + \frac{q}{2f^3} + \frac{u}{3f^4} , \tag{6.87}$$

$$d_{Igr} = d_{Igr}^{(1)} + d_{Igr}^{(2)} + d_{Igr}^{(3)} = \frac{p}{f^2} + \frac{q}{f^3} + \frac{u}{f^4} , \tag{6.88}$$

where the parameters $p$, $q$, and $u$ are defined in SI units as

$$p = K\int n_e ds = 40.309\int n_e ds , \tag{6.89}$$

$$q = 2.2566\cdot 10^{12}\int n_e B\cos\Theta ds , \tag{6.90}$$

and

$$u = 2437\int n_e^2 ds + 4.74\cdot 10^{22}\int n_e B^2(1+\cos^2\Theta)ds . \tag{6.91}$$

Figure 6.7 gives an impression of the maximum size of the different error types. Considering the L1 navigation signal frequency at low elevation at extremely high ionization level (here 250 TECU), first-order ionospheric range errors can exceed 100 m. Assuming that the gyrofrequency $f_g$ defined by (6.76) is usually less than 1.4 MHz ($B = 50\,\mu T$) and the propagation is along the field line ($\Theta = 0$, maximum range error condition) the second-order error should fulfill the condition

$$d_I^{(2)} \leq \frac{5.6\cdot 10^7}{f^3}\mathrm{STEC} , \tag{6.92}$$

i. e., $d_I^{(2)}$ should generally be less than 12 cm for L1 (25 cm for L2 and 29 cm for L5) frequency even at low elevation and high solar activity conditions.

The asymmetry can be observed at a selected GPS receiver site in particular in the North–South direction

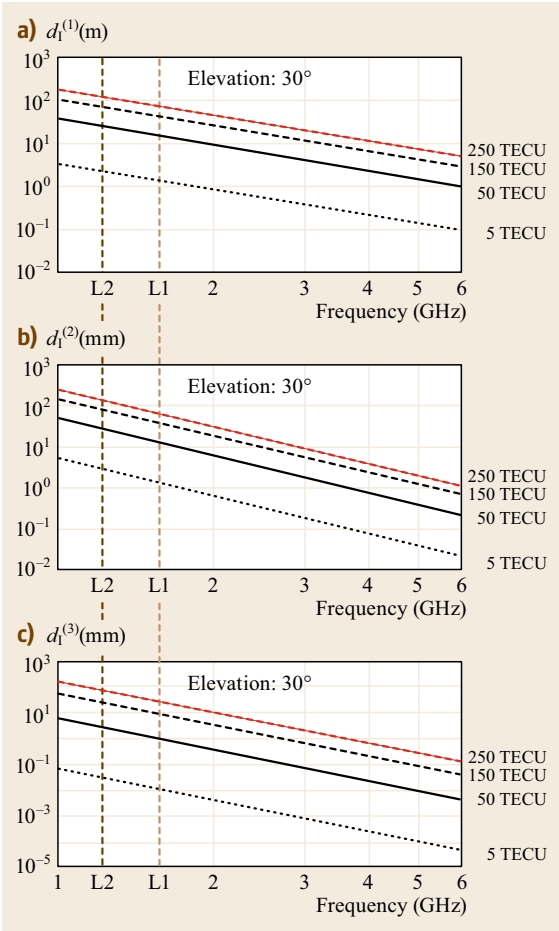

**Fig. 6.7a–c** Frequency dependence of **(a)** first-, **(b)** second- (longitudinal propagation, that is, $\Theta = 0$) and **(c)** third-order ionospheric range errors for radio waves between 1 and 6 GHz at different levels of vertical TEC for 30° elevation angle of the radio link. GPS frequencies L1 and L2 are marked by *dashed lines*

as shown e.g., by [6.52, 53, 55, 56]. Due to its systematic character, the effect is meaningful in dual frequency precise geodetic measurements and satellite orbit determination where millimeter accuracy is required [6.56].

The third-order effect defined in (6.93) is more difficult to estimate due to its dependence from the vertical electron density profile shape [6.50, 57, 58]. Following [6.53] one gets

$$d_1^{(3)} \leqslant \frac{812.3}{f^4} \int n_e^2 \mathrm{d}s \approx \frac{534.2}{f^4} N_m F_2 \,\mathrm{STEC}\,, \quad (6.93)$$

where $N_m F_2$ means the peak electron density of the electron density profile (Fig. 6.4). Considering extreme values for $N_m F_2$ and STEC, it can be stated that the third-order error for L1 frequency is generally less than 6 mm for L1 (16 mm for L2 and 19 mm for L5) frequency, that is, in most cases it can be ignored. It should be mentioned that according to (6.87) and (6.88), the corresponding group delays have to be multiplied by a factor of 2 for the second and by a factor of 3 for the third-order terms. So the group delays at L1 signal should generally be less than 24 cm and 18 mm for the second- and third-order effects, respectively. The corresponding worst case values for the new L5 signal are 58 cm and 57 mm for the second- and third-order effects, respectively.

To complete the discussion of higher order effects, we will now consider the bending effect $\Delta s_B$ as already sketched in Fig. 6.6 and introduced in (6.79). The bending effect has been estimated so far by analytical approaches [6.58] or by numerical ray-tracing computations (e.g., [6.53, 59–61]).

Based on numerical ray-tracing computations, the approximate relation

$$\Delta s_B = \frac{b_1}{f^4} \left( \frac{1}{\sqrt{1 - b_2 \cos^2 E}} - 1 \right) \mathrm{STEC}^2 \quad (6.94)$$

(hereafter denoted as JPM94 model) has been established in [6.59] for the excess path length due to bending of GNSS signals. Here $b_1 = 2.495 \cdot 10^8$, $b_2 = 0.859$ and $E$ is the elevation angle in radians. The excess path length $\Delta s_B$ in (6.94) will be given in millimeters when STEC is measured in TECU and the frequency $f$ is measured in MHz. The model depends only on STEC and therefore can easily be applied.

A more refined approximation, which includes electron density profile parameters such as the atmospheric scale height $H$ and the peak density height $h_m F_2$ is given by

$$\Delta s_B = \frac{7.5 \,\exp(-2.13E)\,\mathrm{STEC}^2}{10^5 f^4 H \,(h_m F_2)^{1/8}} \quad (6.95)$$

(H&J08 model [6.53]), where $\Delta s_B$ is measured in meter, STEC is measured in TECU, the frequency $f$ is measured in GHz, scale height $H$ and peak density height $h_m F_2$ are measured in kilometer and elevation $E$ is measured in radians. It has been found that this approach showed the best performance in comparison with ray-tracing computations (Fig. 6.8).

As shown in Fig. 6.9, bending errors can practically be ignored at elevation angles larger than 60° but can exceed the 1 cm level at elevation angles less than 30°. Even under high solar activity conditions, the bending error should generally be less than 5 cm at the L1 frequency (< 14 cm at L2, < 17 cm at L5).

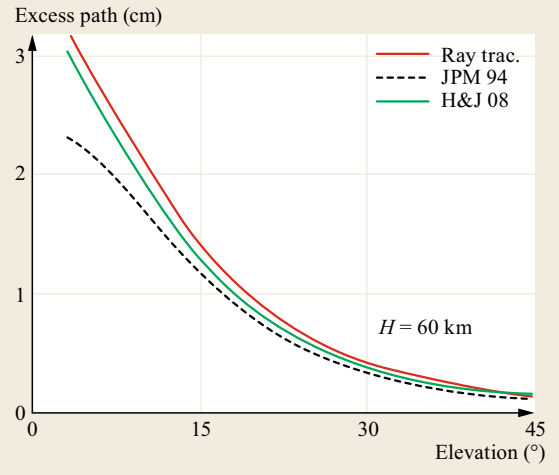

**Fig. 6.8** Comparison of JPM94 and H&J08 approximations for the excess path at L2 frequency with ray-tracing computations using a VTEC value of 123 TECU and electron density profile shape parameters $N_m F_2 = 4.96 \cdot 10^{12}\ \mathrm{m}^{-3}$, $H = 60$ km, and $h_m F_2 = 350$ km

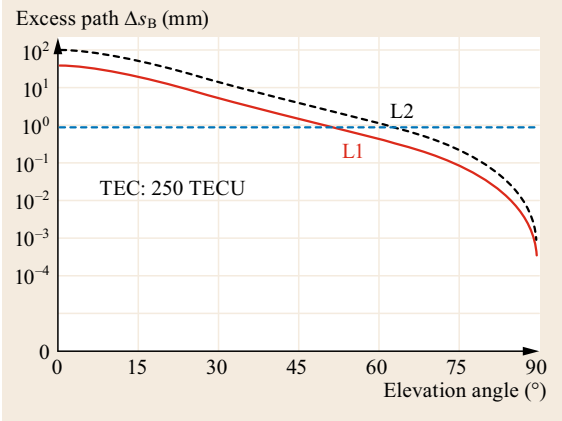

**Fig. 6.9** Elevation angle dependence of the excess path length at GNSS frequencies for VTEC = 250 TECU. The 1 mm level is marked by a *dashed line*

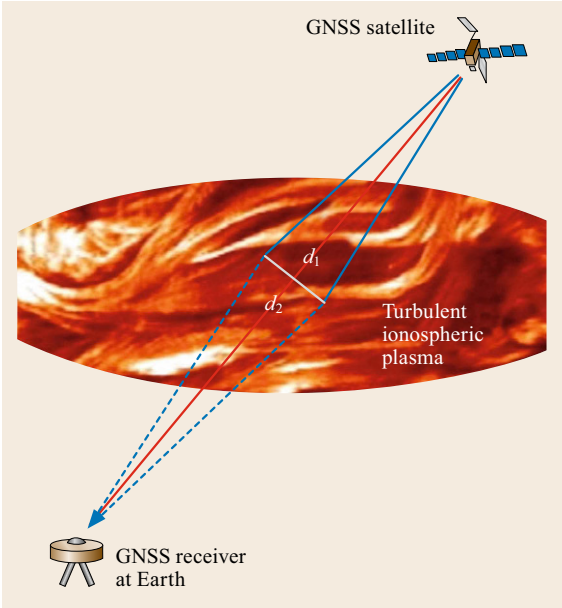

**Fig. 6.10** Superposition of diffracted and scattered radio signals at the receiver antenna due to plasma density turbulences

### 6.3.3 Diffraction and Scattering of GNSS Signals

If typical scales of ionospheric electron density variations are comparable with the wavelength, principles of geometric optics are no longer valid. The propagation of radio waves through the ionosphere must then be described by diffraction and scattering theories [6.62, 63]. Here, we confine our attention to describe the phenomenological impact of small scale ionospheric irregularities on radio signals. Such irregularities cause rapid changes in the amplitude and/or phase of radio signals commonly known as radio scintillations [6.64]. Scintillations superposing the signal reduce the accuracy and reliability of radio systems and may even result in a complete loss of lock of the signal. Scintillation effects on satellite signals cover a broad frequency range from 30 MHz up to 10 GHz. Strong scintillations can typically last up to several hours.

To estimate the spatial size of ionospheric irregularities causing scintillations at radio signals of wavelength $\lambda$, the first Fresnel zone can be considered. The corresponding radius $F_1$ is defined by

$$F_1 = \sqrt{\frac{\lambda\, d_1\, d_2}{d_1 + d_2}}\,. \tag{6.96}$$

Here, $d_1$ and $d_2$ denote the distance from the transmitter and receiver, respectively (Fig. 6.10). In the case of GNSS applications, the first Fresnel radius is in the order of about 300 m. Irregularities of this size or smaller are most effective in producing multiple diffracted and scattered radio waves that interfere at the receiver antenna.

Small-scale electron density irregularities (illustrated in Fig. 6.10) split the primary ray into many different rays causing strong and rapid signal fluctuations at the receiver level. If the fading depth is strong enough, the receiver loses signal tracking, that is, the availability of signals for positioning and navigation might heavily be reduced.

Ionospheric irregularities are closely related to plasma instabilities. One of them is the Rayleigh–Taylor instability (RTI) [6.65]. The RTI describes the behavior of two fluids or plasma volumes moving in the opposite directions. This regularly happens in the low latitude ionosphere in particular during the sunset hours when plasma diffusion is directed downward due to plasma cooling and on the other hand, plasma is uplifted due to an eastward directed electric field. Although the actual geophysical conditions modify the establishment of the RTI, enhanced scintillation activity between sunset and midnight is a well-known phenomenon at low latitudes. Enhanced scintillation activity can also be observed along strong ionization gradients probably initiated by the gradient drift instability [6.66]. Furthermore, irregular precipitation of energetic particles originating from the solar wind may also create chaotic plasma structures resulting at high latitudes in radio scintillations [6.67].

At low latitudes, the so-called equatorial plasma bubbles (EPBs) may be formed by nonlinear plasma processes probably closely related to the RTI. Inside a plasma bubble, the electron density is extremely low (less than 10% of the background density). Hence, there is a sharp gradient of electron density when crossing the surface of an EPB. In TEC data, this is indicated by a rapid drop-off when the ray path enters the EPB and recovery when the ray path leaves the EPB. Whereas EPBs are shaped along magnetic field lines up to more than 1000 km, they are rather thin perpendicular to field lines (up to about 100 km). As RTI is establishing near sunset, EPBs occur and drift eastward at a velocity of about 100–200 m/s [6.68]. The occurrence probability depends on solar activity and on season with highest values around equinoxes over Africa and around solstices at the American sector [6.69].

Low-level geomagnetic activity is anticorrelated with the generation of EPBs, whereas severe magnetic storms may cause enhanced generation of EPBs.

The scintillation strength of received signals is commonly described by the scintillation index $S_4$. Other parameters useful for characterizing scintillations are the phase standard deviation $\sigma_\varphi$, the probability and duration of fades, and their depth in the signal strength.

The $S_4$ index is commonly defined via the signal intensity SI by

$$S_4 = \left( \frac{\langle \mathrm{SI}^2 \rangle - \langle \mathrm{SI} \rangle^2}{\langle \mathrm{SI} \rangle^2} \right)^{1/2} , \tag{6.97}$$

where $\langle\,\rangle$ means the average value over a 1 min interval. $S_4$ index values are usually between 0 and 1. Values lower than 0.2 represent low, values around 0.5 medium and values greater than 0.7 severe scintillation activity. The phase scintillation index widely used is defined by

$$\sigma_\varphi = \sqrt{\frac{1}{N-1} \sum_{i=1}^{N} (\varphi_i - \langle \varphi \rangle)^2} , \tag{6.98}$$

where $\varphi$ means the signal phase and $N$ the number of observations. Parameters $S_4$ and $\sigma_\varphi$ are commonly defined over a period of 1 min.

The scintillation activity depends on radio frequency. In a first approximation, the scintillation level varies with the inverse of the frequency in the range $1.7\,\mathrm{GHz} < f < 4\,\mathrm{GHz}$.

Severe scintillation conditions may cause loss of lock of the signal thus reducing the availability of signals, that is, the position dilution of precision (PDOP) quality. Summarizing, most severe scintillation effects are observed at and near the equatorial regions and at high latitudes. In the auroral and polar cap latitudes, any significant magnetic storm activity can produce scintillation effects. Usually high-latitude scintillations are not as severe as those measured in the near-equatorial belt. However, they can last for many hours, even days, and are not limited to the local late evening hours as the near-equatorial scintillation effects. The maximum fading depth observed on GPS L1 C/A code signals from the north polar cap region was approximately about 10 dB, whereas in the equatorial anomaly region the fading depth is observed to be as much as 25 dB [6.70]. Typical aspects of scintillation occurrence probability at a selected site are described in scintillation models such as the WideBandMODel (WBMOD) [6.71] and the Global Ionospheric Scintillation Model (GISM) [6.72, 73]. The occurrence of strong scintillations is closely related to the solar activity. During the years of maximum solar activity strong scintillation effects on GPS are observed in the equatorial and low-latitude region. Further details of scintillation characteristics including seasonal dependency will be discussed in Chap. 39. It has been shown that high rate GNSS measurements are suitable to monitor scintillations for studying and modeling ionospheric scintillations.

### 6.3.4 Ionospheric Models

As pointed out in Sect. 6.3.2 and expressed in (6.85), the first-order ionospheric propagation error depends only on the electron density distribution along the ray path. Therefore, ionospheric models that describe the 3-D electron density distribution around the globe as a function of time enable estimating link-related ionospheric propagation errors.

Since the correction term depends only on the integral of the electron density along the ray path (STEC), the availability of a much simpler 2-D model of the vertical TEC (VTEC) can be sufficient for numerous applications. As described in the previous section, the vertical TEC must be transformed to the required slant ray path to finally get STEC.

Generally speaking, when using ionospheric models for correcting ionospheric propagation errors for single frequency measurements, the goodness of correction depends on the quality of the model used. When using a TEC model, the quality of correction depends additionally on the correctness of the applied mapping function. Whereas GPS users rely on a simple TEC model (GPS or Klobuchar model) that is broadcasted to single-frequency users, the European satellite navigation system Galileo offers the internal use of a 3-D model (NeQuick) for single frequency corrections. Both models are described in the following in comparison with two other models currently available for first-order ionospheric corrections. Correction approaches for higher order and bending errors have been discussed already in Sect. 6.3.2.

### Mapping Function

Ionospheric correction models provide normalized information in terms of vertical delay or VTEC. If vertical TEC is provided as reference, any link related slant TEC (STEC) can be computed by using a so-called obliquity factor or mapping function $M(E)$ that depends only on the ray path elevation $E$ (Fig. 6.11). Since such a transformation requires additional knowledge about the spatial structure of the ionosphere that is not commonly available, mapping errors result.

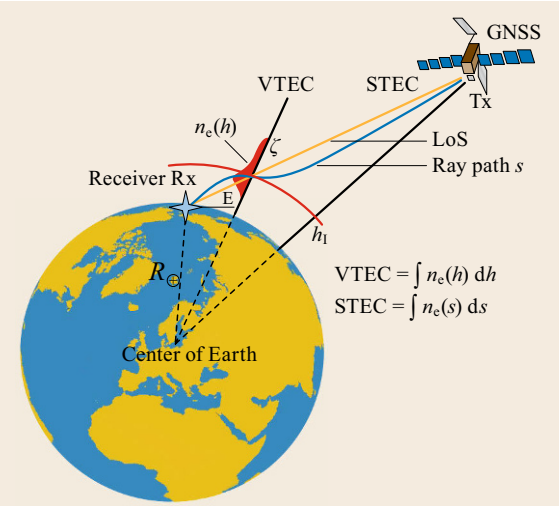

**Fig. 6.11** Thin-shell mapping function approach for ionospheric corrections of slant GNSS measurements deduced from vertical TEC (VTEC) and vice versa for mapping VTEC deduced from STEC measurements

The conversion of vertical to STEC information and vice versa is illustrated in Fig. 6.11, where the ionosphere is reduced to a thin shell. Within this simplification, the piercing point of the ray path $s$ from the satellite transmitter Tx to the receiver Rx along the line-of-sight (LOS) with the shell at height $h_I$ defines geographic coordinates (often called subionospheric point), for which the TEC transformation is valid. The thin-shell mapping function is utilized in most GNSS single-frequency applications, including, for example, satellite-based augmentation systems (SBASs) for aviation.

Assuming a thin-shell-ionosphere and applying simple geometric relationships (Fig. 6.11), the mapping function $M(E)$ for converting VTEC to the corresponding STEC at the piercing point of the ray path $s$ with the ionospheric shell at the height $h_I$ is given by

$$M(E) = \frac{\text{STEC}}{\text{VTEC}} = \frac{1}{\cos\zeta} = \left[1 - \left(\frac{R_\oplus \cos E}{R_\oplus + h_I}\right)^2\right]^{-1/2}, \qquad (6.99)$$

where $R_\oplus$ is the Earth radius, $h_I$ is the height of the thin shell representing the ionosphere and $E$ is the elevation angle. The ionospheric shell height is usually fixed within the height interval of 350–450 km. In SBAS like the Wide Area Augmentation System (WAAS) and the European Geostationary Navigation Overlay Service (EGNOS) the thin-shell height is fixed at 350 km [6.74]. After fixing the ionospheric shell height $h_I$ at a certain value, the thin-shell mapping function is solely dependent on the ray path elevation angle. Thus it ignores the spatial structure of the ionosphere, in particular also horizontal gradients.

According to [6.74], a thin-shell mapping function may introduce vertical range errors of up to 10 m, which increase by a factor of 2–3 at low elevation. Such large mapping errors are due to strong deviations from ionospheric equilibrium conditions in conjunction with strong horizontal gradients of ionospheric ionization as occurred during the Halloween storm by the end of October 2003. Since slant range errors of 15 m or more violate the protection level of SBAS, the navigation service becomes unavailable under such conditions.

Several attempts have been made to improve the TEC mapping in single frequency applications in both the directions, that is, for correcting slant GNSS measurements by given VTEC and for converting measured STEC into VTEC in monitoring systems. It is obvi-

ous from Fig. 6.11 that the mapping improves when the shell height $h_I$ used in (6.99) is adapted to height variations of the center of ionospheric ionization, that is, when $h_I$ follows the variations of the peak density height $h_mF_2$ as shown by *Sakai* et al. [6.75]. Unfortunately, such specific information is not available on a regular base. To improve the TEC mapping from STEC measurements, one option is to separate the ionosphere into different spherical layers with specific mapping functions of type (6.99) [6.75, 76]. Another option is to apply tomographic methods that provide 3-D estimations of the ionospheric electron density [6.77]. The tomographic method is only applicable if sufficient data coverage is available. The above mentioned multilayer shell model as well as the tomographic mapping method have been developed specifically for generating vertical TEC maps as precise as possible. They are not applicable to correct slant GNSS measurements from vertical delay or VTEC without additional information. To improve the correction of slant GNSS measurements by using VTEC without additional information, a new mapping function has been proposed in [6.78], which takes benefit from current knowledge of the typical vertical structure of the ionosphere as described by the Chapman layer in (6.68). The method is applied along the ray path trace through numerous ionospheric shells of incremental thickness taking into account associated VTEC values. Consequently, it is possible to include horizontal ionization gradients in the mapping procedure. Compared with the single thin-shell algorithm, the mapping function error is reduced by more than 50% under high as well as low solar activity conditions.

### GPS Klobuchar Model

GPS offers a simple ionospheric TEC model for 50% corrections of single frequency measurements. This model or ionospheric correction algorithm (ICA), published by *Klobuchar* [6.79] provides a mean vertical delay at L1, for given geomagnetic location and local time. Here the diurnal variation of the vertical ionospheric delay is simply modeled by a half-cosine function with varying amplitude and period, depending on time and geomagnetic latitude (Fig. 6.12). During night time, the vertical ionospheric delay is fixed at a constant value of 5 ns (1.5 m at the L1 frequency).

The amplitude and period of the half-cosine form are centered at 14:00 local time. Accordingly, the time delay $T_{ion}$ at L1 frequency is defined by the relation

$$T_{ion} = A_1 + A_2 \cos\left[\frac{2\pi(t_{GPS} - A_3)}{A_4}\right], \qquad (6.100)$$

where $A_1$ is the constant night-time value (5 ns), $A_2$ is the amplitude, $A_3$ is a constant phase shift fixed at 14:00 local time and $A_4$ is the period of the cosine function.

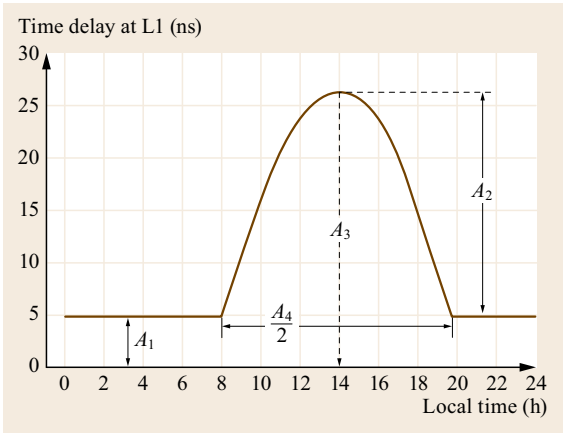

**Fig. 6.12** Illustration of the Klobuchar GPS correction model

The model approach is realized by third-order polynomials for the amplitude $A_2$ and the period $A_4$. The eight coefficients are updated daily by the GPS master control station, uploaded to the GPS satellites and transmitted back to the users via the navigation message. The amplitude and the period are defined by

$$A_2 = \sum_{n=0}^{3} \alpha_n \phi_m \qquad (6.101)$$

and

$$A_4 = \sum_{n=0}^{3} \beta_n \phi_m \,. \qquad (6.102)$$

Here, $\alpha_n$ and $\beta_n$ denote satellite-transmitted coefficients of cubic polynomials for the amplitude of the vertical delay and the period of the model, whereas $\phi_m$ denotes the geomagnetic latitude of the Earth projection of the ionospheric piercing point. The mean ionospheric height is assumed to be 350 km.

Knowing receiver and satellite position, the ionospheric piercing point can immediately be determined to compute the associated vertical ionospheric delay using (6.100)–(6.102).

The obliquity factor $M(E)$ for transforming the vertical delay to the required slant delay is defined by a simple approach according to

$$M(E)_{GPS} = 1 + 16\,(0.53 - E)^3\,, \qquad (6.103)$$

where the elevation angle $E$ is given in semicircles. A detailed description of the model can be found in [6.79].

It is worth to note that the ionospheric correction model of the Chinese Beidou Navigation Satellite System (BDS, previously known as COMPASS) is very

similar to the GPS model [6.80]. There are only a few modifications of the formulas given above. Thus, instead of the geomagnetic reference frame a geodetic reference frame is used in the COMPASS ionospheric model (CIM). Furthermore, instead of the mapping function approach $M(E)_{\mathrm{GPS}}$ for GPS, the standard thin-shell mapping function (6.99) is used. The eight coefficients are updated every 2 h. A preliminary evaluation of CIM has indicated a similar over-all performance as obtained by the Klobuchar model – slightly better in the Northern Hemisphere and worse in the Southern Hemisphere [6.80].

### The NeQuick Model

The NeQuick model is a three dimensional electron density model of the ionosphere/plasmasphere systems developed at the International Centre for Theoretical Physics (ICTP) Trieste, Italy, and at the University of Graz, Austria [6.81–83]. Compared with the international reference ionosphere (IRI) model [6.84] in favor of reduced computing time it is less complex and models only the electron density. Thus, it is tailored to numerically integrate the electron density along any GNSS satellite–receiver ray path to calculate TEC at global scale.

The vertical electron density profile is given by a sum of specific functions for the ionospheric layers $E, F_1$, and $F_2$. The topside ionosphere is described by a separate function whose scale height increases with height. The peak heights of different layers are also described by separate functions. The spatial and temporal behavior of key parameters such as $N_{\mathrm{m}}F_2$ is deduced from monthly tables of Comité Consultatif International des Radiocommunications (CCIR) coefficients [6.85]. In addition to latitudinal and longitudinal dependence of these coefficients, a geomagnetic field dependence expressed by the modified dipole parameter modip $\mu$ was included (CCIR 1967). The parameter was introduced by *Rawer* in 1963 [6.86] according to

$$\tan(\mu) = \frac{I}{\sqrt{\cos\varphi}} \,, \tag{6.104}$$

where $I$ is the magnetic inclination at 300 km and $\phi$ is the geographic latitude of the piercing point location. The CCIR coefficients are given for low and high solar activities characterized by the 12 months running mean of the sunspot number $R$ at levels $R_{12} = 0$ and $R_{12} = 100$, respectively. To prepare coefficients for any other solar conditions the coefficients are linearly interpolated. Thus, the model is able to provide a global 3-D electron density distribution during a full solar cycle. Instead of sunspot number index $R_{12}$ also the radio flux index $F_{10.7}$ can be used via the relationship

$$F_{10.7} = 63.7 + 0.728\,R_{12} + 0.00089\,R_{12}^2 \,. \tag{6.105}$$

A specific version, known as NeQuick-G, is used as the single frequency correction model in the European navigation satellite system Galileo [6.87]. Here, the external solar activity index $R_{12}$ is replaced by an *effective ionization level* Az which is computed by the Galileo operation center in order to get the best representation of the current ionization level by the model. Az is valid for 24 h on a global scale and is defined by

$$\mathrm{Az}(\mu) = a_0 + a_1\,\mu + a_2\,\mu^2 \,, \tag{6.106}$$

where the coefficients $a_0$, $a_1$, and $a_2$ are optimized every 24 h and broadcasted to the user for computing TEC along ray paths that are used for positioning. Initial performance results obtained during the in-orbit validation (IOV) phase are reported in [6.88].

### The NTCM Model

The development of a global TEC model was initiated in the Deutsches Zentrum für Luft- und Raumfahrt (DLR) to assist calibration, mapping, and forecasting in TEC monitoring procedures [6.89–91].

The TEC model NTCM-GL (Neustrelitz TEC Model-GLobal) described by *Jakowski* et al. [6.89] provides a multiplicative representation of temporal and spatial variations of global TEC for a full solar cycle. Essential dependencies from local time, season, geomagnetic field, and solar activity are treated in a similar manner as applied for regional models developed for TEC mapping [6.91]. New approaches were added for describing low latitude features such as the low latitude crest in an effective way. To keep the number of coefficients as small as possible, the terms describing the above mentioned dependencies are combined in a multiplicative way as shown in (6.107). The coefficients and data are related through a nonlinear system of equations given by

$$\mathrm{VTEC}_{\mathrm{NTCM\text{-}GL}} = F_{\mathrm{LT}}\,F_{\mathrm{seas}}\,F_{\mathrm{mag}}\,F_{\mathrm{crest}}\,F_{\mathrm{sol}} \,. \tag{6.107}$$

The 12 coefficients are determined by an iterative nonlinear least-squares technique. The different terms describe specific approaches related to local time ($F_{\mathrm{LT}}$), seasonal ($F_{\mathrm{seas}}$) and geomagnetic field ($F_{\mathrm{mag}}$) variation of TEC. The terms $F_{\mathrm{crest}}$ and $F_{\mathrm{sol}}$ describe longitudinal dependencies of low latitude crest parameters and solar activity dependency, respectively. The local time variation is basically described by diurnal, semi- and ter-diurnal harmonic functions. The seasonal variation includes an annual and semiannual harmonic function.

The latitudinal dependence is described by a dipole approach of the geomagnetic latitude and a special expression for the crests at both sides of the geomagnetic equator.

The solar activity level is quantified by the solar radio flux at 10.7 cm wavelength being a proxy of the ionizing radiation of the Sun in the EUV wavelength range. Further details of the model approach can be found in [6.89].

The model coefficients were determined by an iterative nonlinear least-squares technique applied to a long-term VTEC dataset from the Center for Orbit Determination in Europe (CODE) at the University of Berne as input. At CODE, the vertical TEC is modeled with a spherical harmonic expansion up to degree 15 and order 15 referring to a solar-geomagnetic reference frame [6.92, 93]. The two-hourly VTEC maps are derived from GPS data of the global network of the international GNSS service (IGS) [6.94]. The high-quality TEC dataset of the first NTCM-GL approach comprises data from more than 130 IGS stations from 1998–2007 over more than half a solar cycle. The nonlinear approach requires only 12 coefficients and the solar activity index $F_{10.7}$ as an external parameter for describing global TEC variations during a full solar cycle at all levels of solar activity. Due to the simplicity of the model approach, the model runs very fast and the implementation in operational systems is easy.

### The IRI Model

The IRI is an empirical model widely used for different applications [6.84]. The development of IRI started in 1968 co-sponsored by the Committee on Space Research (COSPAR) and the International Union of Radio Science (URSI).

IRI is a complex model that describes the electron concentration, electron temperature, ion temperature, and ion composition in the altitude range from 50 km to about 2000 km for a given location, time, and date. Due to the upper boundary limitation the vertical electron content can be computed only up to 2000 km height. The solar activity dependence is introduced by the solar radio flux $F_{10.7}$ or the sunspot number $R_{12}$. Concerning the description of a key parameter such as $f_0F_2$, IRI can alternatively use CCIR coefficients adopted in 1967 as used also in NeQuick or a set of coefficients proposed by the URSI in 1989. Instead of using such coefficients, IRI can include also current observation values of key parameters such as $N_mF_2$. The electron density distribution of the topside ionosphere is described by the NeQuick approach.

Newer versions of IRI also contain a storm model that improves the modeling results during ionospheric storms compared with the classical climatology approach [6.96]. The storm model is driven by the planetary geomagnetic $K_p$ index. The IRI model is updated periodically and has evolved over a number of years as the result of the work of the international science community. The most recent version of IRI can be found in [6.97].

The major limitation of IRI previous versions in terms of electron density representation appears to be its electron distribution in the region above the peak of the F2 region. Due to the complex character of

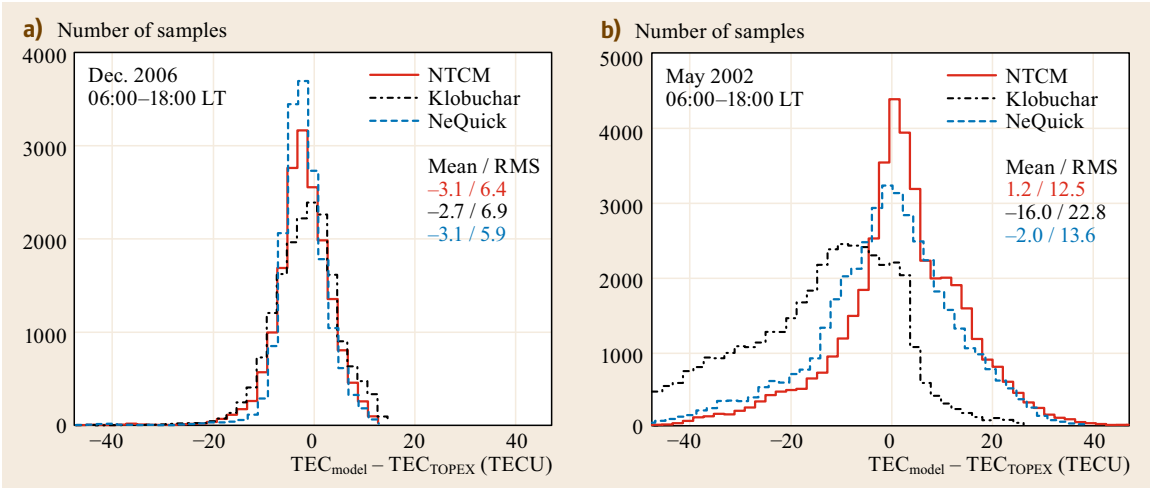

**Fig. 6.13a,b** Comparison of daytime ionospheric VTEC estimations derived from models: Klobuchar ICA-GPS, NeQuick and NTCM-GL with VTEC estimations from dual frequency satellite altimetry data at TOPEX/Poseidon. Selected data samples from December 2006 at low solar activity **(a)** and May 2002 at high solar activity **(b)**. Mean deviations and RMS values are given in TECU (after [6.95])

IRI, it is well-suited for research and case studies. However, internal time consuming computations of various parameters such as ion composition and electron temperature are not needed for TEC computations. Furthermore, the limitation in height at 2000 km appears to be an obstacle in using IRI for GNSS-based TEC monitoring.

#### Comparison of Models

Whereas 3-D models allow estimating TEC by integrating the electron density distribution along the concrete ray path, 2-D TEC models require a mapping function, which is a principal source of errors in particular at low elevation angles as discussed in the previous section. Nevertheless, three dimensional electron density models such as IRI or NeQuick may also fail in estimating TEC even if the peak electron density is modeled very well [6.98].

The comparative analysis of three ionospheric correction models for single frequency transionospheric range errors clearly shows that TEC estimations of NeQuick and NTCM-GL are very similar (Fig. 6.13). This confirms earlier performance checks of NTCM-GL in comparison with NeQuick indicating that the 12 coefficient TEC model NTCM-GL achieves practically the same performance as the much more complex electron density model NeQuick [6.83]. Moreover, it has to be stated, that the Klobuchar or GPS model performance deviates from NeQuick and NTCM-GL significantly although the coefficients are regularly updated. The comparison is in particular worse at night time when TEC is fixed at 9.22 TECU (5 ns at L1 frequency) in the Klobuchar model.

### 6.3.5 Measurement-Based Ionosphere Correction

#### Single-Frequency Measurements

In single-frequency applications, ionospheric range errors can be estimated to a certain degree by utilizing model values [6.79], external TEC monitoring data [6.99] or the code–carrier divergence [6.100]. The latter solution is theoretically based on opposite signs of the first-order terms in the refractive indices for carrier and group phases as can be seen in (6.78) and (6.82). Utilizing this unique relationship, *Yunck* [6.100] proposed the *group and phase ionosphere correction* (GRAPHIC) in 1993 to mitigate the first-order ionospheric range error in single frequency GNSS signals. Computing the arithmetic mean of code and carrier phases, the ionospheric first-order term cancels out in a similar way as in dual frequency solutions. Compared with dual frequency code-measurements the GRAPHIC-method reduces the noise level by 50%. Although still rarely

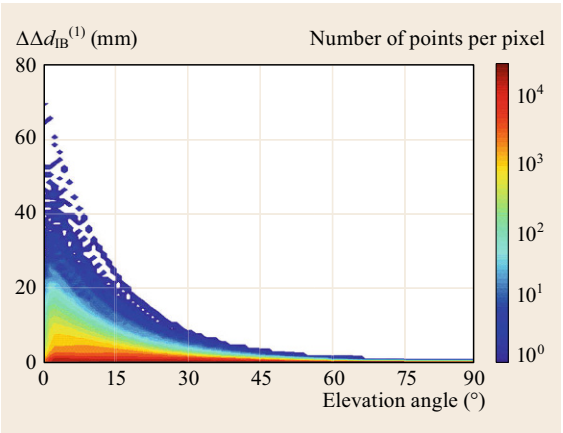

**Fig. 6.14** Residual range error in the ionosphere-free linear combination of L1 and L2 frequencies due to different STEC obtained at L1 and L2 ray paths. First-order estimations have been carried out using electron density profiles derived from CHAMP radio occultation data in 2002 (after [6.104])

applied in terrestrial positioning [6.101], the method is wide-spread in spaceborne navigation [6.102]. The linear combination of code and carrier phases can even be used for ionospheric monitoring when code noise is low [6.103].

#### Dual-Frequency Measurements

To essentially reduce the ionospheric error in precise applications, dual-frequency measurements are made. Utilizing the dispersive nature of the ionosphere the first-order ionospheric error is mitigated in a linear combination of phase measurements at both frequencies according to

$$\varphi_{IF} = \frac{f_1^2}{f_1^2 - f_2^2}\varphi_1 - \frac{f_2^2}{f_1^2 - f_2^2}\varphi_2 \,. \qquad (6.108)$$

While the first-order error $d_I^{(1)}$ is cancelled out, some higher order terms including bending remain in the error budget. Following *Hoque* and *Jakowski* [6.53], we can write for the $\varphi_{IF}$ linear combination

$$\varphi_{IF} = \rho + \Delta d_I^{(2)} + \Delta d_I^{(3)} - \Delta\Delta s_B + \Delta s_{\varphi B} \,. \qquad (6.109)$$

Besides the difference of higher order errors $\Delta d_I^{(2)}$ and $\Delta d_I^{(3)}$, the difference of the bending effect at both frequencies is considered.

In addition to former discussion the linear combination (6.108) requires to consider also the difference of phase error effect at different ray paths (Fig. 6.5) which we call $\Delta s_{\varphi B}$. According to *Hoque* and *Jakowski* [6.53] different STEC values along different ray paths con-

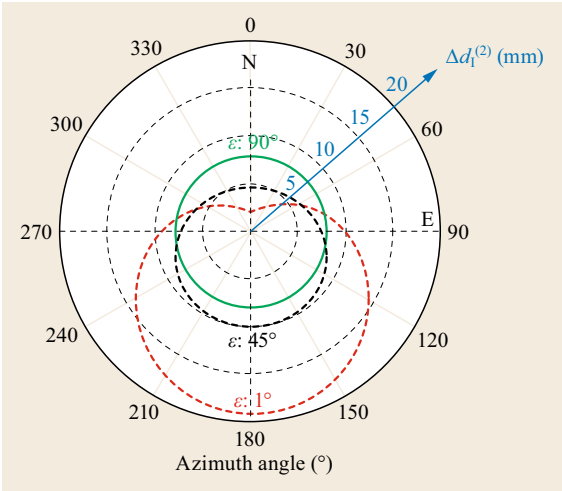

**Fig. 6.15** Azimuth dependence of the second-order residual phase error for different elevation angles at the location 48°N, 15°E in Europe assuming a vertical TEC of 100 TECU (after [6.53])

tribute with a residual error of up to 6 cm as shown in Fig. 6.14.

A model approach for estimating TEC-related bending errors in the ionosphere-free linear combination of L1 and L2 measurements and a related statistics is published by *Hoque* and *Jakowski* [6.53]. The vertical structure of the ionosphere is modeled by a Chapman layer function as discussed in Sect. 6.3.1. The maximum error obtained in the statistical estimates was about 5 cm for 1° elevation.

Model computations have been performed also to mitigate the Faraday effect in dual frequency positioning [6.53, 105]. Figure 6.15 shows the typical asymmetry of the second-order residual phase range error in the ionosphere-free linear combination for L1 and L2 measurements. Since the geomagnetic field changes smoothly over a certain area like Germany or mid-Europe, model approaches with fixed geomagnetic geometry have been developed by *Hoque* and *Jakowski* [6.53, 106] to estimate the second-order residual carrier phase error for L1/L2 GPS frequencies. To characterize the ionosphere, only TEC is used as an input parameter. The achieved accuracy of the model approach is in the order of 2–3 mm for Germany and mid-Europe. The estimation may help at least to improve the phase ambiguity resolution in precise positioning.

A more detailed discussion of characteristic residual errors which remain in the so-called ionosphere-free linear combination is given by *Hoque* and *Jakowski* [6.53].

*Acknowledgments.* Norbert Jakowski would like to express his gratitude to his colleagues from the German Aerospace Center with whom he has worked over many years. In particular he thanks his colleague Dr. Mohammed Mainul Hoque for close cooperation for more than a decade.

# 7. The Global Positioning System (GPS)

Christopher J. Hegarty

This chapter presents an overview of the US Global Positioning System (GPS), which became the first operational global navigation satellite system (GNSS) core constellation when it was declared fully operational in 1995. First, the space segment is described, including key characteristics of the different satellite types. Then, an overview of the control segment is given, including its operations and evolution of capabilities. This is followed by an overview of the GPS signals, current and future, as well as a description of the navigation data content. Then, the time and coordinate systems used by GPS are described. The chapter is concluded with a brief description of services and performance.

The Global Positioning System (GPS) [7.1–4] is a satellite navigation system operated by the United States. The system consists of a constellation of nominally 24 satellites in medium altitude earth orbit (MEO), as well as a worldwide ground network to monitor and control the satellites. The GPS program began in the early 1970s and the system was declared fully operational in 1995. Internationally, the GPS constellation is considered to be just one component within the global collection of navigation satellites that is referred to as the global navigation satellite system (GNSS). This chapter provides an overview of GPS, including its space and control segments (CS), signals, services, and performance.

## 7.1 Space Segment

### 7.1.1 Constellation Design and Management

The GPS constellation nominally consists of 24 satellites in circular orbits with an orbital radius of 26 559 km [7.5] (Table 7.1). The satellite orbits are inclined 55° with respect to the equatorial plane. Four satellites are contained in each of six orbital planes, which are equally spaced with respect to their orientation around the Earth's spin axis. The six orbital planes are identified by letter designators, from A to F. The nominal 24 satellite locations at a specified epoch are referred to as *slots*, and are designated by a letter–number combination, for example, A1 for the first satellite slot within the A plane. The nominal slot

**Table 7.1** Nominal GPS constellation parameters

| Parameter | Value |
|---|---|
| Number of operational satellites | 24 |
| Number of orbital planes | 6 |
| Number of satellites in a plane | 4 |
| Orbit type | Near circular |
| Eccentricity | $e < 0.02$ |
| Inclination | $i = 55°$ |
| Nominal orbital altitude | $h = 20\,180$ km |
| Period of revolution | $T = 11$ h 58 m |
| Long. of asc. node between planes | $\Delta\Omega = 60°$ |
| Ground track repeat cycle | 2 orbit/$1^{d}_{sid}$ |

locations for $00^{h}\ 00^{m}\ 00^{s}$ coordinated universal time (UTC), 1 July, 1993, are provided in Fig. 7.1 [7.5]. The Greenwich hour angle for this epoch is $18^{h}\ 36^{m}\ 14.4^{s}$.

From Fig. 7.1, it may be noted that the four slots within each orbital plane are asymmetrically spaced. This design was determined to be robust against probable satellite failures [7.6]. The orbital altitude was chosen, in part, to support early system testing when the constellation was only partially populated. The nominal altitude provides an orbital period of one-half a sidereal day (approximately $11^{h}\ 58^{m}$) so that the satellite ground tracks repeat daily (Fig. 7.2). Although repeating ground tracks are convenient for planning certain GPS applications, they result in resonant forces on each GPS satellite due to the Earth's nonuniform gravitational field, which in turn results in the need for more frequent satellite station-keeping maneuvers. The current constellation design was also influenced by many historical constraints that no longer apply, including early plans to launch the GPS satellites using the space shuttle that were abandoned after the Challenger disaster.

**Table 7.2** Expandable slots in the baseline GPS 24-satellite constellation

| Expandable slot | | Right ascension of ascending node (RAAN) | Arg. of latitude |
|---|---|---|---|
| B1 expands to: | B1F | 332.847° | 94.916° |
| | B1A | 332.847° | 66.356° |
| D2 expands to: | D2F | 92.847° | 282.676° |
| | D2A | 92.847° | 257.976° |
| F2 expands to: | F2F | 212.847° | 0.456° |
| | F2A | 212.847° | 334.016° |

In recent years, the constellation has been overpopulated with up to 31 operational satellites. The first 3 satellites beyond 24 are placed into *expandable slots* within the baseline 24-satellite constellation [7.5]. Each of the three slots B1, D2, and F2 may be split into two slots as shown in Table 7.2 to accommodate up to 27 total satellites in the constellation. *Surplus* satellites (operational satellites beyond the 27th) are typically placed in locations adjacent to satellites that are expected to require replacement the soonest.

As with any satellite constellation, occasional station-keeping maneuvers are required to keep the GPS satellites close to their nominal positions (slots). GPS satellite maneuvers are performed as necessary (typically once every 1–2 years per satellite) with the goal of keeping for each satellite the eccentricity within the range of 0–0.02, the inclination within the range of 52–58°, and the argument of latitude spacing within 4° of nominal values [7.5]. When a GPS satellite has reached end of life, its navigation signals are switched off and it is boosted by around 500 km in altitude to a disposal orbit [7.7].

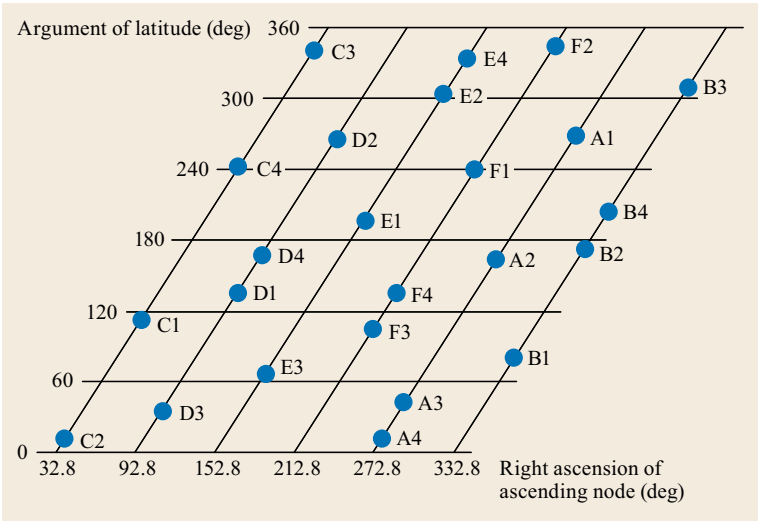

**Fig. 7.1** Nominal GPS 24-satellite constellation for 1 July 1993 (after [7.5])

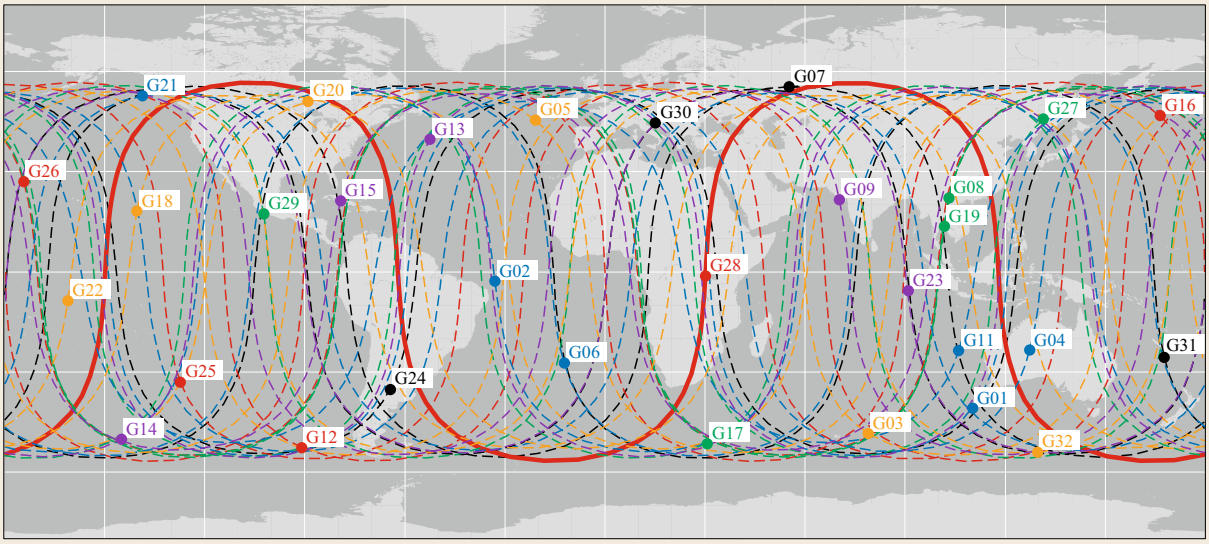

**Fig. 7.2** Ground tracks of the GPS satellites for September 1, 2015, 00:00–24:00 UTC. Markers indicate the positions at the initial midnight epoch and different colors are used to distinguish the six orbital planes (*black*: A, *red*: B, *green*: C, *blue*: D, *orange*: E, *orchid*: F)

## 7.1.2 GPS Satellites

From 1978 until the present time, 67 GPS satellites were successfully launched into orbit out of which 31 are currently operational. Redundant atomic clocks, rubidium and/or cesium, are key components of each satellite so that signals that are precisely synchronized to a common timescale can be broadcast. The capabilities of the satellites have increased over time, as has their size, weight, and cost. Some key characteristics of each satellite type are listed in Table 7.3.

### Block I Satellites

A contract to build and launch a set of test satellites for GPS, referred to as the Block I space vehicles (SVs), was awarded to Rockwell International in Au-

**Table 7.3** GPS satellites overview

| Parameter | Block I | Block II/IIA | Block IIR/IIR-M | Block IIF | GPS III |
|---|---|---|---|---|---|
| First launch | 1978 | 1989 | 1997 | 2010 | 2017 (planned) |
| Manufacturer | Rockwell International | Rockwell International | General Electric's Astro Space Division (now Lockheed Martin) | Rockwell International (now Boeing) | Lockheed Martin |
| Design life-time (years) | 5 | 7.5 | 7.5 | 12 | 15 |
| Mass (kg) | 450 | > 850 | 1080 | 1630 | 2200 |
| System power (W) | 400 | 700 | 1140 | 2610 | 4480 |
| Solar array size ($m^2$) | 5 | 7.2 | 13.6 | 22.2 | 28.5 |

| Signals | L1, L2 | L1, L2 | L1,L2 | L1, L2, L5 | L1, L2, L5 |
| Cross link | | × | × | × | × |
| Laser reflector | – | × (space vehicle number (SVN) 35, 36) | – | – | × (later satellites) |

gust 1974 [7.8]. Eleven Block I satellites, designated as GPS space vehicle numbers (SVN) 1–11, were launched from Vandenberg Air Force base (approximately 230 km northwest of Los Angeles) on refurbished Atlas-E/F intercontinental ballistic missiles from February 1978 to October 1985. All but one made it successfully into orbit. The exception was SVN 7, which was destroyed in a launch vehicle failure in December 1981. All of the Block I satellites carried three rubidium clocks, and the last eight additionally carried one cesium clock [7.9]. The Block I satellites had an on-orbit mass of approximately 450 kg and spanned 5.3 m from end to end of the deployed solar arrays. The Block I satellite power system included two solar arrays with a combined area of 5 $m^2$ to provide approximately 400 W of power and nickel cadmium (NiCd) batteries for power storage. The last six Block I and all subsequent GPS satellite blocks carry a secondary payload to detect nuclear explosions in the Earth's atmosphere and near space. The Block I satellites had a design life of 5 years, but some were in service for over 10 years. The last operational Block I satellite was decommissioned in late 1995.

### Block II/IIA Satellites

In 1983, Rockwell International was awarded a contract to build and launch 28 operational GPS satellites, referred to as Block II. In March 1984, a decision was made to modify the 10th and successive Block II satellites to allow extended operations of up to 180 days without ground contact, in addition to several other new capabilities. The modified vehicles are referred to as Block IIA. The 9 Block II and 19 Block IIA satellites were launched between February 1989 and November 1997. All of these satellites were designed to carry two rubidium and one cesium clock. The design life was 7.5 years. As of today (2015), only three Block IIA satellites remain in operation. The remaining Block II/IIA satellites have been decommissioned.

A Block IIA satellite is shown in Fig. 7.3. Two solar arrays are visible on either side of the main body of the satellite. The solar arrays cover an area of 7.2 $m^2$ and are part of a 700 W power system that also includes NiCd batteries for energy storage. The wingspan of the satellite is approximately the same as for the Block I satellites, 5.3 m. The on-orbit mass is 990 kg, which is significantly higher than the Block I satellites and slightly higher than the 850 kg Block II satellites. An array antenna with 12 helical elements arranged in two concentric rings (8 in the outer ring and 4 in the inner ring) is visible on the main body of the spacecraft. This array antenna is used to broadcast the L-band navigation signals from the spacecraft to the Earth. The L-band antenna is boresighted toward the center of the Earth. It is designed to direct most of the radiated power toward the surface of the Earth where most GPS users are expected to be. The antenna is broadband and has a peak gain of 13.2 dBi at 1575 MHz. The antenna gain pattern was optimized to provide near uniform received power levels over the surface of the Earth [7.10].

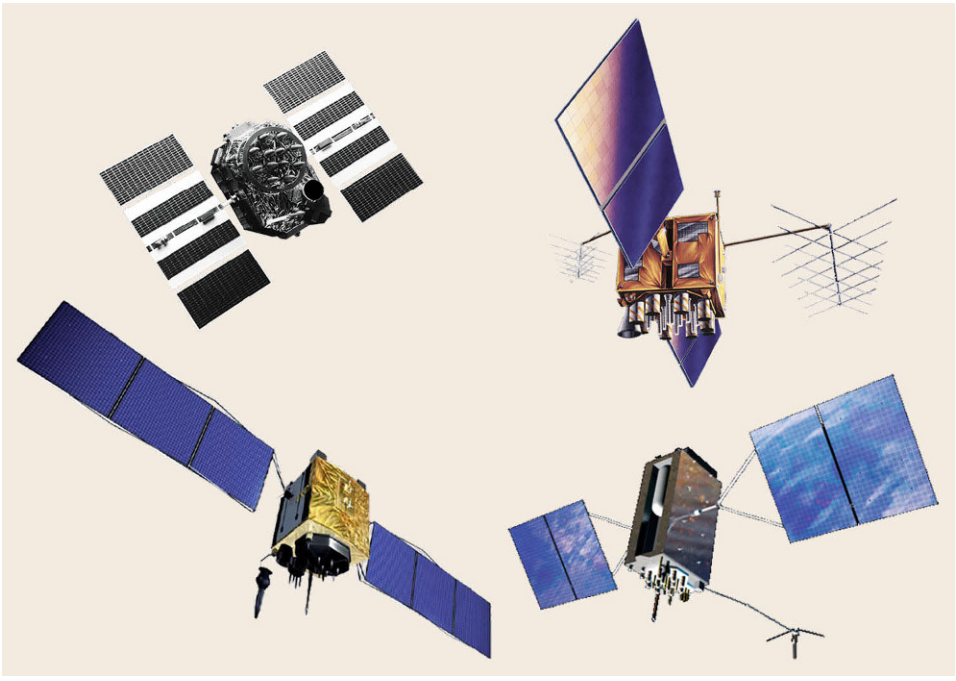

**Fig. 7.3** The GPS satellite family: *Block IIA* (*top left*), *Block IIR* (*top right*), *Block IIF* (*bottom left*), *GPS III* (*bottom right*) (courtesy of USAF)

To accomplish this objective, less gain is provided at boresight (where the surface of the Earth is closer and thus path loss is less) than toward off-boresight angles of 13.8°, which corresponds to the limb of the Earth.

Ultra-high frequency (UHF) crosslinks provide a means to relay nuclear detection (NUDET) sensor data between satellites. Sensors related to the NUDET mission, and also an antenna for S-band tracking, telemetry, and control (TT and C), may be seen below the L-band Earth-coverage antenna on the bulkhead of the satellite in Fig. 7.3.

Two Block IIA satellites – SVNs 35 and 36 – carried satellite laser retroreflectors. Both of these satellites are now decommissioned.

### Block IIR and IIR-M Satellites

A contract for 21 Block IIR (*R* for replenishment) GPS satellites (Fig. 7.3) was awarded to General Electric's Astro Space Division (now Lockheed Martin) in 1989 [7.11]. The last eight IIR satellites were modernized, as discussed in the subsequent section, and are now referred to as Block IIR-M [7.12]. The remaining 13 Block IIR satellites were launched from January 1997 to November 2004. The first Block IIR launch was unsuccessful and IIR-1 was destroyed on January 1997. As of today (2015), all of the remaining Block IIRs are still in operation. The Block IIR and IIR-M satellites carry three rubidium clocks. The design life is 7.5 years. Power is provided by two solar arrays with an area of 13.6 $m^2$ yielding 1140 W, with nickel hydrogen ($NiH_2$) batteries for storage.

A similar 12-element array design is used for the L-band navigation signals as was described earlier for the Block II/IIA satellites. The IIR L-band antenna gain pattern is slightly narrower than the IIA antenna gain pattern, which provides more power to terrestrial GPS users, but less power to GPS receivers on spacecraft in certain orbits. A modified antenna design was incorporated for the last four IIR and all eight IIR-M satellites that provided yet further gain increases toward the Earth (but yet further power decreases for the much smaller number of space users) [7.13].

The eight Block IIR-M satellites were launched from September 2005 through August 2009. These satellites add new civilian and military signals [7.14], which are described in detail in Sect. 7.3. The seventh Block IIR-M satellite (SVN 49) carried a demonstration payload for the third civilian GPS signal, referred to as *L5* (Sect. 7.3). Unfortunately, this demonstration payload resulted in signal reflections for the primary L-band navigation payload [7.15] and thus this satellite has been set unhealthy since its launch.

### Block IIF Satellites

A contract to build the GPS Block IIF (*F* for *follow-on*) was awarded to Rockwell International (now Boeing) in 1996. The initial contract included options for up to 33 satellites, but only 12 were procured. Each Block IIF satellite [7.16, 17] (Fig. 7.3) is approximately 17.5 m from end to end. Six solar panels, populated with gallium arsenide (GaAs) solar cells with the total area of 22.2 $m^2$, provide primary power. The power system, which also includes $NiH_2$ batteries, is capable of providing 2610 W at the end of a 12-year satellite design life. The on-orbit mass is approximately 1630 kg. The IIF satellites provide all of the navigation signals provided by the Block IIR-M satellites and additionally a new civilian signal at 1176.45 MHz (Sect. 7.3). The first Block IIF satellite was launched in May 2010. As of 2015, 9 of the 12 IIF satellites have been launched.

### GPS III Satellites

In May 2008, the United States Air Force awarded a contract to Lockheed Martin to develop the third generation of GPS satellites. The contract called for the delivery of two satellites with options for up to 10 more. These satellites were originally referred to as Block III, but are now referred to as GPS III. These satellites [7.18] are anticipated to be launched beginning in 2017. Each GPS III satellite carries three rubidium clocks, and will provide a fourth civilian GPS navigation signal (Sect. 7.3), in addition to all the navigation signals broadcast by the Block IIF satellites. The on-orbit mass of the GPS III satellites is approximately 2200 kg. The power system includes four GaAs solar arrays with a total area of 28.5 $m^2$ and $NiH_2$ batteries, and is designed to provide 4480 W of power at the end of a 15 year design life. The satellite main body is approximately 3.4 m × 2.5 m × 1.8 m. Later GPS III satellites are expected to reintroduce satellite laser retroreflectors, a capability not seen on GPS since the decommissioning of Block IIA satellites SVNs 35 and 36 (Sect. 7.1.2). Plans are also being made to introduce a search and rescue (SAR) payload on later GPS III satellites. This SAR payload will be interoperable with the International Cospas–Sarsat System.

### Launch Operations

The Block I GPS satellites were launched from Vandenberg Air Force Base in California. All later satellites have been launched from Cape Canaveral Air Station in Florida. Atlas–E/F launch vehicles were used for the Block I satellites, and Delta II launch vehicles for the Blocks II, IIA, IIR, and IIR-M. The Atlas-F and Delta II launch vehicles (Fig. 7.4) were not powerful enough to directly place the satellites into their final circular MEO

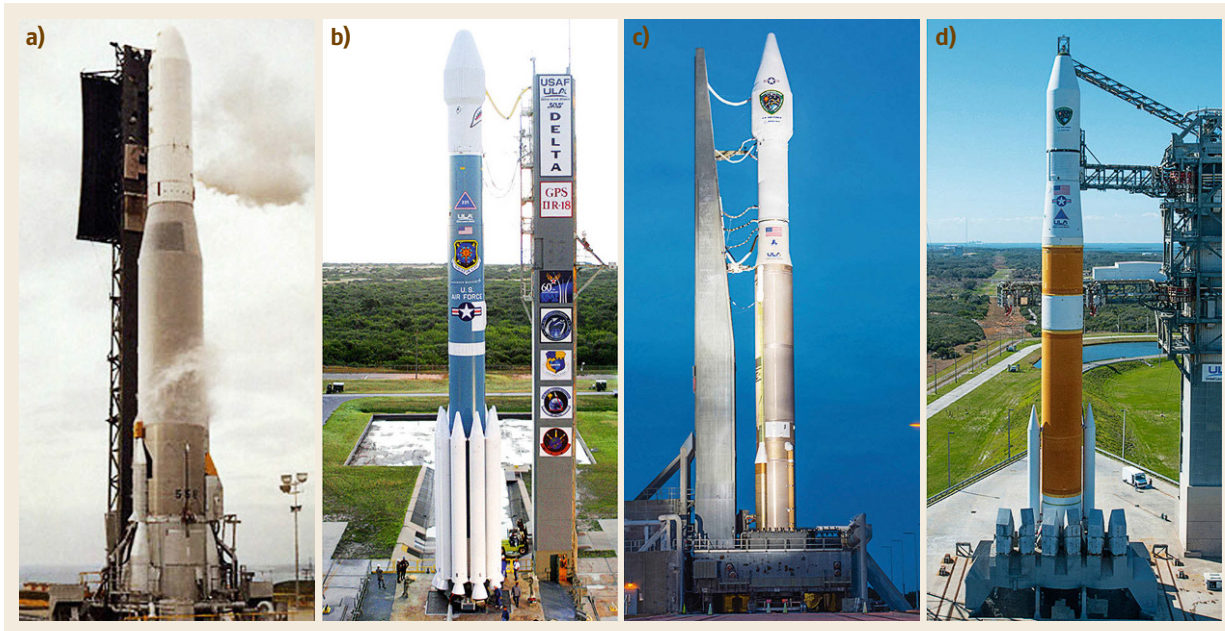

**Fig. 7.4a–d** The GPS launch vehicles: *Atlas–F SGS1* **(a)**, *Delta II* **(b)**, *Atlas V* **(c)**, *Delta IV* **(d)** (courtesy of USAF **(a)** and United Launch Alliance **(b,c,d)**)

orbits, but rather into highly elliptical transfer orbits with apogees near the correct final circular orbit altitude of approximately 20 000 km. Apogee kick motors (AKM) on-board the satellites were required to insert the satellites into their final circular orbits. The Block IIF satellites are being launched with evolved expendable launch vehicles (EELV) including the Delta IV and Atlas V boosters (Fig. 7.4). These launch vehicles are powerful enough to directly insert the IIF satellites into their final circular orbits without the need for AKMs. The GPS III satellites will also be launched using EELVs. However, their mass is significantly higher than that of the Block IIF satellites, and a liquid apogee engine is again required for final orbit insertion.

For launch, each GPS satellite is placed into a stowed configuration, for example, the solar arrays are folded against the side of the satellite. The satellite is mounted atop the launch vehicle within a *payload fairing*, which is a cover designed to eventually break away but to protect the satellite during ascent through the Earth's atmosphere. From this point, the launch details vary with satellite Block. As one example, the last Block IIR-M satellite launch was accomplished on August 17, 2011 using a Delta II vehicles with three stages in its 7925 configuration [7.19]. The cylindrical launch vehicle dimensions were approximately 38 m × 2.4 m. The first (main) stage was 26 m in length at the bottom of the launch vehicle and burned a mixture of rocket propellant and liquid oxygen stored in large on-board tanks. The first stage was assisted by nine smaller solid rocket motors attached to its base. At liftoff ($t = 0$ s), both the main stage and six of the solid rocket motors were fired. After about a minute, the six ground-start solid rocket motors were expended and jettisoned, and the remaining three solid rocket motors were ignited. These remaining solid rocket motors burnt out at $t =$ 128 s and were jettisoned shortly thereafter. The main engine cut off at $t = 263$ s and then separated from the rest of the launch vehicle. The second stage, which was a restartable, hypergolic rocket engine manufactured by Aerojet, was ignited at $t = 277$ s. The second stage included the flight guidance electronics. The payload fairing was jettisoned 20 s later at $t = 297$ s. After a series of maneuvers and a first cut-off and restart, the second stage was cutoff a final time and jettisoned at approximately $t = 1$ h. The third stage, a solid rocket motor, was then ignited for less than 2 min before being cut off. The satellite was separated from the third stage at $t = 1$ h 8 min, and reached first apogee of the transfer orbit at $t = 4$ h 3 min. On August 19, the IIR-M satellite used its AKM to raise itself into its final circular orbit.

### Attitude Control

As the GPS satellites orbit the Earth, they are 3-axis stabilized to simultaneously point the L-band navigation antenna toward Earth and the solar arrays toward the Sun. Earth-pointing accuracy is typically well below 0.5°. Continuous yawing around the L-band antenna

boresight direction is required to achieve these objectives. Attitude control is accomplished using momentum wheels, magnetic torquers, and Earth–Sun sensors in system designs that vary with satellite Block. Modeling satellite yaw, particularly during eclipse season when a portion of the satellite orbit is hidden from the Sun by the Earth, is of importance for a number of high-precision positioning applications (Chaps. 19 and 25). Suitable yaw models for the Block II/IIA, IIR, and IIF satellites may be found in [7.20–22].

## 7.2 Control Segment

### 7.2.1 Overview

The GPS satellites are monitored, commanded, and controlled by a ground network referred to as the GPS CS. The CS includes a master control station (MCS) at Schriever Air Force Base (AFB) in Colorado (Fig. 7.5), and a global network of monitor stations and ground antennas (Fig. 7.6). The monitoring stations include high-precision GPS receivers that track the L-band navigation signals broadcast by each visible satellite using antennas with *hemispherical* (i. e., all directions above the local horizon) gain antennas. Measurements are continuously communicated back to the central MCS.

**Fig. 7.5** Schriever air force base, Colorado, site of the GPS MCS (courtesy of USAF)

The MCS includes the computing facilities for processing these measurements to generate estimates of the GPS satellite positions, satellite velocities, clock errors, and clock drift rates. The MCS is manned 24 h a day, 7 days of week, and the trained US Air Force personnel that work here also monitor the health of the GPS satellites and manage satellite maneuvers and navigation upload data.

High-gain, highly directional ground antennas are used to read telemetry data from the GPS satellites and to provide command and navigation data uplinks. This TT&C function is accomplished using signals compliant with the Air Force Space Ground Link Subsystem (SGLS) channel plan. An uplink frequency of 1783.74 MHz and a downlink frequency of 2227.50 MHz are used. The ground antennas are large

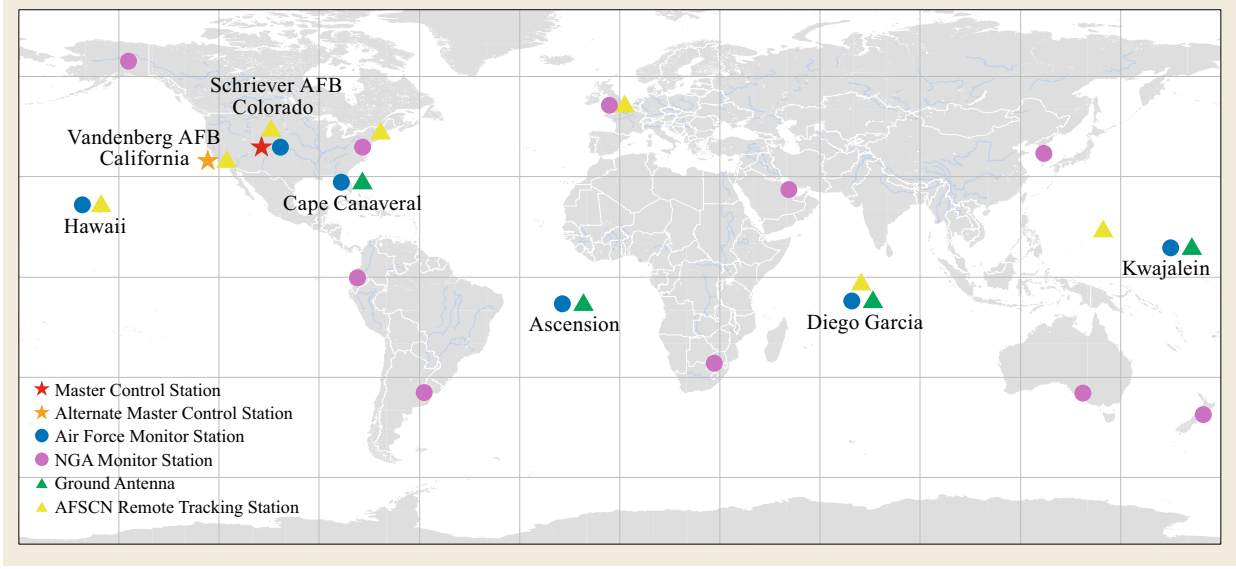

**Fig. 7.6** GPS control segment

(≈ 10 m) and must be pointed to an individual GPS satellite, so scheduling is required by the operators at the MCS.

Routine navigation data uploads are performed as follows. First, as mentioned above, the MCS processing facilities continually estimate satellite position and clock parameters. These facilities also predict these quantities some number of days into the future (e.g., where the satellite is expected to be in the future, and what clock error is expected in the future). The exact prediction timeframe varies from satellite block to block. Typically once per day, the MCS schedules ground contact with each GPS satellite. Clock, ephemeris, and other data are uploaded to the satellite sufficient for that satellite to broadcast navigation data (Sect. 7.4.4) to the GPS users over one or more days without further ground contact from the CS. The operators are quite busy over the course of a day, since in recent years 31 satellites need to be uploaded so an upload must be accomplished at least once every 45 min so that the entire constellation is provided an upload in a day. Furthermore, problematic satellites with poor-performing clocks may need more frequent uploads (e.g., twice/day) to maintain desired levels of accuracy, and any anomalous satellite behavior needs to be managed.

### 7.2.2 Evolution of Capabilities

Since the GPS program began, the CS has undergone a number of significant transitions. The contract for the initial control segment (ICS) was awarded to General Dynamics in September 1974. The ICS included four monitor stations (Hawaii, Alaska, Guam, and Vandenberg AFB), which provided measurements to an MCS at Vandenberg AFB. A single upload station (ULS) was located at Vandenberg and provided navigation data to the GPS satellites. The ICS was operated from 1978 to 1985 primarily to support system development and user equipment testing at Yuma, Arizona [7.23].

In September 1980, a contract was awarded to IBM Federal Systems to develop the operational control segment (OCS) [7.2, 3, 24]. The OCS became operational in 1985 and was used until 2007. The OCS originally included six monitor stations (labeled as *Air Force Monitor Station* in Fig 7.6) and four dedicated ground antennas (Fig 7.6). Eight of the ten additional monitor stations, operated by the National Geospatial-Intelligence Agency (NGA), as shown in Fig 7.6, were added in 2005–2006 (all those shown in Fig 7.6 except Alaska and South Korea). The addition of the eight NGA monitor stations was part of a program referred to as the Legacy Accuracy Improvement Initiative (L-AII) that also included improvements to the OCS data processing algorithms [7.25]. The MCS was originally situated at Vandenberg AFB, but then moved to Falcon AFB (now Schriever AFB) in 1986. Data processing at the MCS was performed by an IBM mainframe computer. A backup MCS in Gaithersburg, Maryland became operational several years later.

A contract was awarded to Lockheed Martin in 1996 to modernize the OCS. Lockheed Martin had acquired the former IBM Federal Systems (that had developed the original OCS) by that point in time. In 2000, as part of the GPS Block IIF satellite procurement, Boeing became the prime contractor for the modernized OCS, with Lockheed Martin as a subcontractor, to develop and deploy the modernized control segment that is still in use today. The modernized OCS hardware and software suite is referred to as the architecture evolution plan (AEP) [7.24]. AEP became operational in September 2007. It originally included the same monitor station, ground antenna, and MCS sites as the original OCS. The MCS uses a distributed set of Sun workstations. When it first became operational in 2007, AEP introduced an alternate master control station (AMCS) at Vandenberg AFB and an enhanced level of compatibility with the Air Force Satellite Control Network (AFSCN). Although not dedicated to GPS, AFSCN ground antennas can be utilized if needed for commanding or uploading data to GPS satellites, as well as downloading telemetry data. Two additional NGA monitor stations (Alaska and South Korea) were added to AEP in 2008. The final set of ground assets is shown in Fig. 7.6.

A further evolution of the CS is planned in a program referred to as the next generation operational control segment or OCX for short [7.26, 27]. The OCX program contract was awarded to Raytheon in 2010. OCX will be deployed in blocks. Block 0 will provide the Air Force the ability to support launch and checkout operations for the GPS III satellites. Block 1 will add functionality to permit the transition from AEP to OCX. At present, the cutover from AEP to OCX Block 1 is anticipated to take place in 2018.

### 7.2.3 Operations

The CS monitor stations continuously track the GPS L1 and L2 P(Y)-code signals from visible satellites using keyed, geodetic-quality receivers. Each monitor station includes additional components including a GPS antenna, redundant cesium clocks, meteorological sensors (not currently used), work stations, and communications equipment. Pseudorange, carrier-phase measurements, demodulated navigation data bits, and signal reception quality indicators are sent to the MCS from each monitor station every 1.5 s.

The MCS (or AMCS) corrects the monitor station measurements for various errors, edits the data, and then feeds the results into an extended Kalman filter. Ionospheric delays are removed using standard linear combinations (Sect. 7.4.3) of the pseudorange and carrier-phase measurements. Tropospheric delays are corrected using the Niell–Saastamoinen model [7.28]. Data editing [7.2, 3] is performed to protect the Kalman filter from suspect measurements.

The measurement update rate and the output estimate rate in the MCS Kalman filter is 15 min. The outputs of the Kalman filter, referred to as *estimated states*, include:

- For each operational GPS satellite: 3 position coordinates and 3 velocities, all in an earth centered inertial (ECI) coordinate system; 2 solar pressure parameters; 3 clock parameters (clock error and its first and second derivative)
- For each monitor station: Tropospheric wet height and 2 clock parameters (clock error and its first derivative).

For the entire operational GPS constellation (31 satellites in 2015) and monitor station network (16 in 2015), the Kalman filter is estimating a very large number of parameters every update cycle – over 380. As currently implemented in AEP, the Kalman filter partitions the states to reduce complexity. For numerical stability, the upper-diagonal (U-D) form of the Kalman filter equations is used [7.3].

Once the CS has the Kalman filter estimates of the satellite position coordinates and clock errors, additional processing is required to predict into the future how these parameters will progress with time. GPS was designed to continue to provide navigation services for extended periods even if the CS was no longer to provide satellite uploads. The Block IIA, IIR, IIR-M, and IIF satellites are uploaded with a minimum of 60 days of navigation data [7.29]. Both the Kalman filter estimation of the satellite positions and the prediction forward in time of these positions require elaborate force models within the CS. At the present time, the GPS satellite force models used by the MCS include [7.3, 24, 25]:

- Earth gravitational model (EGM) of 1996, $12 \times 12$ spherical harmonic expansion coefficients
- Sun–Moon gravity
- Solid Earth tide modeling per [7.30]
- Jet Propulsion Laboratory (JPL) empirical solar radiation pressure models
- Zonal and diurnal–semidiurnal tidal corrections to Earth orientation parameters.

When OCX becomes operational, improved measurement processing and improved satellite force models are expected to significantly reduce the control segment's contribution to the overall GPS error budget [7.26, 27].

The GPS CS includes interfaces with multiple external systems. NGA provides the data from the NGA monitor stations, as well as Earth orientation parameter predictions (EOPP) that are needed by the CS Kalman filter for ECI-ECEF coordinate transformations [7.31]. The United States Naval Observatory (USNO) provides time services that are needed to keep GPS time in synchronization with coordinated universal time (UTC). These service including maintenance of the USNO alternate master clock (AMC) that was installed and became operational at Schriever AFB in 1996. The Jet Propulsion Laboratory (JPL) provides estimates of GPS satellite hardware-induced group delay biases between signals on different carrier frequencies [7.32].

Lastly, the GPS CS generates a number of data files for use by the GPS community. These include constellation almanacs and notice advisory to NAVSTAR users (NANU). The data files are made available to the general public by the US Coast Guard, and descriptions of the files are provided in [7.33].

## 7.3 Navigation Signals

This section provides an overview of the GPS navigation signals, present and future. The timing for all components of all of the GPS navigation signals are coherently derived from an onboard frequency synthesizer driven by the active atomic clock. This onboard synthesizer is designed to produce a 10.23 MHz frequency as apparent to a user on or near the surface of the Earth. An observer moving along with the satellite would see the fundamental clock frequency to run at a slightly slower rate, approximately 10.229999995453 MHz, due to the combined effects of special and general relativity [7.2].

### 7.3.1 Legacy

The oldest 15 of the 31 operational satellites, comprising Block IIA and IIR vehicles launched up through 2004, only broadcast what are now referred to as the *legacy* GPS signals. The legacy GPS signals include the coarse/acquisition- (C/A-) code signal on the link 1 (L1)

carrier frequency of 1575.42 MHz and the precision- (P-) code signal on both L1 and the link 2 (L2) frequency of 1227.6 MHz [7.29]. The C/A-code is open (unencrypted). The P-code signal is only intended for authorized (military) use and is normally encrypted. When the P-code is in this encrypted mode of operation, it is formally referred to as the *Y-code*. In either mode of operation, the signal is most commonly referred to as the *P(Y)-code*.

Both legacy GPS signals are generated using direct sequence spread spectrum (DSSS) modulation, illustrated in Fig. 7.7. A DSSS signal may be formed as the product of three components:

1. A radio frequency (RF) carrier
2. A data waveform
3. A spreading waveform.

For C/A-code or P(Y)-code, the RF carrier is simply a pure sinusoid at L1 or L2. The data waveform is a series of contiguous 20 ms, unit amplitude rectangular pulses generated at 50 Hz with the polarity of the pulses determined by the binary, 50 bps navigation data to be conveyed from the satellite to the user. The spreading waveform is a contiguous series of rectangular pulses generated using a deterministic, digital pseudo-random noise (PRN) code. The minimum period between transitions in the spreading waveform is referred to as a *chip* denoted $T_c$ and the reciprocal of this period as the *chipping rate*, $R_c$, which is the clock rate of the binary PRN code.

The PRN code for each C/A-code signal is taken from the family of length-1023 Gold codes [7.34], and is generated at 1.023 MHz. A unique PRN is used for each signal-type broadcast by each GPS satellite. The PRN codes for the Y-code are generated at 10.23 MHz using private key encryption. Both the algorithm and the keys for Y-code are only available to authorized (e.g., military) users.

It should be noted that Fig. 7.7 is not drawn to scale. There is a tremendous difference in timescales between the GPS signal components that would be difficult to illustrate on a single plot. For instance, for the C/A-code, there are 1540 cycles of the RF carrier for every single chip in the spreading waveform, and 20 460 chips in the spreading waveform for every one data bit. If one visualizes the signal traveling through free space from the satellite to a user on or near the surface of the Earth, each period in the RF carrier stretches over approximately 19 cm, each C/A-code chip over 297 m, and each data bit over nearly 6000 km.

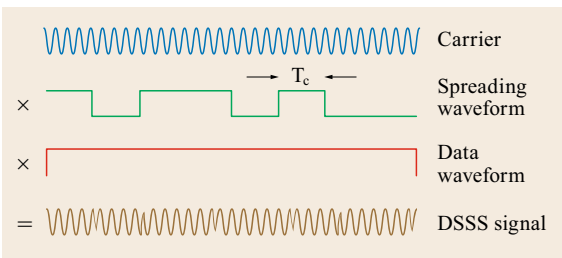

**Fig. 7.7** Direct sequence spread spectrum modulation

The legacy signals have baseband power spectra that are characteristic for any DSSS signals using rectangular chips, which is

$$S(f) = T_c \frac{\sin^2(\pi f T_c)}{(\pi f T_c)^2} , \tag{7.1}$$

with $T_c = 1/(1.023\,\text{MHz})$ for C/A-code, and $T_c = 1/(10.23\,\text{MHz})$ for P(Y)-code.

### 7.3.2 Modernized Signals

Figure 7.8 illustrates the evolution of the GPS signals over satellite blocks. The figure shows the normalized power spectra (on a logarithmic scale) of the GPS signals for each block versus frequency, beginning with the legacy signals broadcast by the Block I, II, IIA, and IIR satellites. The legacy signals exhibit the baseband power spectra provided in equation (7.1). Several of the modernized signals exhibit power spectra with the same spectral characteristics because they are also using DSSS modulations with C/A- or P(Y)-code chipping rates. Table 7.4 gives an overview of the GPS signals.

The eight Block IIR-M satellites launched between 2005 and 2009 introduced two new navigation signals – a new military signal on L1 and L2 referred to as the M code [7.35], and a new civil signal on L2 referred to as L2C [7.29, 36]. (As mentioned earlier, only seven of the eight are broadcasting usable signals today; the seventh Block IIR-M satellite is set unhealthy). The Block IIF satellites, launched since 2010 (9 thus far, with 12 in total planned), introduced a third civil signal on a new carrier frequency. Both the carrier and the signal are referred to as L5 [7.37, 38]. The GPS III satellites, which are anticipated to be launched beginning in 2017, will introduce one further signal – a fourth civil signal referred to as L1C on the L1 carrier.

Compared with the legacy signals, the modernized GPS signals have a number of advanced design features. For all of the modernized civilian signals, these features include dataless components, longer PRN codes, and various improvements to the navigation data encoding and content. L5 and L2C additionally employ secondary codes, and L5 and L1C use wider bandwidth modulations.

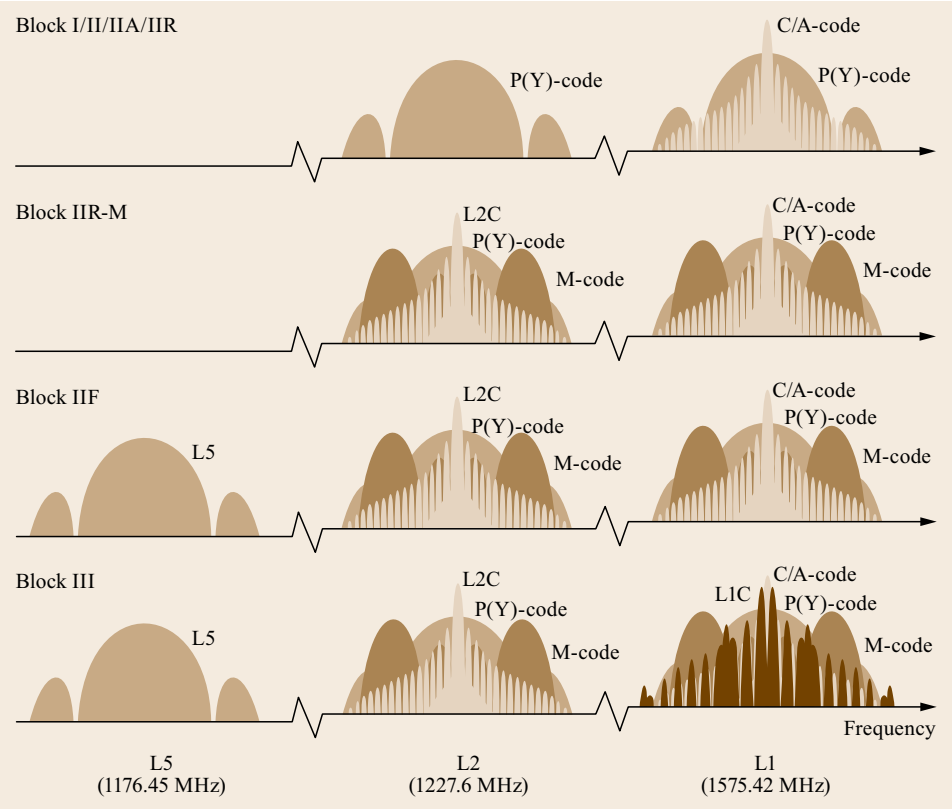

**Fig. 7.8** Evolution of the GPS signals

**Table 7.4** GPS signals overview. See text and Chap. 4 for a description of the various modulations forms and the meaning of the corresponding acronyms

| Band | Signal | Frequency (MHz) | Code length chips | Code rate (MHz) | Data rate (bps/sps) | Modulation | Block | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | | I/II/IIA/IIR | IIR-M | IIF | III |
| L1 | P(Y) | 1575.42 | n/a[a] | 10.23 | 50/50 | BPSK(10) | × | × | × | × |
| | C/A | 1575.42 | 1023 | 1.023 | 50/50 | BPSK(1) | × | × | × | × |
| | L1C | 1575.42 | 10 230 | 1.023 | 50/100 | TMBOC(6,1,4/33) | | | | × |
| | L1C | 1575.42 | 10230/1800 | 1.023 | – | TMBOC(6,1,4/33) | | | | × |
| | M | 1575.42 | n/a[a] | 5.115 | n/a[a] | $BOC_{sin}(10,5)$ | | × | × | × |
| L2 | P(Y) | 1227.60 | n/a[a] | 10.23 | 50/50 | BPSK(10) | × | × | × | × |
| | L2 CM | 1227.60 | 10 230 | 0.5115 | 50(25)/50 | BPSK(1) mux | | × | × | × |
| | L2 CL | 1227.60 | 767 250 | 0.5115 | – | BPSK(1) mux | | × | × | × |
| | M | 1227.60 | n/a[a] | 5.115 | n/a[a] | $BOC_{sin}(10,5)$ | | × | × | × |
| L5 | I5 | 1176.45 | 10230/10 | 10.23 | 50/100 | BPSK(10) | | | × | × |
| | Q5 | 1176.45 | 10230/20 | 10.23 | – | BPSK(10) | | | × | × |

[a] Indicates nonavailability of public information for signals of regulated/military services.

A dataless component (also referred to as a *pilot*) is a portion of a GNSS signal that is not modulated by navigation data. The motivation for including a dataless component is to enable more robust tracking of the signal by a receiver in low signal-to-noise conditions. The receiver can track the RF carrier component of a pilot using a pure phase locked loop (PLL), whereas a Costas loop is required to track a signal modulated by unknown binary data. A PLL can track a signal with approximately one-quarter the signal-to-noise ratio necessary for a Costas loop. Even though only one-half of the total power in each transmitted L2C and L5 signal is devoted to a dataless component, there is still a net 3 dB tracking robustness benefit allowing a receiver to continue

to provide measurements in the presence of more interference or more signal attenuation (due, for example, to obstructions in the line of sight between the user and satellite).

The dataless components for the modernized GPS signals are implemented differently. For L2C, a time division multiplexing scheme is used to implement the pilot component as shown in Fig. 7.9. Two unique PRN codes per satellite are generated at 511.5 kHz, which is half of the 1.023 MHz C/A-code chipping rate. The chips from the two PRN codes are alternated, that is, the first transmitted chip is from the first PRN, the second chip from the second PRN, the third chip from the first PRN, and so forth. The chips generated from the first PRN code are modulated by navigation data, and the chips generated from the second PRN code are not. The resultant signal has the same power spectrum as the C/A-code (ignoring finescale structure due to the periodic PRN codes) but only half the chips in the spreading waveform are modulated by navigation data.

To implement a pilot component for L5, two equal-power DSSS signals per satellite are broadcast in phase quadrature upon the same carrier, using unique PRN codes per signal. The inphase signal is referred to as I5 and is modulated by navigation data. The quadraphase signal, known as Q5, is not modulated by the navigation data. A similar method is used to generate a pilot component for L1C, except that the two L1C components are inphase with each other and for L1C, 3/4 of the signal power is devoted to the pilot.

All the modernized GPS civil signals use PRN codes that are at least 10 times longer than those used for the legacy civilian C/A-code signal. Longer PRN codes reduce interference between signals when being processed by a receiver that is receiving signals simultaneously from multiple satellites. Whereas the C/A-code uses length-1023 PRN codes, L5 and L1C use two length-10 230 codes for each satellite (one for the data component and one for the dataless component of each signal). L2C uses two different PRN lengths per satellite for its data and dataless components. A length-10 230 PRN, referred to as the moderate-length code (CM) is used for the data component, and a long code (CL) of length-767 250 is used for the pilot. The L2C and L5 PRN codes can be generated by linear feedback shift registers. The L1C PRN codes are constructed in a more complicated manner [7.39]. User equipment can either replicate this construction process in software/hardware or, alternatively, may simply store these length-10 230 PRNs in memory.

The L5 and L1C signal components are further modulated by *secondary codes* (also referred to as *overlay codes*). Secondary codes reduce interference between GNSS signals and also facilitate robust data bit synchronization within GNSS receivers. The specific secondary codes used for L5 are referred to as Neuman–Hofman codes after the researchers that identified them for another application over 40 years ago [7.40]. The Neuman–Hofman code for I5 is 10 bit in length, and the code for Q5 is 20 bit in length. Like all binary synchronization codes, the Neuman–Hofman codes are generated at the PRN code repetition interval (1 ms) and simply either leave each repetition of the PRN code as it originally was or inverts it, depending on whether the corresponding synchronization code value is a digital 0 or 1. For instance, the Neuman–Hofman code for I5 is 0000110101. For every 10 repetitions of the I5 PRN code, the first 4 repetitions are transmitted as is, the 5th and 6th inverted, the 7th as is, the 8th inverted, the 9th as is, and the 10th inverted.

The M code uses a variant of DSSS modulation referred to as a binary offset carrier (BOC) [7.41]. BOC

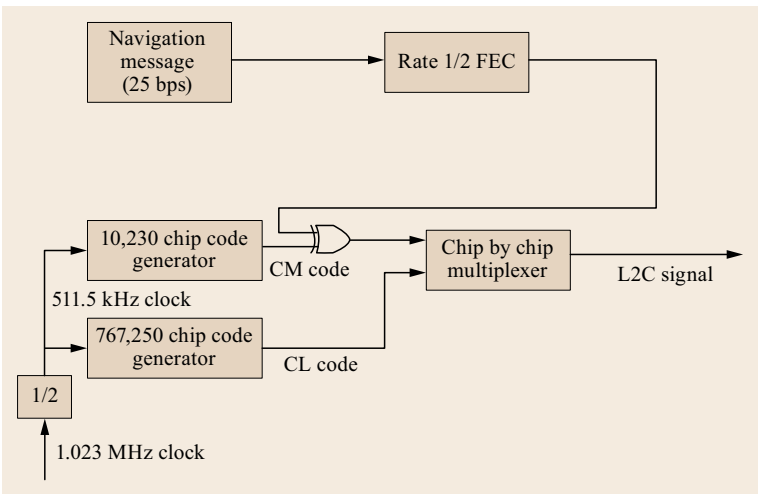

**Fig. 7.9** Baseband L2C signal generation

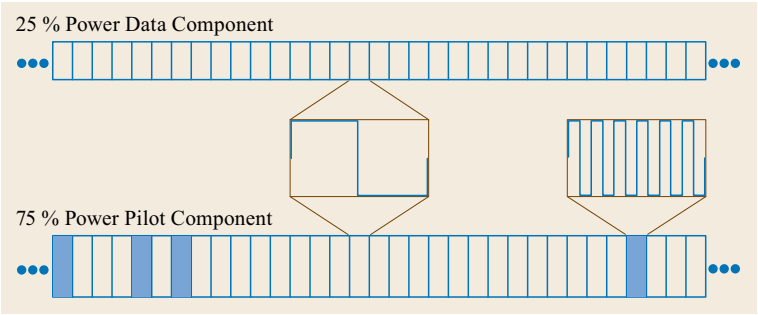

**Fig. 7.10** L1C signal design

modulation adds a fourth component – a deterministic square wave – to the three normal DSSS components shown in Fig 7.1. For M-code, the spreading waveform is generated with a 5.115 MHz chipping rate and the square-wave component is clocked at 10.23 MHz so that there are two cycles of square wave per spreading waveform chip. The addition of the square-wave component gives rise to a power spectrum (Fig. 7.8) that resembles the superposition of two equal-power DSSS power spectra (7.1) at the same chipping rate (5.115 MHz), offset in frequency from the carrier by plus and minus the square-wave frequency. The effect of the square-wave component is thus similar in effect to amplitude modulation double sideband, which uses a sinusoid rather than a square wave. The notation BOC$(m,n)$ is widely used to refer to a BOC modulation with an $m\times$ 1.023 MHz square-wave frequency and an $n\times$ 1.023 MHz chipping rate. Using this notation, the M-code may be stated to employ a BOC(10,5) modulation.

As is well known, in estimation theory [7.42], a receiver's ability to precisely estimate the time of arrival of an arbitrary signal in the presence of additive white Gaussian noise is well predicted by the root-mean-square (RMS) signal bandwidth. The RMS signal bandwidth is defined as the integral of the signal's power spectrum weighted by the squared frequency deviation from the carrier frequency. The larger a signal's RMS bandwidth, the more precise the time-of-arrival measurement. Thus, BOC signals enable more precise pseudorange measurements than would be obtained by a DSSS signal with the same chipping rate and signal-to-noise ratio. L5 provides a signal with a large RMS bandwidth for civilian users, but does so using ordinary DSSS with a 10 times higher chip rate than the C/A-code.

The L1C signal [7.43, 44] also provides an RMS bandwidth greater than that of the C/A-code or L2C. L1C uses a mixture of two BOC modulations referred to as multiplexed BOC (MBOC) [7.45]. The construction of L1C is illustrated in Fig. 7.10. The L1C data component uses BOC(1,1) modulation and has one-fourth of the overall L1C power dedicated to it. The pilot component is more complicated and is perhaps most easily understood through the viewpoint of its generation, employing DSSS but with 1.023 MHz symbols that are not rectangular pulses but rather either one or six cycles of a square wave – BOC(1,1) or BOC(6,1) symbols, respectively. As shown in Fig. 7.10, 29 of every 33 symbols in the spreading waveform are BOC(1,1) and 4 of 33 are BOC(6,1). Since three-fourth of the L1C power is in the pilot, overall $\frac{3}{4}\times\frac{4}{33}=\frac{1}{11}$ of the signal power is devoted to BOC(6,1) modulation and the remaining $\frac{10}{11}$ of the power is BOC(1,1).

**Table 7.5** GPS civil signal minimum specified power levels

| Signal | Minimum specified received power (dBW) |
|---|---|
| C/A-code | −158.5 |
| L2C | −160 (IIR-M/IIF), −158.5 (III) |
| L5 | −154.9 (IIF), −154 (III) |
| L1C | −157 |

### 7.3.3 Power Levels

The minimum specified received power levels for the GPS civil signals are summarized in Table 7.5. These levels are applicable for satellites at or above 5° elevation angle and assume that the user is located on or near the surface of the Earth with a 3 dBi linearly polarized antenna at worst normal orientation. To achieve the C/A-code received power requirement, each GPS satellite must broadcast this signal with an effective isotropic radiated power (EIRP) of around 26.4 dBW. Assuming a Block IIA antenna (Sect. 7.1.2) with 13.2 dBi gain towards the edge of Earth, this EIRP requires that approximately 20 W of C/A-code power be provided to the satellite antenna input port.

## 7.4 Navigation Data and Algorithms

### 7.4.1 Legacy Navigation (LNAV) Data Overview

The content of the 50 bps navigation data upon the C/A and P(Y)-code signals is summarized in Fig. 7.11. The data is organized into 300 bit subframes, comprising ten 30 bit words. Each 30 bit word conveys only 24 information bits. The remaining 6 bit are used for parity so that user equipment can detect transmission errors (Sect. 7.4.2).

Each subframe begins with a telemetry word (TLM) and handover word (HOW) with substantive content summarized in Table 7.6. Subframe 1 (Sect. 7.4.3) includes clock correction data to relate the time kept by the satellite clock to the common GPS system timescale. Subframe 1 also includes information on the broadcasting satellite's health and predicted accuracy. Subframes 2 and 3 provide ephemeris data, to be used for determining the satellite's precise position. Subframes 4 and 5 provide less important data at a slow rate. These subframes are cycled through 25 pages each and include almanac and health data for the remaining GPS satellites as well as ionospheric correction data and the time difference between UTC and GPS system time.

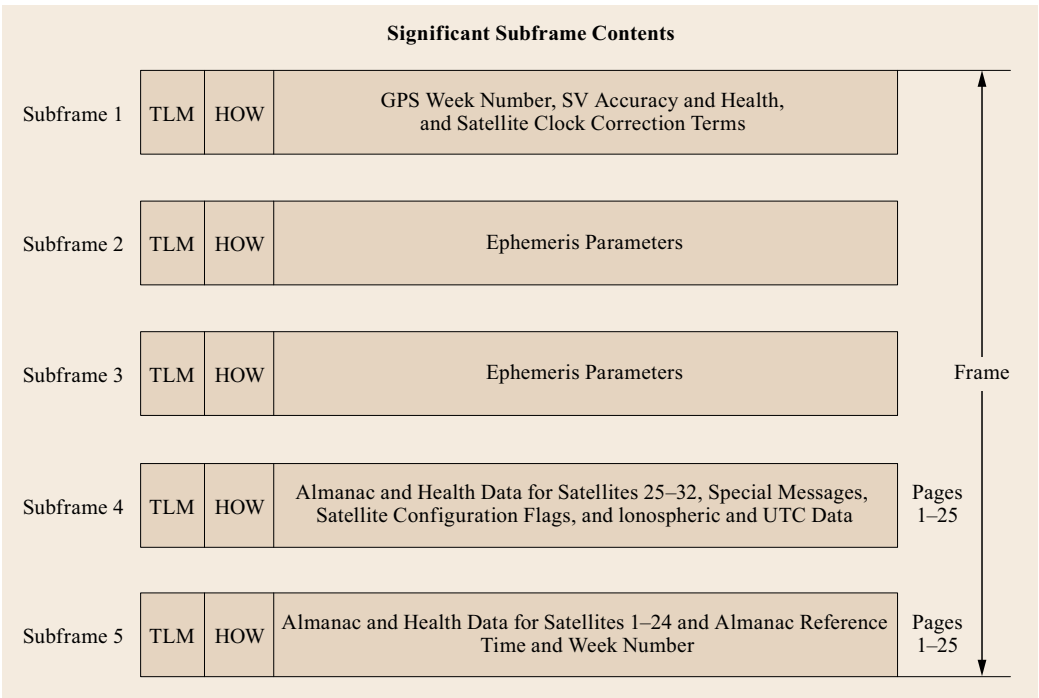

**Fig. 7.11** Legacy GPS signal navigation data

**Table 7.6** Substantive TLM and HOW word content

| Word | Subframe bit number | Parameter | Description |
|---|---|---|---|
| TLM | 1–8 | Preamble | Fixed bit pattern 10001011 to help user equipment synchronize with navigation data subframes |
| TLM | 9–22 | TLM message | Reserved for authorized users and control segment |
| TLM | 23 | Integrity status flag | Today set to 0. In future, may be set to 1 to indicate a higher level of integrity [7.29, Sect. 20.3.3.1] |
| HOW | 1–17 | Time of week count | Provides a timestamp (the integer number of 1.5 s epochs that have elapsed in the GPS timescale since Saturday night at midnight) corresponding to the leading edge of the next subframe |
| HOW | 18 | Alert flag | When set, use this satellite at your own risk |
| HOW | 19 | Anti-spoof flag | When set, indicates that the P-code is encrypted into the Y-code |
| HOW | 20–22 | Subframe identification (ID) | Indicates which of the five subframes is being broadcast following the HOW |

The first broadcast of the navigation data includes the Subframes 1–3 data followed by the first page of Subframe 4 and the first page of Subframe 5. Subframes 1–3 are repeated, followed by the second page of Subframe 4 and the second page of Subframe 5, and so on. It takes 12.5 min for the entire set of data to be broadcast, but during this period typically the same critical clock and ephemeris data will be received 25 times within Subframes 1–3.

### 7.4.2 LNAV Error Detection Encoding

An extended Hamming block code is utilized to generate each 30 bit word. This code is referred to as a (32, 26) code because it is generated using 26 information (source) bits (the 24 information bits to be conveyed in the word,plus the last 2 bits of the previous 30 bit word) and results in a 32 bit output. The 32 bit are truncated to 30 bit by discarding 2 bit. The overall algorithm to produce the transmitted 30 bit word is shown in Fig. 7.12 Note that the encoding is *systematic*, that is, the information bits are included in the transmitted data stream, with one twist – if the last bit in the preceding word is a 1, then all 24 information bits are inverted. For each 30 bit word, the parity scheme enables the user equipment to detect all possible combinations of up to 3 bit errors.

One method that the user equipment can use to detect parity is as follows. First, read the first 24 bit of the word as transmitted. If the 30th bit of the previous word is 1, invert these 24 bit. Apply the parity encoding equations as shown in Fig. 7.12 and compare with the transmitted parity. If there are any differences, a transmission error has occurred, so disregard the data.

### 7.4.3 LNAV Data Content and Related Algorithms

The following subsections provide an overview of the data content of the 50 bps LNAV data conveyed by the GPS C/A-code and P(Y)-code signals, as well as the associated algorithms. For details, the reader is referred to [7.33].

#### Subframe 1

Subframe 1 provides the data parameters listed and described in Table 7.7. The last four parameters are used by receivers to correct for the offset between the broadcasting satellite clock (referred to as *SV time*) and the GPS time scale. GPS receivers form raw pseudorange measurements by differencing the transmit time of each satellite signal (determined by the phase of the received PRN code), $t_{SV}$, from reception time (determined by the receiver clock), $t_r$

$$\rho = c(t_r - t_{SV}) \,, \tag{7.2}$$

where $c$ is the speed of light in a vacuum (299 792 458 m/s). Dual-frequency GPS equipment will measure raw pseudoranges on both L1 and L2 from

$$
\begin{aligned}
D_1 &= d_1 \oplus D_{30}{}^{\star} \\
D_2 &= d_2 \oplus D_{30}{}^{\star} \\
D_3 &= d_3 \oplus D_{30}{}^{\star} \\
&\bullet \\
&\bullet \\
&\bullet \\
&\bullet \\
D_{24} &= d_{24} \oplus D_{30}{}^{\star} \\
D_{25} &= D_{29}{}^{\star} \oplus d_1 \oplus d_2 \oplus d_3 \oplus d_5 \oplus d_6 \oplus d_{10} \oplus d_{11} \oplus d_{12} \oplus d_{13} \oplus d_{14} \oplus d_{17} \oplus d_{18} \oplus d_{20} \oplus d_{23} \\
D_{26} &= D_{30}{}^{\star} \oplus d_2 \oplus d_3 \oplus d_4 \oplus d_6 \oplus d_7 \oplus d_{11} \oplus d_{12} \oplus d_{13} \oplus d_{14} \oplus d_{15} \oplus d_{18} \oplus d_{19} \oplus d_{21} \oplus d_{24} \\
D_{27} &= D_{29}{}^{\star} \oplus d_1 \oplus d_3 \oplus d_4 \oplus d_5 \oplus d_7 \oplus d_8 \oplus d_{12} \oplus d_{13} \oplus d_{14} \oplus d_{15} \oplus d_{16} \oplus d_{19} \oplus d_{20} \oplus d_{22} \\
D_{28} &= D_{30}{}^{\star} \oplus d_2 \oplus d_4 \oplus d_5 \oplus d_6 \oplus d_8 \oplus d_9 \oplus d_{13} \oplus d_{14} \oplus d_{15} \oplus d_{16} \oplus d_{17} \oplus d_{20} \oplus d_{21} \oplus d_{23} \\
D_{29} &= D_{30}{}^{\star} \oplus d_1 \oplus d_3 \oplus d_5 \oplus d_6 \oplus d_7 \oplus d_9 \oplus d_{10} \oplus d_{14} \oplus d_{15} \oplus d_{16} \oplus d_{17} \oplus d_{18} \oplus d_{21} \oplus d_{22} \oplus d_{24} \\
D_{30} &= D_{29}{}^{\star} \oplus d_3 \oplus d_5 \oplus d_6 \oplus d_8 \oplus d_9 \oplus d_{10} \oplus d_{11} \oplus d_{13} \oplus d_{15} \oplus d_{19} \oplus d_{22} \oplus d_{23} \oplus d_{24} \oplus
\end{aligned}
$$

Where

$d_1, d_2, \ldots, d_{24}$ are the source data bits;
the symbol ★ is used to identify the last 2 bits of the previous ward of the subframe;
$D_{25}, D_{26}, \ldots, D_{30}$ are the computed parity bits;
$D_1, D_2, \ldots, D_{29}, D_{30}$ are the bits transmitted by the SV;
$\oplus$ is the "modulo-2" or "exclusive-or" operation.

**Fig. 7.12** LNAV data parity encoding (after [7.33])

each satellite and combine these in a manner that removes the group delay effects of the ionosphere

$$\rho = \frac{\rho_{L2} - \gamma\rho_{L1}}{1-\gamma} , \tag{7.3}$$

where $\gamma = (f_{L1}/f_{L2})^2$, $f_{L1}$ is the L1 carrier frequency (1575.42 MHz), and $f_{L2}$ is the L2 carrier frequency (1227.6 MHz). This linear combination is referred to as the *ionospheric-free* pseudorange. A pseudorange correction, $\Delta\rho$, that can be very large (up to 300 km) is added to the ionospheric-free pseudorange using the last four parameters listed in Table 7.7

$$\Delta\rho = c\left[a_{f0} + a_{f1}(t_{SV} - t_{oc}) + a_{f2}(t_{SV} - t_{oc})^2\right] . \tag{7.4}$$

Single-frequency equipment must apply an additional correction to account for the fact that there are generally group delay biases in the satellite transmission chain between the L1 and L2 signals, and additionally the CS is determining the clock corrections using ionospheric-free pseudorange measurements. L1-only users apply an additional correction (to be subtracted from the pseudorange)

$$\Delta\rho = c\,T_{GD} \tag{7.5}$$

and L2-only users apply the additional correction (again to be subtracted from the pseudorange)

$$\Delta\rho = c\,\gamma\,T_{GD} . \tag{7.6}$$

The accuracy of the broadcast clock corrections, averaged across all operational GPS satellites for the time period from 2008 to 2014 is assessed in [7.46] to be at the 50 cm level (68%) and 1.85 m (95%).

If the satellite clock deviates from GPS time by more than can be corrected by the clock correction parameters (approximately ±1 ms), the satellite may be set unhealthy by the CS to slew the satellite clock back into range [7.47]. Such maintenance action is required typically about once per year for the Block IIA satellites. The clocks on later-generation satellites (Block IIR and beyond) can be controlled in phase, frequency, and frequency drift. For these satellites, after initialization, the CS typically makes adjustments in the frequency drift only while the satellite is still set healthy which largely obviates the need for this type of maintenance action.

### Subframes 2–3

Subframes 2–3 are used to convey ephemeris data to the user. The ephemeris parameters are listed in Table 7.8, along with their number of bits, scale factor (magnitude of the least significant bit (LSB)), and range. The ephemeris parameters include six traditional Keplerian elements (Chap. 3) with associated reference time, $t_{oe}$:

- Semimajor axis, $A$ – provided as the square-root of $A$
- Eccentricity, $e$
- Mean anomaly, $M_0$ – valid for the reference time, $t_{oe}$
- Longitude of ascending node, $\Omega_0$ – valid for the GPS weekly epoch (time of week = 0 s)
- Inclination angle, $i_0$ – valid for the reference time, $t_{oe}$
- Argument of perigee, $\omega$.

All but one of the remaining parameters in Table 7.8 (the exception is IODE, which is described below) provide corrections to the elliptical, stationary orbits that are provided by the Keplerian elements. These are necessary, since as discussed in Chap. 3, Keplerian (elliptical) orbits are only perfectly valid for the two-body problem and in reality there are many more forces acting upon the GPS satellites. The supplied corrections include:

- Cosine and sine harmonic corrections to the argument of latitude, orbital radius, and inclination angle. The amplitudes of these corrections are provided by $C_{us}$, $C_{uc}$ (sine and cosine argument of latitude, respectively); $C_{rs}$, $C_{rc}$ (sine and cosine orbital radius, respectively); $C_{is}$, $C_{ic}$ (sine and cosine inclination angle, respectively).
- Mean motion difference from computed value, $\Delta n$.
- Rate of right ascension, $\dot{\Omega}$
- Rate of inclination angle, IDOT.

The accuracy of the broadcast ephemeris data, averaged across all operational GPS satellites for the time period from 2008 to 2014 is assessed in [7.46] to be 18, 98, and 60 cm (68%, for radial, along-track, and cross-track directions, respectively) and 0.43, 2.23, 1.25 m (95%, for radial, along-track, and cross-track directions, respectively).

The final Subframes 2–3 parameter is issue-of-data ephemeris (IODE). IODE is an 8 bit unsigned integer broadcast in both Subframes 2 and 3 that is intended to provide a means for user equipment to detect when changes have been made to the broadcast ephemeris data. IODE is set equal to the 8 LSBs of the 10 bit IODC (Sect. 7.4.3) for the same data set. By specification [7.29], the transmitted IODE will be different from any value transmitted by the SV over the preceding 6 h.

The broadcast ephemeris parameters are used to compute satellite $(x, y, z)$ coordinates in the World Geodetic System of 1984 (WGS 84) coordinate system (Sect. 7.5) using the algorithm provided in Table 7.9. Importantly, as described in Sect. 7.2, the broadcast ephemeris data is generated by the GPS CS using

**Table 7.7** Subframe 1 parameters

| Subframe bit number | Parameter | Description |
|---|---|---|
| 61–70 | Week number | 10 bit integer (0–1023) that counts weeks elapsed since midnight January 5, 1980 (in the GPS timescale). A rollover occurred at midnight August 21, 1999, and the next rollover will occur at midnight April 6, 2019 |
| 71–72 | Code on L2 | 2 bit to indicate whether PRN on L2 is P(Y) (01) or C/A (10). This reflects a legacy satellite capability to transmit either the P(Y)- or C/A-code on L2. To date, P(Y) has been the normal mode of operation for all GPS satellites. The remaining 2 bit combinations are reserved |
| 73–76 | User range accuracy (URA) index | URA is defined to be a conservative estimate of root-mean-square user range errors (URE) due to signal-in-space error sources (i. e., satellite clock, ephemeris, and hardware group delay errors). In recent years, the 4 bit broadcast URA index for healthy satellites has typically been 0, 1, or 2 most of the time, corresponding to URA ranges of 0–2.4, 2.4–3.4, or 3.4–4.85 m, respectively. Higher URA index values are mapped to larger URA values. A URA index of 15 means that URA is unbounded and the user should use the satellite at their own risk |
| 77–82 | SV health | These 6 bit convey health information for the broadcasting SV. Currently, only two SV health bit patterns are broadcast the vast majority of the time: 000000 for healthy satellites or 111111 for satellites that are deemed unhealthy |
| 83–84, 211–218 | Issue-of-data clock (IODC) | The 10 bit IODC is an unsigned integer that changes whenever the broadcast clock parameters changes. The transmitted IODC is specified to be different from any value transmitted by the SV during the preceding 7 days |
| 91 | L2P data flag | When set, this bit indicates that the L2 P(Y)-code signal is NOT modulated by navigation data |
| 197–204 | $T_{GD}$ | L1/L2 correction term |
| 219–234 | $t_{oc}$ | 16 bit unsigned integer multiplied by 16 s yields the SV clock correction reference time, $t_{oc}$ |
| 241–248 | $a_{f2}$ | 8 bit signed (two's complement) integer multiplied by $2^{-55}$ s/s$^2$ yields the SV clock drift rate correction, $a_{f2}$ |
| 249–264 | $a_{f1}$ | 16 bit signed (two's complement) integer multiplied by $2^{-43}$ s/s yields the SV clock drift correction, $a_{f1}$ |
| 271–292 | $a_{f0}$ | 22 bit signed (two's complement) integer multiplied by $2^{-31}$ s yields the SV clock bias correction, $a_{f0}$ |

**Table 7.8** Subframe 2–3 parameters

| Parameter | Number of bits | Scale factor (LSB) | Range | Units |
|---|---|---|---|---|
| IODE | 8 | 1 | 0–255 | Dimensionless |
| $C_{rs}$ | 16[a] | $2^{-5}$ | $\pm 1024$ | m |
| $\Delta n$ | 16[a] | $2^{-43}$ | $\pm 3.73 \cdot 10^{-9}$ | Semicircles/s |
| $M_0$ | 32[a] | $2^{-31}$ | $\pm 1.0$ | Semicircles |
| $C_{uc}$ | 16[a] | $2^{-29}$ | $\pm 6.10 \cdot 10^{-5}$ | rad |
| $e$ | 32 | $2^{-33}$ | 0–0.03 | Dimensionless |
| $C_{us}$ | 16[a] | $2^{-29}$ | $\pm 6.10 \cdot 10^{-5}$ | rad |
| $\sqrt{A}$ | 32 | $2^{-19}$ | 0–4096 | $\sqrt{m}$ |
| $t_{oe}$ | 16 | $2^{4}$ | 0–604 784 | s |
| $C_{ic}$ | 16[a] | $2^{-29}$ | $\pm 6.10 \cdot 10^{-5}$ | rad |
| $\Omega_0$ | 32[a] | $2^{-31}$ | $\pm 1.0$ | Semicircles |
| $C_{is}$ | 16[a] | $2^{-29}$ | $\pm 6.10 \cdot 10^{-5}$ | rad |
| $i_0$ | 32[a] | $2^{-31}$ | $\pm 1.0$ | Semicircles |
| $C_{rc}$ | 16[a] | $2^{-5}$ | $\pm 1024$ | m |
| $\omega$ | 32[a] | $2^{-31}$ | $\pm 1.0$ | Semicircles |
| $\dot{\Omega}$ | 24[a] | $2^{-43}$ | $\pm 9.54 \cdot 10^{-7}$ | Semicircles/s |
| IDOT | 14[a] | $2^{-43}$ | $\pm 9.31 \cdot 10^{-10}$ | Semicircles/s |

[a] Signed (two's-complement) integer. All other values in table are unsigned integers.

a curve-fit procedure. Thus, the user equipment should use only the algorithm prescribed within [7.29] including the exact values of the constants involved:

- WGS 84 value of the Earth's gravitational constant, $\mu = 3.986005 \cdot 10^{14}\,\mathrm{m^3/s^2}$
- WGS 84 value of the Earth's rotation rate, $\dot{\Omega}_\mathrm{e} = 7.2921151467 \cdot 10^{-5}\,\mathrm{rad/s}$
- $\pi = 3.1415926535898$.

For positioning with GPS, it is necessary to determine where the satellites were at different times in the past, that is, the locations of the satellites when they transmitted the signals that are received at a common time of reception. The transmit time, $t$, in Table 7.9 is typically 60–90 ms earlier than the time of reception (for a user on or near the surface of the Earth) depending on each satellite's elevation angle. When computing the time from reference epoch (third equation in Table 7.9), it is necessary to account for the weekly rollovers in GPS time of week. As one final note on Table 7.9, the sixth line requires solving Kepler's equation for eccentric anomaly. Methods for solving this equation are described in Chap. 3.

As noted in Sect. 7.3, the GPS satellite clock is intentionally set to run slow as apparent to an observer moving along with the satellite to compensate for the effects of both special and general relativity. This compensation method is only sufficient for GPS satellites that are in their ideal, circular orbits. In practice, the GPS orbits are slightly elliptical. At times the GPS satellites are further from the Earth than nominal, in which case they are traveling slower than nominal and higher in the Earth's gravitational field than nominal. Other times, they are closer to the Earth than nominal, traveling faster than nominal and lower in the Earth's gravitational field. These deviations from the nominal orbit result in the need for changes to the special and general relativistic corrections. A pseudorange correction, $\Delta\rho$, is added to the measured pseudorange (after correction for SV clock and group delay bias as described in Sect 7.4.3) to account for this effect

$$\begin{aligned}\Delta\rho &= c\,\Delta t_\mathrm{r} \\ &= c\,e\,F\sqrt{A}\sin E_\mathrm{k}\,, \qquad (7.7)\end{aligned}$$

where

$$\begin{aligned}F &= -\frac{2\sqrt{\mu}}{c^2} \\ &= -4.442807633 \cdot 10^{-10}\,\frac{\mathrm{s}}{\sqrt{\mathrm{m}}}\,. \qquad (7.8)\end{aligned}$$

This relativistic correction can be as large as 14 m in magnitude, assuming an orbital ellipticity of up to 0.02.

**Table 7.9** Determination of GPS satellite position using broadcast ephemeris data (after [7.29])

| $A = (\sqrt{A})^2$ | Semimajor axis |
|---|---|
| $n_0 = \sqrt{\frac{\mu}{A^3}}$ | Computed mean motion (rad/s) |
| $t_\mathrm{k} = t - t_\mathrm{oe}$ | Time from ephemeris reference epoch |
| $n = n_0 + \Delta n$ | Corrected mean motion |
| $M_\mathrm{k} = M_0 + n t_\mathrm{k}$ | Mean anomaly |
| $M_\mathrm{k} = E_\mathrm{k} - e \sin E_\mathrm{k}$ | Kepler's equation for eccentric anomaly (rad) |
| $\nu_\mathrm{k} = \tan^{-1}\left\{\frac{\sin\nu_\mathrm{k}}{\cos\nu_\mathrm{k}}\right\} = \tan^{-1}\frac{\sqrt{1-e^2}\sin E_\mathrm{k}/(1-e\cos E_\mathrm{k})}{(\cos E_\mathrm{k}-e)/(1-e\cos E_\mathrm{k})}$ | True anomaly |
| $E_\mathrm{k} = \cos^{-1}\left\{\frac{e+\cos\nu_\mathrm{k}}{1+e\cos\nu_\mathrm{k}}\right\}$ | Eccentric anomaly |
| $\Phi_k = \nu_\mathrm{k} + \omega$ | Argument of latitude |
| $\delta u_\mathrm{k} = c_\mathrm{us}\sin 2\Phi_\mathrm{k} + c_\mathrm{uc}\cos 2\Phi_\mathrm{k}$ | Argument of latitude correction |
| $\delta r_\mathrm{k} = c_\mathrm{rs}\sin 2\Phi_\mathrm{k} + c_\mathrm{rc}\cos 2\Phi_\mathrm{k}$ | Radius correction |
| $\delta i_\mathrm{k} = c_\mathrm{is}\sin 2\Phi_\mathrm{k} + c_\mathrm{ic}\cos 2\Phi_\mathrm{k}$ | Inclination correction |
| $u_\mathrm{k} = \Phi_\mathrm{k} + \delta u_\mathrm{k}$ | Corrected argument of latitude |
| $r_\mathrm{k} = A(1 - e\cos E_\mathrm{k}) + \delta r_\mathrm{k}$ | Corrected radius |
| $i_\mathrm{k} = i_0 + \delta i_\mathrm{k} + (\mathrm{IDOT})t_\mathrm{k}$ | Corrected inclination |
| $x'_\mathrm{k} = r_\mathrm{k}\cos u_\mathrm{k}$<br>$y'_\mathrm{k} = r_\mathrm{k}\sin u_\mathrm{k}$ | Positions within orbit coordinate system |
| $\Omega_\mathrm{k} = \Omega_0 + (\dot{\Omega} - \dot{\Omega}_\mathrm{e})t_\mathrm{k} - \dot{\Omega}_\mathrm{e} t_\mathrm{oe}$ | Corrected longitude of ascending node |

#### Subframes 4–5

As described in Sect. 7.4.1, both Subframes 4 and 5 are paged, with 25 pages of data each. A summary of the content of Subframes 4 and 5 is provided in Table 7.10. Many of the pages are reserved for authorized users or internal system use.

Pages 1–24 of Subframe 5 and Pages 2, 3, 4, 5, 6, 8, 9, and 10 of Subframe 4 provide *almanac* data. This data is essentially truncated and simplified (i. e., using fewer parameters) ephemeris data for all of the satellites in the constellation. The same algorithm as used for the ephemeris data (Table 7.9) can be used by the user equipment to determine the coarse positions of other satellites to aid acquisition.

Page 13 of Subframe 4 is specified to contain elements of a navigation message correction table (NMCT). The NMCT is only intended for authorized users and may be encrypted [7.33]. This table, which is also referred to as the wide area GPS enhancement (WAGE), essentially contains pseudorange corrections for all of the other GPS satellites [7.48].

For the benefit of single-frequency L1-only GPS users, Page 18 of Subframe 4 includes ionospheric delay correction parameters. These parameters provide to the single-frequency user an estimate of the vertical ionospheric delay errors in the form of a half-cosine during local daylight hours. The broadcast parameters are determined by a table lookup by the GPS MCS using daily measurements of solar flux at 10.7 cm and the day of the year [7.49].

Subframe 4 also provides data necessary to relate the GPS timescale to UTC as maintained by the US Naval Observatory – UTC (USNO).

### 7.4.4 Civil Navigation (CNAV) and Civil Navigation-2 (CNAV-2) Data

All of the modernized civil GPS signals provide similar navigation data content to that provided by the C/A-code and P(Y)-code signals. L1C and L5 convey navigation data at 50 bps, and L2C at 25 bps. The navigation data format for L2C and L5 is referred to as CNAV, and the format for L1C is referred to as CNAV-2.

Several improvements relative to the C/A-code are notable. First, all the modernized signals use forward error correction (FEC) encoding such as rate 1/2 convolutional encoding (e.g., L2C and L5) or low-density parity check codes (L1C). FEC techniques take the raw navigation data bits to be conveyed to the end-user and judiciously add redundancy to them. Although the rate of binary data is increased (by a factor of 2 for rate 1/2 encoding), the receiver is able to decode the raw navigation data bits with a smaller probability of error. For the reader without a communication theory background, it may be helpful toward understanding GNSS signal specifications to know that the rate of raw navigation data, $R_b$, is normally specified in units of bits/second (bps) and the resultant higher data rate after FEC is applied, $R_s$, in units of symbols/second (sps). The net benefit of FEC is that the receiver can read the navigation data bits in poorer signal-to-noise conditions.

All of the modernized GPS civil signals also utilize an improved error detection scheme. The Hamming (32, 26) code used for the LNAV data for error detection (Sect. 7.4.2) is very inefficient in that 6 parity bits are used for every 30 bit word. The modernized civil signals use a 24 bit cyclic redundancy check (CRC) code along with a much longer word length (e.g., 300 bit for L5). This CRC scheme is much more efficient and allows receivers of the modernized signals to more robustly detect the occurrence of one or more bit errors.

The clock and ephemeris navigation data fields, although similar to those conveyed via C/A-code and P(Y)-code, have more precise least significant bits and some additional terms, for example, in the satellite ephemeris representation, to ensure that the data field design will not significantly limit pseudorange measurement precision in the future. New navigation data fields are also added to CNAV and CNAV-2 as

**Table 7.10** Content of Subframes 4 and 5 (after [7.29])

| Subframe | Page(s) | Data |
|---|---|---|
| 4 | 1, 6, 11, 16, and 21 | Reserved |
| | 2, 3, 4, 5, 7, 8, 9, and 10 | Almanac data for SV 25 through 32, respectively |
| | 12, 19, 20, 22, 23, and 24 | Reserved |
| | 13 | Navigation message correction table (NMCT) |
| | 14 and 15 | Reserved for system use |
| | 17 | Special messages |
| | 18 | Ionospheric and UTC data |
| | 25 | A-S flags/SV configurations for 32 SVs, plus SV health for SV 25 through 32 |
| 5 | 1 through 24 | Almanac data for SV 1 through 24 |
| | 25 | SV health data for SV 1 through 24, the almanac reference time, the almanac reference week number |

compared to LNAV. These include intersignal corrections, Earth orientation parameters, and an improved set of differential corrections that break apart clock and ephemeris errors as compared to the NMCT in LNAV that provides only a lumped pseudorange correction. For details, refer to [7.32, 37, 43].

## 7.5 Time System and Geodesy

GPS uses its own timescale, referred to as *GPS time*. GPS time was set equal to UTC as maintained by the US Naval Observatory (UTC [USNO]) on midnight on the night of January 5, 1980/morning of January 6, 1980. However, unlike UTC, GPS time is a continuous timescale, that is, there are no leap seconds. GPS time used to be maintained by a single physical clock in the GPS CS until 1985. Since the CS transitioned to the IBM-delivered system in 1985, GPS time has been created using a composite clock [7.50], that is, the weighted average of the aggregate set of atomic clocks within GPS. As discussed in Sect. 7.1, there are rubidium or cesium clocks on-board all of the GPS satellites, and as discussed in Sect. 7.2, there are additionally atomic clocks situated at the monitor stations and at the MCS.

The GPS CS steers GPS time to keep it within 1 μs of UTC (USNO) by specification [7.29]. As noted in Sect. 7.3, the broadcast GPS navigation data includes parameters to relate GPS time and UTC (USNO). This data is specified to be accurate to within 90 ns, one-sigma [7.29]. Actual performance is much better. GPS time is usually maintained to within 20 ns of UTC (USNO) and application of the broadcast GPS-UTC corrections typically yields UTC (USNO) within 5 ns [7.51].

As discussed in Sect. 7.4.3, each satellite has its own timescale referred to as *SV time* [7.29]. The clock correction data included within the navigation data (e.g., Subframe 1 for the legacy signals) is intended to allow the user to relate each satellite's SV time to the common GPS time. SV time may deviate from GPS time by up to 1 ms, which is the range of the Subframe 1 clock correction data.

The GPS satellite positions are provided to the user, via computations enabled by the Subframe 2 ephemeris data, within the World Geodetic System 1984 (WGS-84) reference frame. The coordinates of the GPS CS monitor stations are periodically readjusted to keep WGS-84 aligned with the International Terrestrial Reference Frame (ITRF). WGS-84 and ITRF are generally considered as being coincident within several centimeters.

## 7.6 Services and Performance

GPS presently provides two services – one for civilian users referred to as the standard positioning service (SPS) [7.5] and one available only to authorized users (primarily the US military, and the militaries of US allies) referred to as the precise positioning service (PPS). The United States has pledged to make the GPS SPS available for civil aviation use on a continuous worldwide basis, free of direct user fees, with a minimum of 6 years advance notice to be provided in the event that this service will be terminated. This commitment was initially made by the Administrator of the Federal Aviation Administration (FAA) in 1994 [7.52]. The commitment to provide GPS SPS service was reiterated in 2007 [7.53], with an additional commitment made at that time, to provide GPS satellite-based augmentation system (SBAS) services in North America, free of direct user charges, through the FAA's Wide Area Augmentation System (WAAS) (Chap. 12 for a description of SBASs, including WAAS).

At one time, the accuracy of the SPS was intentionally degraded using a technique referred to as selective availability (SA), which was observed to be implemented as a pseudorandom dithering of the satellite clock that could be removed only by PPS receivers with the knowledge of the generation algorithm and cryptographic keys [7.2]. On May 12, 2000, the intentional degradation of SPS performance due to SA was ceased [7.54] and more recently, in September 2007 the United States announced that the capability to implement SA will be removed from future GPS satellite procurements [7.55].

The specified accuracy of the GPS SPS is 13 m, 95%, for horizontal positioning and 22 m, 95%, for vertical positioning [7.5]. This specification is for the signal-in-space (SIS) only (i. e., it does not include errors due to the atmosphere, multipath, or user equipment), and is based upon a global average. Actual performance is typically significantly better than the specification. For instance, the observed 95% horizontal and vertical positioning accuracies for 28 GPS SPS receivers distributed throughout North America from April 01 to June 30, 2013 were 3.0 and 4.3 m, re-

spectively [7.53]. Further, the data reported in [7.53] includes all real-world errors, whereas the accuracy specification in the SPS performance standard [7.5] only includes SIS errors. PPS users typically enjoy even better accuracies, on the order of 1–2 m, 95%, for both horizontal and vertical positioning. GPS users employing differential techniques, as described in later chapters of this text, can achieve accuracies better than 1 cm.

Although not an intended service for GPS, many civilian users are tracking the encrypted P(Y)-code signals on L1 and L2 without requiring access to the cryptographic keys using codeless or semicodeless techniques [7.56]. A public notice was made in 2008 [7.57] to commit the US government to supporting codeless–semicodeless access to the GPS P(Y) signals until December 31, 2020. In 2015, this commitment was superseded by a new one to continue support to codeless–semicodeless receivers *... until at least 2 years after there are 24 operational satellites broadcasting L5* [7.58]. Users of codeless–semicodeless GPS receivers are advised to transition to new user equipment utilizing the modernized GPS signals (L2C, L5).

# 8. GLONASS

Sergey Revnivykh, Alexey Bolkunov, Alexander Serdyukov (deceased), Oliver Montenbruck

The Global'naya Navigatsionnaya Sputnikova Sistema (GLONASS) is a global navigation satellite system developed by the Russian Federation. Similar to its US counterpart, the NAVSTAR global positioning system (GPS), GLONASS provides dual-frequency L-band navigation signals for civil and military navigation. Initiated in the 1980s, the system first achieved its full operational capability in 1995. Following a temporary degradation, the nominal constellation of 24 satellites was ultimately reestablished in 2011 and the system has been in continued service since then. This chapter describes the architecture and operations of GLONASS and discusses its current performance. In addition, the planned evolution of the space and ground segment are outlined.

## 8.1 Overview

Next to GPS, GLONASS is the second fully operational and global navigation satellite system. This section outlines the history of GLONASS and describes its basic characteristics.

### 8.1.1 History and Evolution

GLONASS is the second-generation dual-use governmental global satellite navigation system of the Russian Federation. The predecessor of GLONASS – the low-altitude satellite navigation/communication system Tsyclon/Tsikada – became operational in 1976 [8.1, 2]. It was available for civil users as well. The system provided a positioning accuracy of 80–100 m with a delay of 1.5–2 h. The idea of using the Doppler radio-frequency shift of signals transmitted from the satellites for navigation implemented in Tsyclon/Tsikada was introduced by Prof. Shebshayevich from the Mozhaysky Military Space Academy in 1957.

GLONASS research and development started in the beginning of the 1970s and was based on the method of instant position determination using measurements of time differences between a navigation receiver and a group of satellites emitting navigation signals with synchronized time tags. The first test satellite of the GLONASS system (named Uragan, or Hurricane, at that time) was successfully launched on 12 October 1982. On 24 September 1993, the GLONASS system with initial operational capability of 12 satellites was commissioned for military service. GLONASS with full operational capability (24 satellites) was deployed in 1995.

Civil use of GLONASS for air safety was first offered in 1988, when details of the GLONASS system and signal were released to the International Organization for Air Safety (ICAO) [8.3]. In parallel to these activities, various Western researchers had already made efforts to identify key properties of the

GLONASS signals through high-gain antenna measurements and a systematic code search [8.4–6]. These enabled early developments of standalone-GLONASS and GPS/GLONASS receivers. In 1995, through the decree of the President of the Russian Federation, GLONASS received the status of a dual-use system available for civil users worldwide. A comprehensive interface control document (ICD) describing the open service signals and navigation message was first made available in the English language in 1998 and has been continuously maintained since then [8.7].

Due to a limited operational lifetime of the early generation of GLONASS satellites and an insufficient replenishment, the number of active satellites gradually decreased down to a minimum of seven active satellites in 2001 (Fig. 8.1) [8.2, 8]. Since 2002, GLONASS sustainment and evolution have been conducted in the framework of the long-term GLONASS Federal Program with a secured budget enabling significant step-by-step performance improvements. Within the following decade, regular launches and the extended lifetime of the new GLONASS-M satellites helped to gradually increase the number of operational satellites. The 24-satellite constellation (Fig. 8.2) required for a fully global service was ultimately re-established in 2011 with the launch of GLONASS-M No. 44.

On 17 May 2007, the decree of the President of the Russian Federation declared the GLONASS open service available to all national and international users without any limitations [8.9]. At the same time, it was demanded that GLONASS-based navigation equipment shall be used by federal authorities for the sake of national security [8.10]. The GLONASS system is thus considered a core element in the implementation of the National Navigation Policy. Its maintenance and modernization in the 2012–2020 time frame are pursued within the GLONASS Federal Program, which aims for a continued performance increase through improvements of both the ground and space system.

The value of GLONASS as a standalone or complementary system for geodesy and precise navigation was recognized early on by the scientific community [8.11] and promoted the buildup of global tracking networks with GLONASS-capable global navigation satellite system (GNSS) receivers. Within the International GLONASS Experiment (IGEX-98 [8.12]) precise orbit solutions were generated for the first time and transformation parameters between the various realizations of the terrestrial reference frame (PZ-90, WGS-84, etc.) could be established. This work was later continued in the International GLONASS Service (IGLOS) pilot project [8.13], which provided the starting point for high-precision GLONASS point positioning applications.

## 8.1.2 Constellation

The GLONASS space segment nominally consists of 24 operational satellites, evenly distributed over three orbital planes (Fig. 8.2). The nominal constellation parameters are summarized in Table 8.1.

For best coverage, GLONASS adopts a so-called Walker 24/3/1 constellation geometry, where the parameters $t/p/f$ specify the total number of satellites, the number of orbital planes and the phasing parameter [8.14]. The longitude of ascending node of each

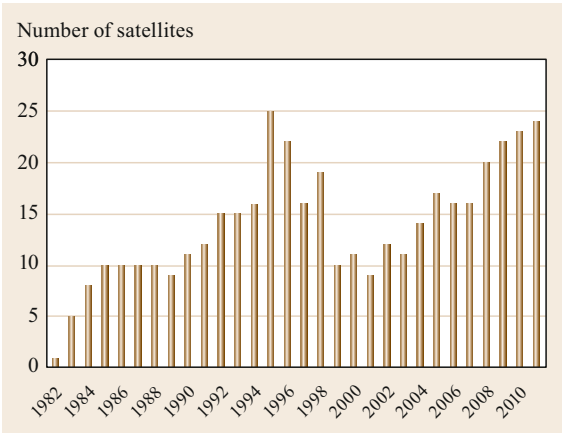

**Fig. 8.1** GLONASS constellation development (after [8.8], courtesy of Springer)

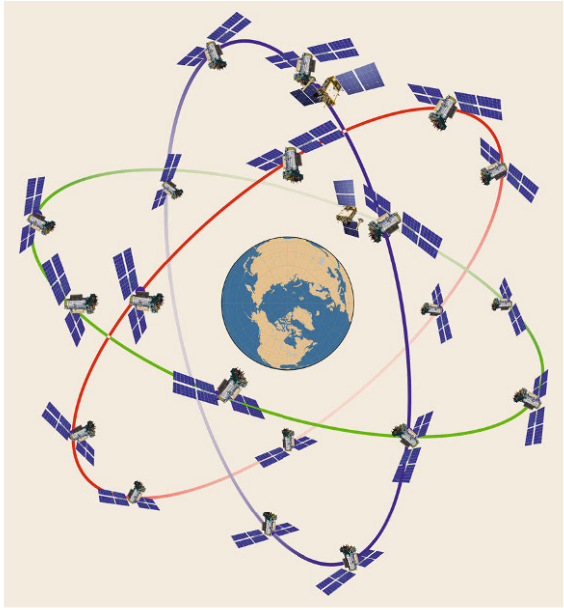

**Fig. 8.2** GLONASS constellation in spring 2016 (courtesy of ISS Reshetnev)

**Table 8.1** Nominal GLONASS constellation parameters

| Parameter | Value |
|---|---|
| Number of operational satellites | $t = 24$ |
| Number of orbital planes, $p$ | $p = 3$ |
| Number of satellites in a plane | $t/p = 8$ |
| Phasing parameter | $f = 1$ |
| Orbit type | Near circular |
| Eccentricity | $e < 0.01$ |
| Inclination | $i = 64.8° \pm 0.3°$ |
| Nominal altitude | $h = 19\,100$ km |
| Period of revolution | $T = 11$ h 15 min 44 s $\pm$ 5 s |
| Longitude of ascending node between planes | $\Delta\Omega = 120°$ |
| Argument of latitude difference | $\Delta u = 45°$ |
| Latitude shift between planes | $\Delta uf/n = 15°$ |
| Ground track repeat cycle | 17 orbits/8 d |

plane differs by $\Delta\Omega = 360°/p = 120°$ from plane to plane. There are $t/p = 8$ satellites per plane, separated by $360°p/t = 45°$ in argument of latitude. The difference in the argument of latitude of satellites in equivalent slots in two different orbital planes is $\Delta u = 360°f/t = 15°$.

Each GLONASS satellite is identified by its *slot* number, which defines the orbital plane and its location within the plane (Fig. 8.3). Slot numbers 1–8 belong to orbital plane 1, while planes 2 and 3 comprise slot numbers 9–16 and 17–24 respectively.

The GLONASS satellites have no resonance with rotation of the Earth (based on gravitational field harmonics). The satellite's period is selected so that satellites make 17 full orbits for eight equinoctial days (approximately eight constituent days). Furthermore, the beginning of each orbit shifts with respect to the Earth's surface. Each eight days a satellite passes over the same point on the Earth's surface. Due to shifting in orbital planes, all the satellites are moving relative to Earth's surface practically along the same ground tracks (Fig. 8.4).

The orbital inclination of the GLONASS satellites ($\approx 65°$) is roughly ten degrees higher than that of other medium altitude Earth orbit (MEO) navigation systems (GPS, BeiDou, Galileo), which provides improved visibility conditions over the area of the Russian Federation. Worldwide GLONASS users likewise benefit from a good sky coverage with a reduced visibility gap around the celestial pole (Fig. 3.8 of Chap. 3).

### 8.1.3 GLONASS Geodesy Reference PZ-90

The parameters and data of the Earth Model PZ-90 [8.15] are applied for GLONASS satellite orbit determination and ephemeris calculation. The PZ-90 system was established in 1990 and superseded the Soviet Geodetic System (SGS-85) that was used by GLONASS until 1993 [8.16].

The PZ-90 definition comprises fundamental geodetic constants, parameters of the Earth ellipsoid, and the Earth gravity field parameters (Table 8.2) as well as the geocentric reference system (GRS), which is defined in accord with common conventions of the International Earth Rotation and Reference Systems Service (IERS) and Bureau International De l'Heure (BIH). The PZ-90 system originates in the Earth's center of mass including the oceans and atmosphere. Its $z$-axis is directed to the conventional reference pole and its $x$-axis points to the intersection of the equatorial plane and the zero meridian as defined by the BIH [8.17, 18].

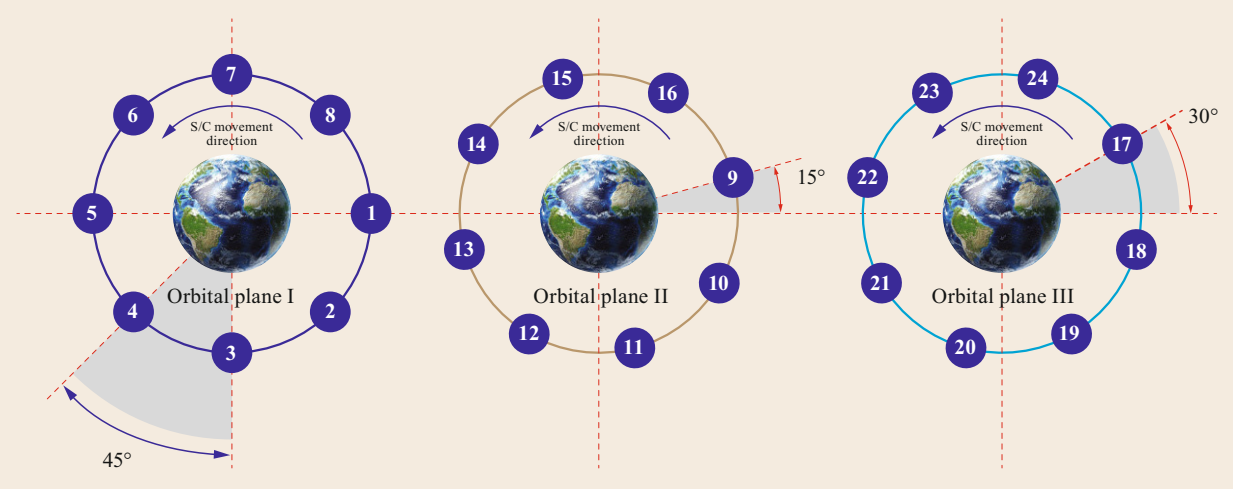

**Fig. 8.3** GLONASS satellite positions within orbital planes (courtesy of ISS Reshetnev)

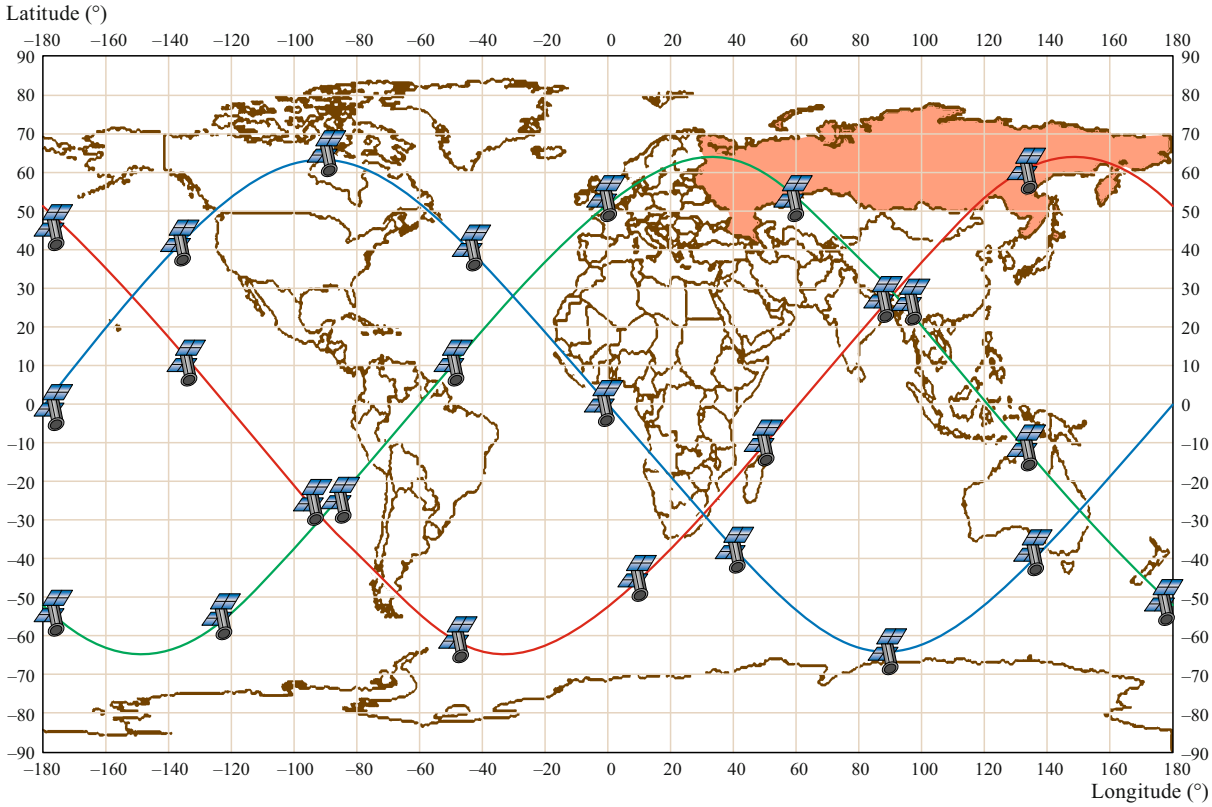

**Fig. 8.4** GLONASS satellite ground tracks

**Table 8.2** Fundamental parameters of the Earth model PZ-90 (after [8.15])

| Parameter | Value |
|---|---|
| Speed of light in vacuum | $c = 299\,792\,458\,\mathrm{m/s}$ |
| Gravitational constant | $G = 6.67259 \cdot 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ |
| Geocentric gravitational coefficient (including atmosphere) | $GM_\oplus = 398\,600.4418 \cdot 10^9\,\mathrm{m^3/s^2}$ |
| Angular velocity | $\omega_\oplus = 7.292115 \cdot 10^{-5}\,\mathrm{rad/s}$ |
| Semimajor axis | $a = 6\,378\,136.0\,\mathrm{m}$ |
| Flattening | $f = 1/298.257\,84$ |

The initial realization of the PZ-90 system had an accuracy of about 1–2 m. In the late 1990s, various efforts were made to establish the transformation between PZ-90 and the WGS-84 frame of GPS based on the joint processing of GPS/GLONASS observations in global networks and the comparison of postprocessed and broadcast GLONASS orbits [8.19–21].

The first major revision of the PZ-90 frame realization refers to the year 2002 and is known as PZ-90.02. It was introduced in GLONASS operations on 20 September 2007 [8.22] and notably improved the consistency of broadcast orbits with WGS-84 and the ITRF.

A further update, PZ-90.11 [8.15, 18] was implemented in the GLONASS operations on 31 December 2013 at 3:00 p.m. The PZ-90.11 GRS is a practical realization of the International Terrestrial Reference System (ITRS) at epoch 2010.0, which is based on the results of GPS/GLONASS data processing from space geodetic network (SGN) sites and a number of International GNSS Service (IGS) sites (Fig. 8.5). The accuracy (root mean square, RMS) of the PZ-90.11 GRS with respect to the Earth center is 0.05 m with relative accuracy of the reference point position on the level of 0.001–0.005 m.

The transition between different frames is commonly described by a seven-parameter similarity transformation (*Helmert* transformation)

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix}_\mathrm{B} = \begin{pmatrix} 1+m & +\omega_\mathrm{z} & -\omega_\mathrm{y} \\ -\omega_\mathrm{z} & 1+m & +\omega_\mathrm{x} \\ +\omega_\mathrm{y} & -\omega_\mathrm{x} & 1+m \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}_\mathrm{A} + \begin{pmatrix} \Delta x \\ \Delta y \\ \Delta z \end{pmatrix} \quad (8.1)$$

for the coordinates $\boldsymbol{r}_\mathrm{A} = (x, y, z)_\mathrm{A}^\top$ and $\boldsymbol{r}_\mathrm{B} = (x, y, z)_\mathrm{B}^\top$ in the original (A) and transformed (B) system, where

**Fig. 8.5** PZ-90.11 reference points on the Russian territory (as of 2011)

**Table 8.3** PZ-90 transformation parameters

| From | To | $\Delta X$ (m) | $\Delta Y$ (m) | $\Delta Z$ (m) | $\omega_x$ ($10^{-3}''$) | $\omega_y$ ($10^{-3}''$) | $\omega_z$ ($10^{-3}''$) | $m$ ($10^{-6}$) | Epoch | Reference |
|---|---|---|---|---|---|---|---|---|---|---|
| PZ-90 | WGS-84 | −1.10 | −0.30 | −0.90 | 0 | 0 | −200 | −0.12 | 1990.0 | [8.17, 23] |
| PZ-90 | ITRF-97 | +0.07 | +0.00 | −0.77 | −19 | −4 | +353 | −0.003 | | [8.21] |
| PZ-90 | PZ-90.02 | −1.07 | −0.03 | +0.02 | 0 | 0 | −130 | −0.22 | 2002.0 | [8.17, 23] |
| PZ-90.02 | WGS-84(1150)/ ITRF-2000 | −0.36 | +0.08 | +0.18 | 0 | 0 | 0 | 0 | 2002.0 | [8.17, 23] |
| PZ-90.11 | ITRF-2008 | −0.003 | −0.001 | +0.000 | +0.019 | −0.042 | +0.002 | −0.000 | 2010.0 | [8.18] |

$\Delta \boldsymbol{r}_B = (\Delta x, \Delta y, \Delta z)^\top$ is the translational offset, $\boldsymbol{\omega} = (\omega_x, \omega_y, \omega_z)^\top$ describes the rotational transformation and $m$ denotes the scale difference. Transformation parameters for past and current realizations of the PZ-90, WGS84, and the International Terrestrial Reference Frame (ITRFs) are summarized in Table 8.3.

### 8.1.4 GLONASS Time

GLONASS System Time (GLST) provides the common reference to which all GLONASS satellite clocks are synchronized. It is based on observations of an ensemble of continuously operating hydrogen masers in the GLONASS ground segment and synchronized to Universal Time Coordinated of Russia, UTC(SU) as a reference timescale. UTC(SU) is itself maintained by the National Metrology Institute of the Russian Federation (VNIIFTRI) [8.24] in Mendeleevo near Moscow as part of the State Time and Frequency Service (STFS). It is realized through an ensemble of hydrogen masers and continuously steered to Coordinated Universal Time (UTC) through satellite time and frequency transfer techniques [8.25]. Differences of UTC and UTC(SU) are routinely monitored by the Bureau International des Poids et Mesures (BIPM) and have decreased from a few tens of ns in 2011 [8.26] to less than 2 ns in 2016.

The comparison of the national timescale, GLST, and UTC is accomplished through common-view GNSS time transfer (using either GPS or GLONASS satellites; Chap. 41) and two-way time and frequency transfer via geostationary satellites (Fig. 8.6).

Unlike GPS time, the GLONASS System Time exhibits no integer offset from UTC, but is offset by 3 h to match the local time zone of Moscow as adopted by the GLONASS ground control segment

$$\mathrm{GLST} = \mathrm{UTC(SU)} + 3\,\mathrm{h} - C\,. \tag{8.2}$$

The fractional difference $C$ is controlled to be less than 1 µs [8.7]. A predicted value thereof, the GLONASS

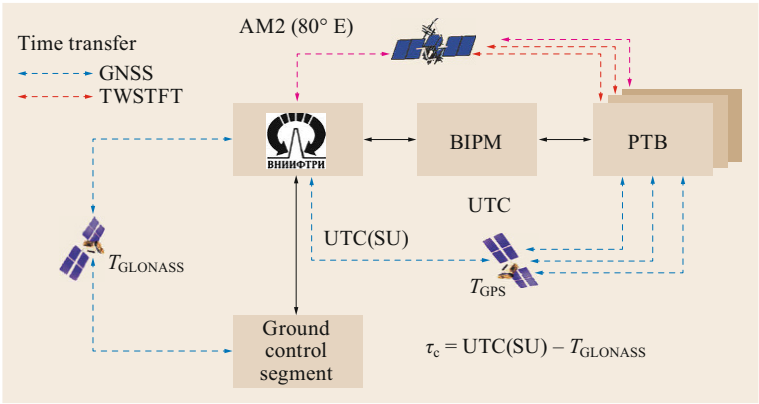

**Fig. 8.6** Generation and monitoring of UTC(SU) and GLONASS system time (GLST) (after [8.27])

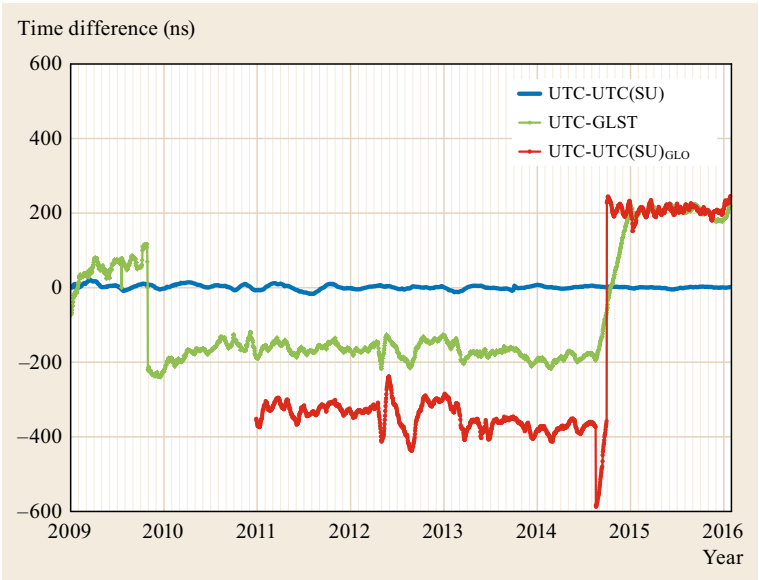

**Fig. 8.7** Difference of UTC with respect to UTC(SU) (*blue*), GLONASS System Time (*green*) and the prediction of UTC(SU) as broadcast by the GLONASS satellites. Illustration based on data provided by the BIPM [8.26]

time correction parameter $\tau_c$, is broadcast as part of the navigation message to provide users with direct access to UTC(SU).

Integer second corrections of the GLST by $\pm 1$ s are performed simultaneously with those of UTC. These UTC corrections are conducted by the Bureau International de l'Heure following the recommendation of the International Earth Rotation and Reference Systems Service (IERS). They are required whenever the UT1-UTC difference grows beyond 0.9 s and normally carried out at the turn of one of the quarters (i. e., at 00:00:00 on 1 January, 1 April, 1 July, or 1 October) of a calendar year.

The GLONASS time synchronization system of the ground control segment generates the system timescale, calculates frequency and time corrections, determines the difference between the system timescale and UTC(SU), and calculates corrections between onboard timescales and the system timescale. The frequency and time corrections are calculated for each orbit and uploaded on board the satellites for transmission to the users. The frequency and time corrections are two parameters of the linear approximation of the onboard timescale offset relative to the system timescale.

Within the frequency and timekeeping facility of the GLONASS *central synchronizer* (CS), the frequencies and phases of four hydrogen frequency standards are continuously compared and the best clock is used as primary standard. The resulting 5 MHz signal exhibits a frequency error of less than $3 \cdot 10^{-14}$ and a stability of better than $2 \cdot 10^{-15}$ over one day. For redundancy purposes, an independent master and backup CS system are operated at Schelkovo (near Moscow) and Komsomolsk, respectively. Monitoring of the CS time with respect to UTC(SU) is performed through common-view time transfer between the CS and STFS. De-

pending on the employed equipment and signals (GPS or GLONASS), a monitoring precision of 3–13 ns is achieved.

The fractional differences between UTC and GLST as well as that of UTC and the prediction $UTC(SU)_{GLO}$ broadcast by the GLONASS satellites are routinely monitored by the BIPM and published as part of the monthly *Circular T*. The values presently demonstrate a stability of better than 10 ns, but are potentially affected by systematic offsets at the level of few hundreds of ns due to overall calibration uncertainties (Fig. 8.7). To improve the alignment of GLONASS System Time and the predicted UTC(SU), various adjustments have been performed starting on 18 August 2014. These included corrected offsets for the broadcast time parameters and a gradual tuning of the ground clocks [8.28]. As a result of the alignment, GLST and $UTC(SU)_{GLO}$ have exhibited a consistency of about 10 ns since early 2015.

## 8.2 Navigation Signals and Services

### 8.2.1 GLONASS Services

In accord with its dual-use status, GLONASS provides two types of services:

- An open service with unencrypted signals in up to three frequency bands (L1, L2, and recently L3) that is globally available for all users without any limitations
- A service for authorized users, using encrypted signals in presently two frequency bands (L1, L2).

The terminology of these services is not well defined, however, and alternative expressions such as *standard positioning service* and *high-precision service* are commonly used in the open literature.

Performance specifications for the two service types have not been released so far, but a GLONASS Open Service Performance Parameters Standard is under discussion within the International Committee on GNSS (ICG). Initial drafts suggest a performance specification of about 5 and 10 m, respectively for the 95% ($2\sigma$) global average position error in horizontal and vertical directions [8.29]. The option of an intentional accuracy degradation of the open service (similar to the *Selective Availability* employed by GPS up to the year 2000) has never been considered in the GLONASS system design.

The authorized service is primarily intended for military users [8.7]:

> *The PP [pinpoint accuracy] signal is modulated by a special code and intended for usage in interests of the Ministry of Defense. Usage of a PP signal should be agreed with the Russian Federation Defense Ministry.*

Unlike GPS, the signals of the authorized service are presently not encrypted. Even though their structure and data contents have not been publicly released by the system providers, the employed ranging code has, nevertheless, been revealed already in the early days of GLONASS through a systematic code search [8.5]. This has enabled the design of geodetic dual-frequency GLONASS receivers and allowed for an early use of GLONASS in precise point positioning applications. In accord with the above disclaimer, access to these signals may, however, be inhibited and its *unofficial* use should be considered with due care.

Each GLONASS satellite transmits signals for both the open and the authorized service. The L1/L2 signals for these two services are designated as standard-accuracy (ST) and high-precision (or pinpoint, PP) signals in the GLONASS ICD [8.7], to reflect the different performance of the employed ranging codes.

Traditionally, GLONASS makes use of frequency division multiply access (FDMA) modulation. Here, signals transmitted by individual satellites employ the same ranging code, but slightly different frequencies to allow concurrent processing in the receiver. With the first *GLONASS-K1* satellite launched in 2011, GLONASS started to transmit additional code division multiple access modulation (CDMA) signals on the new L3 signal. As part of the ongoing GLONASS modernization, CDMA signals will also be transmitted in the L1 and L2 bands to improve interoperability with other GNSSs, specifically GPS. An overview of current and planned signals is given in Table 8.4.

**Table 8.4** GLONASS signals overview. Signals are identified by the frequency band (first two characters), the service type (O: open, S: authorized special), and the modulation type (F: FDMA, C: CDMA)

| Satellites | FDMA | | CDMA | | |
|---|---|---|---|---|---|
| | L1 | L2 | L1 | L2 | L3 |
| GLONASS | L1OF<br>L1SF | L2SF | | | |
| GLONASS-M | L1OF<br>L1SF | L2OF<br>L2SF | | | (L3OC) |
| GLONASS-K1 | L1OF<br>L1SF | L2OF<br>L2SF | | | L3OC |
| GLONASS-K2 | L1OF<br>L1SF | L2OF<br>L2SF | L1OC<br>L1SC | L2OC<br>L2SC | L3OC |

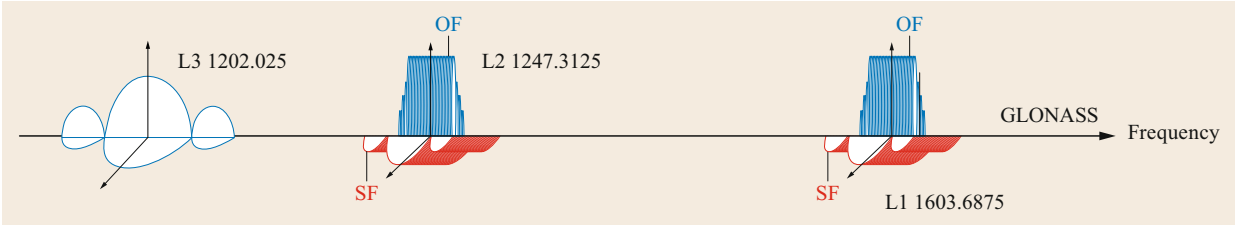

**Fig. 8.8** GLONASS frequency division multiple access (FDMA) and code division multiple access (CDMA) signals in the L1, L2 and L3 band (status 2015)

The spectral distribution of currently transmitted signals in the L1, L2, and L3 bands is illustrated in Fig. 8.8. The L1 and L2 FDMA signals employ slightly higher ($\approx 20$ MHz) frequencies than the corresponding GPS signals. The GLONASS L3 signal, in contrast, is transmitted at a widely different frequency ($f_{L3} = 1202.025$ MHz) than the L3 frequency allocated to the GPS nuclear detection (NUDET) payload ($f_{L3} = 1381.05$ MHz). In fact, the GLONASS L3 frequency closely matches the Galileo E5b frequency with only a small negative offset.

For the provision of positioning, navigation and timing services, the GLONASS signals include navigation messages with ephemeris data in the PZ90 reference system and timing parameters related to GLONASS System Time.

The open service signals as well as the contents of the navigation message are detailed in the public signal ICD [8.7], which presently covers the L1/L2 FDMA signals and will be updated with L3 and CDMA signals as soon as these become fully operational.

## 8.2.2 FDMA Signals

GLONASS has been transmitting FDMA signals since the first satellite was launched. Despite the ongoing system evolution and the introduction of new CDMA signals, GLONASS will continue to provide the legacy FDMA signals in the future to provide backward compatibility with the user equipment already in use.

FDMA signals are transmitted in the L1 and L2 bands and comprise the open service (standard-accuracy) and authorized service (high-precision) ranging codes (Table 8.5). In analogy with GPS, the two codes are commonly described as GLONASS C/A-code (coarse and acquisition code) and P-code (precise code) respectively, even though these terms are not mentioned in the ICD and do not represent an official designation.

The open service signal was only transmitted on the L1 frequency in the first generation of GLONASS satellites, but has been made available on both frequencies starting with the GLONASS-M series of spacecraft. Also, the L2 signal power, which was initially about 6 dB lower, has been adjusted to the same level as L1.

### Signal Frequencies

GLONASS FDMA signals use a distinct set of *channels* for different signals. Each channel is identified by its channel number $k$, which uniquely defines the corresponding signal frequency

$$f_{L1}(k) = (1602.0 + k\,0.5625)\ \text{MHz}\,,$$
$$f_{L2}(k) = (1246.0 + k\,0.4375)\ \text{MHz}\,. \qquad (8.3)$$

**Table 8.5** Main characteristics of the legacy GLONASS FDMA signals. Parameters of the authorized service signals (L1SF, L2SF) that have not been publicly released are marked as N/A (not available)

| Signal | Received power (dBW) | Center frequency (MHz) | Code and Data | Modulation | Bandwidth (MHz) | Data rate (bps) |
|---|---|---|---|---|---|---|
| L1OF | −161 | 1598.0625 . . . 1605.375 | C/A-code (511 chips, 1 ms) Open service navigation message | BPSK(0.5) | $\approx \pm 0.5$ | 50 |
| L1SF | −161 | same | P-code (5.11 MHz) Authorized service navigation message | N/A | $\approx \pm 5$ | N/A |
| L2OF | −161 | 1242.9375 . . . 1248.625 | C/A-code (511 chips, 1 ms) Open service navigation message | BPSK(0.5) | $\approx \pm 0.5$ | 50 |
| L2SF | −161 | Same | P-code (5.11 MHz) Authorized service navigation message | N/A | $\approx \pm 5$ | N/A |

Neighboring channels are separated by $\Delta f \approx 0.5$ MHz, which roughly corresponds to the half-width of the open service signal spectral and is sufficient to distinguish transmissions from different satellites in the receiver. For a given channel number $k$, the ratio of the L1 and L2 frequencies attains a fixed value of

$$\frac{f_{L1}(k)}{f_{L2}(k)} = \frac{9}{7} \,. \tag{8.4}$$

In the original GLONASS design, use of a unique frequency channel number in the range of $k = 0, \ldots, 24$ (corresponding to an L1 frequency in the range of 1602.0–1615.5 MHz) was considered for each individual spacecraft in the 24-satellite constellation along with a spare channel for testing purposes [8.30].

The initial frequency allocation was later modified in compliance with recommendation RA 769 of the International Telecommunication Union (ITU) on protection criteria used for radio astronomical observations [8.31], when it became obvious that GLONASS L1 transmissions interfered with observations of the hydroxyl radical (OH) near 1612 MHz [8.32]. Starting in 1998, the frequency indices were restricted to $k = 0, \ldots, 12$ (yielding a maximum center frequency of 1608.75 MHz). In a second update, conducted in 2005, negative channel numbers were introduced and the covered range was changed to $k = -7, \ldots, +6$ [8.7] (including two channels commonly used for testing new satellites). In addition, the GLONASS satellites were equipped with bandpass filters to reduce transmissions in the frequency band relevant for radio astronomy. This can readily be seen from the L1 signal spectrum of the GLONASS satellites, which exhibits a sharp gap around 1612 MHz (Fig. 8.9).

The limitation of only 12–14 channels for 24 satellites is handled by assigning identical frequency channel numbers to antipodal satellites, that is satellites in opposite slots of the same orbital plane. Such satellites should never be jointly visible for a terrestrial observer and can therefore make use of the same signal frequency.

The use of different signal frequencies in the GLONASS FDMA signals enables use of a common ranging code for all satellites and offers protection against narrow-band interference compared to CDMA signals, since such interferences would only affect one or a few satellites at a time [8.33]. However, it also results in an increased complexity of the front-end design and is commonly a source of undesired group and phase delay variations in GLONASS receivers (Chap. 13). Nevertheless, the existing data processing methodology allows the detection of these delays at the user level providing precise point positioning computations.

### Open Service Signal

The FDMA open service signal transmitted on the L1 and L2 frequencies employs a binary phase-shift keying (BPSK) modulation. The carrier is modulated with a binary sequence, which results from the modulo-2 addition (i. e., exclusive or combination) of three individual components:

- The pseudorandom noise (PRN) ranging code
- The navigation data
- An auxiliary meander sequence.

The ranging code has a length of 511 chips and is clocked at 511 MHz, thus yielding a total duration of 1 ms. Data bits are transmitted at a 50 Hz rate and have a length of 20 ms per data bit. The third component is a 100 Hz sequence of alternating 1 s and 0 s with a duration of 10 ms per symbol. It is termed a *meander* sequence or *Manchester code* and ensures that there is at least one transition in the modulo-2 sum of the meander and data sequence within each data bit interval. The

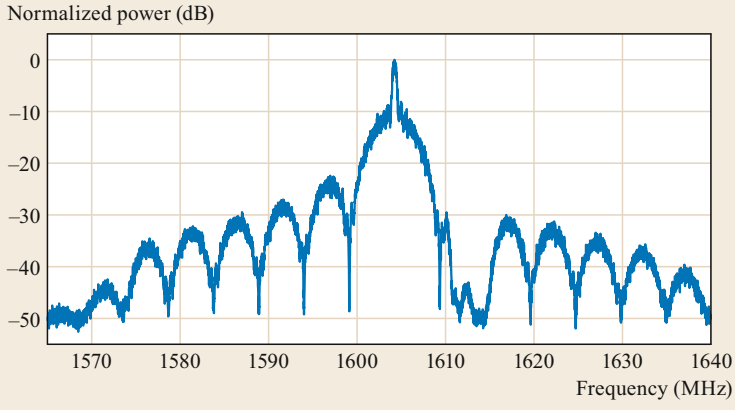

**Fig. 8.9** Example of GLONASS L1 signal spectrum. The center frequency of 1604.25 MHz corresponds to a frequency channel number $k = +4$. The central peak results from the 511 kHz open service coarse and acquisition (C/A) code, while the wider lobes reflect the 5.11 MHz P-code modulation. Transmissions near 1612 MHz are masked by a bandpass filter to protect radio astronomical observations of hydroxyl (OH) emissions (courtesy of S. Thölert, Deutsches Zentrum für Luft- und Raumfahrt (DLR))

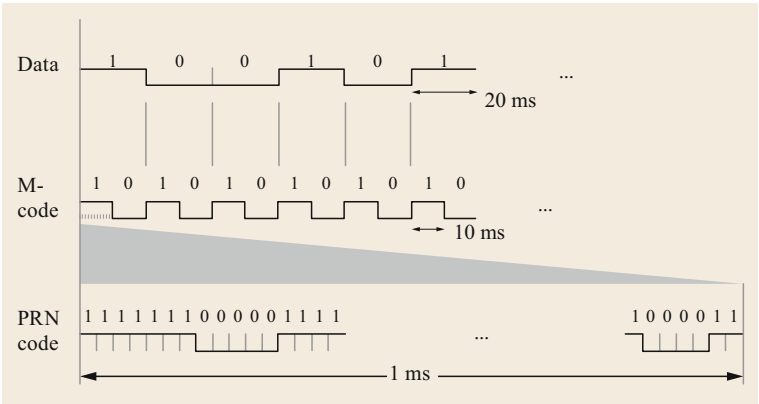

**Fig. 8.10** Structure of the GLONASS open service signal

three signal components are synchronized to each other, that is there are 10 full ranging codes within a Manchester code symbol and 20 codes within a data bit. The overall signal structure is illustrated in Fig. 8.10.

The FDMA concept allows for use of a common PRN code by all GLONASS satellites and the same code is in fact also used on the two frequencies. Unlike the Gold codes of GPS, the GLONASS ranging code is obtained from just a single maximum-length linear feedback shift register (LFSR). Gold codes, in contrast, require a combination of two shift registers, from which a large family of PRN sequences with good cross-correlation properties can be constructed. This is important for use of CDMA signals in a GNSS constellation such as GPS, since distinct, high-quality PRN sequences are needed for the various spacecraft [8.34]. GLONASS, in contrast requires only a single ranging code and achieves a low cross-correlation between different satellites through the frequency separation of different transmission channels [8.33].

A more simple PRN code generator based on a 9 bit register can therefore be employed, which provides a maximum length pseudorandom sequence of 511 ($= 2^9 - 1$) chips (Fig. 8.11). The register is initialized with all 1s and the PRN ranging code is extracted at the output of the seventh stage of the shift register (Fig. 8.11).

The chipping rate and duration of the GLONASS ranging code are directly reflected in the corresponding

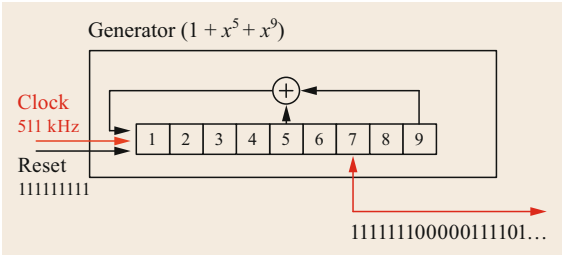

**Fig. 8.11** GLONASS C/A-code generator

open service signal spectrum [8.4]. It exhibits an overall bandwidth of about 1 MHz with spectral nulls at multiples of 511 kHz relative to the center frequency and individual lines spaced at 1 kHz (i. e., the inverse of the code length). It may be noted that the bandwidth is larger than the spacing of individual frequency channels on both the L1 and L2 frequencies. This does not, however, inhibit a safe acquisition and tracking of the GLONASS signals, since the correlation bandwidth is substantially smaller (about 1 kHz for a 1 ms integration interval).

### Authorized Service Signal

Both the L1 and L2 frequencies carry an additional authorized service signal, which is transmitted in phase quadrature to the open service signal. The authorized signal is intended for military use only, and its signal structure has never been publicly disclosed by official sources.

Nevertheless, it has been possible to reveal important properties already in the early days of GLONASS from inspection with a high-gain antenna and a systematic testing of different hypotheses on the code design. This work has mainly been conducted by the University of Leeds [8.4, 5, 35, 36] and forms the basis of today's understanding of the military signal and its implementation in geodetic receivers. Knowledge of the GLONASS P-code was of particular interest prior to the GLONASS-M satellite generation, since it provided access to the signal second frequency and thus enabled ionospheric correction of GLONASS observations in precise positioning applications. Also, the higher chipping rate offered a somewhat better noise and multipath performance [8.36] than the C/A-code. It must be kept in mind, though, that the P-code signal is not intended for public use and may change without prior notice.

### Navigation Message Structure

GLONASS navigation messages for the FDMA open service use a fixed structure made up of individual

*frames* and *strings*. The entire set of frames is designated a *superframe* and repeated at regular intervals (Table 8.6).

The structure of the FDMA open service navigation message is illustrated in Fig. 8.12 based on information in [8.7]. Each string is made up of 85 bit and a time mark. This time mark consists of 30 symbols (corresponding to a hexadecimal value of 0x3E375096 [8.36]) and serves as a postamble. At a bit length of 20 ms and a symbol length of 10 ms, the entire string is transmitted in 1.7 s + 0.3 s = 2 s. The 85 bit comprise of a zero bit, the 4 bit string number, 72 bit of navigation data and 8 Hamming code parity bits offering single-error correction [8.36].

Strings 1–4 of each frame provide *immediate* (ephemeris) data of the transmitting satellite, which are required for the positioning and repeated once every 30 s. The remaining strings 4–15 contain subcommutated *nonimmediate* (almanac) data for up to five satellites. The remaining bytes in the fifth frame hold additional parameters for conversion from GLONASS System Time to UT1 as well as the announcement of leap-second adjustments.

The entire superframe is transmitted in 2.5 min and continuously repeated between ephemeris updates (nominally once every 30 min). The overall message structure is adapted to support the current 24-satellite constellations but leaves some spare bytes for adding additional information.

Unlike GPS, the GLONASS system does not make use of an orbital elements representation of the ephemeris data, but provides the state vector (position and velocity) along with corrections in the Earth-fixed PZ90 coordinate system at the given reference epoch. Based on this information, the trajectory in the vicinity of this epoch can be obtained by numerical integration of the equation of motion (Sect. 3.3.3). To simplify the complexity of the orbit model, only the dominating Earth oblateness term is explicitly considered. However, additional acceleration corrections accounting for the effect of lunisolar perturbations are provided as part of the navigation message for improved accuracy. The ephemeris data are typically updated at half-hourly intervals (i. e., at full and half hours) and are valid for ±15 min around the reference epoch in the center of the interval. Satellite clock offsets of the satellite with respect to GLST are described through a linear clock polynomial, which directly yields the apparent clock with no need for application of a relativistic correction. Furthermore, the immediate data of the GLONASS navigation message comprise health information, GLST to UTC time conversion data and a timing group delay parameter for consideration of differential code biases in single-frequency positioning.

The *nonimmediate* data of the FDMA open service navigation message provide timescale information (for GLST to UTC(SU) and GLST to GPS time conversion), which is repeated in string 5 of each frame as well as two strings of almanac data per satellite. Aside from orbital elements and a coarse clock offset value, the almanac includes health information as well as the slot and frequency channel number of the respective satellite.

Descriptions of the FDMA authorized navigation message as inferred from the analysis of transmitted P-code data in the late 1990s are provided in [8.35, 36].

It may be noted that the GLONASS FDMA navigation messages provide ephemeris, almanac and time system information but no ionospheric correction data for single-frequency users. For best positioning accuracy, an ionospheric compensation using dual-frequency L1/L2 observations is therefore recommended.

**Table 8.6** Navigation data structure of open service GLONASS FDMA signals. HC and TM denote the 8 bytes of the Hamming error correction code and the 30 symbols of the time mark

| Structure | Duration | Elements |
|---|---|---|
| Superframe | 2.5 min | 5 frames |

### 8.2.3 CDMA Signals

As part of the GLONASS signal evolution plan, new CDMA signals are made available to the users as a complement to the legacy FDMA signals. Key reasons for introducing CDMA signals include an improved navigation accuracy, an improved resistance to interference, and the improved separation of open and authorized services. The GLONASS signal evolution plan is based on a phased approach. A first CDMA signal in the L3 band has been made available since 2011 and further signals will be added with each new generation of GLONASS satellites. An initial assessment of GLONASS CDMA L3 ambiguity resolution and positioning performance is provided in [8.37].

Similar to FDMA signals, there are two types of GLONASS CDMA signals: open and encrypted, providing public and authorized services. The frequency allocations for L1 and L2 CDMA signals are defined within the original GLONASS frequency bands (Fig. 8.13), while L3 is a newly allocated frequency next to the Galileo E5b and BeiDou B2 band. In addition, the provision of modernized civil navigation signals (L1OCM, L5OCM) on the L1/E1 and L5/E5a

frequencies of the GPS and Galileo system are under study to achieve a maximum compatibility with these other constellations.

The main parameters of current and proposed GLONASS CDMA signals are presented in Table 8.7 [8.8, 38, 39]. The open service L1OC and L2OC signals are planned to provide time-multiplexed data and pilot components using BPSK(1) and BOC(1,1) modulations respectively [8.8]. The L1SC and L2SC authorized service signals, in contrast, will use BOC(5,2.5) modulation for both the pilot and data components and are transmitted in phase quadrature relative to the open signals. The BOC(5,2.5) modulation offers a good spectral separation of open and authorized signals, while simultaneously suppressing emissions in the radio astronomical frequency band around 1612 MHz [8.38].

A first CDMA signal, namely the L3OC open service signal, was introduced by the GLONASS-K1 satellite launched in 2011 and is also made available by the latest version of GLONASS-M satellites launched since 2014. While a formal ICD is pending, basic information on the signal structure has been publicly released in [8.38]. The signal comprises a data and

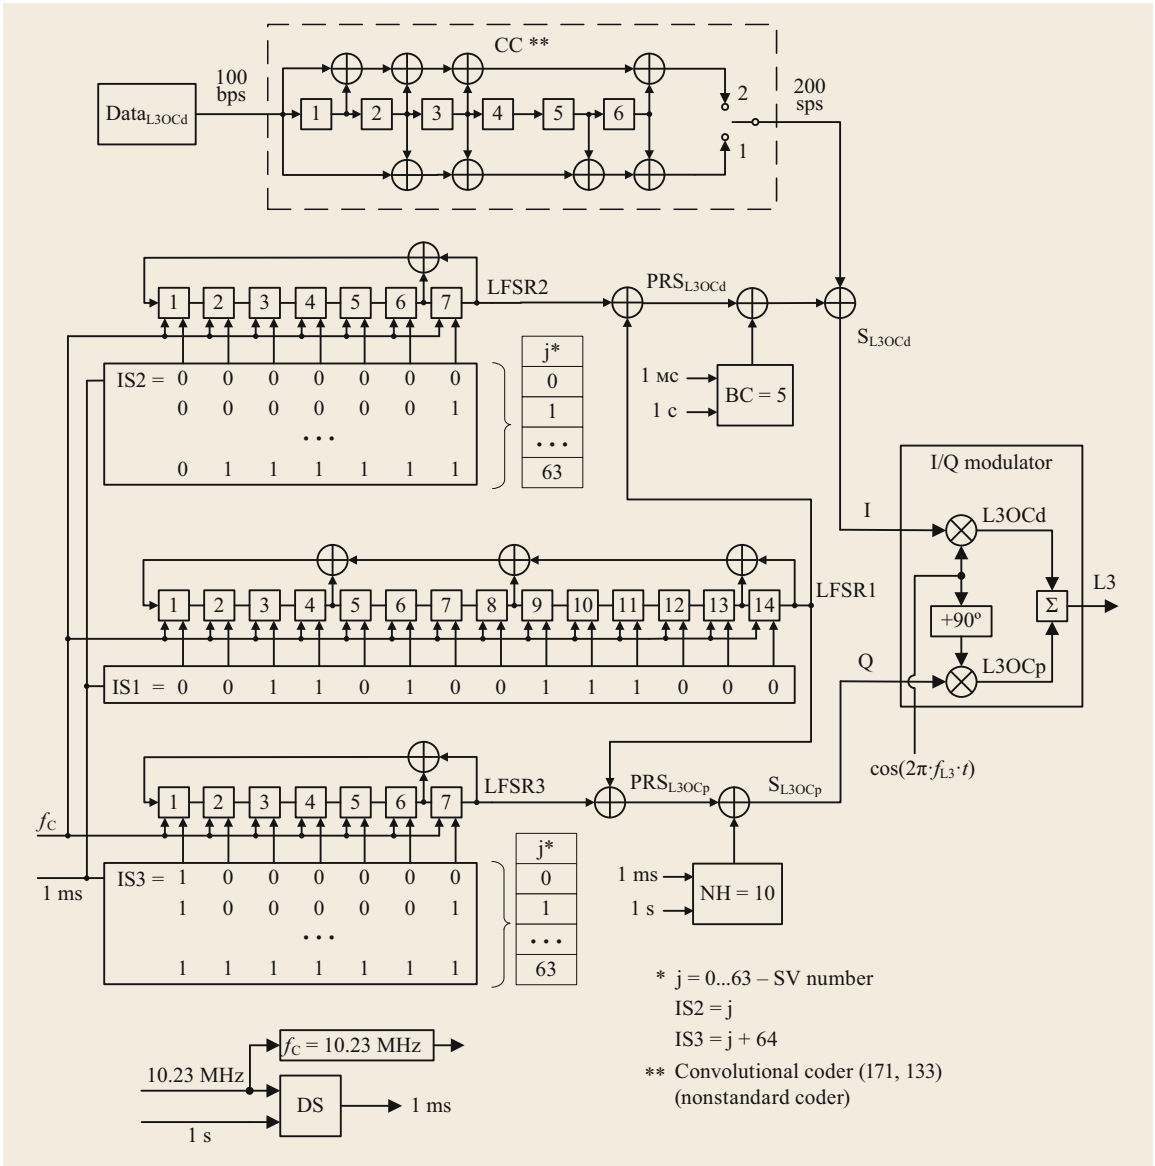

**Fig. 8.14** GLONASS L3 open service CDMA signal generation (courtesy of Russian Space Systems Corporation)

a pilot component in phase quadrature using BPSK(10) modulation.

As illustrated in Fig. 8.14, the pseudorandom code for both components is generated from the modulo-2 addition of the outputs of a 14 bit shift register (IS2; with feedback taps 4, 8, 13, and 14) and a seven-stage shift register (IS1/IS3 for the pilot/data code; with feedback taps 6 and 7). While the initial state of the IS2 register is common to all spacecraft, satellite-dependent initial values are used for the IS1 and IS3 registers. The resulting PRN sequences are known as *Kasami* sequences [8.40] and exhibit a very low cross correlation for an entire family of individual codes [8.41]. The L3OC codes have a native length of $2^{14}-1 = 16\,383$ bit, but are truncated at 10 230 chips and achieve a cross correlation of −40 dB. At the employed chipping rate of 10.23 MHz, the primary code duration amounts to 1 ms.

Navigation data are modulated at a rate of 100 bps using a 1/2 convolutional encoding for error correction (yielding a symbol rate of 200 sps). In addition to the ranging code and the encoded navigation data, the data channel is modulated with a 5-bit Barker code at a rate of 1 kHz. The Barker code (BC) is synchronized with

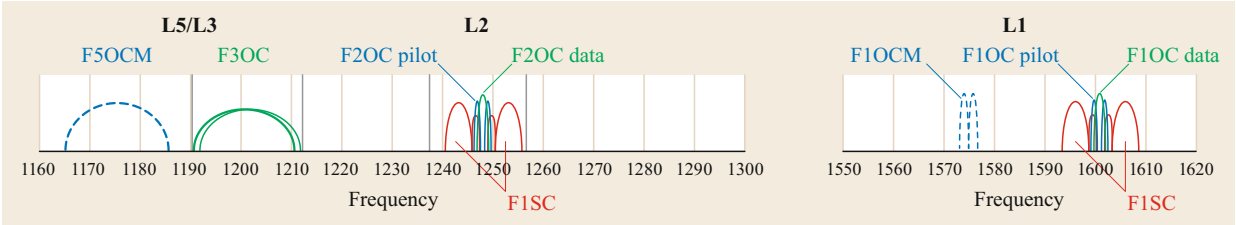

**Fig. 8.13** GLONASS CDMA signal frequency allocations

the ranging sequence and covers the duration of a single navigation data symbol (i. e., 5 ms). For the pilot channel, a secondary (or Neuman–Hofman, NH) code with a length of 10 bit is employed. This yields an effective code length of 10 ms and offers increased robustness and weak-signal tracking capabilities. A detailed characterization of the L3OC signal as transmitted by the GLONASS-K1-1 satellite is provided in [8.42] based on analyses with a high-gain antenna and a software receiver.

Along with the advanced modulation scheme, the L3 CDMA signal also introduces a new navigation message concept. Unlike the fixed superframe structure of the FDMA navigation message, the L3OC signal uses a flexible message system [8.38, 39]. Similar to the CNAV (civil navigation) message of the GPS L2C and L5 signals, a set of distinct messages is defined, each of which provides a specific subset of navigation data. Each message is uniquely identified by its message number and carries a cyclic redundancy check (CRC) field for error protection. Information from different messages is combined at user level to obtain the full set of navigation data. Since unknown messages types are specified to be ignored by a receiver, the new scheme greatly facilitates the addition of new messages along with signal upgrades and service improvements. Among others, the new navigation message is not limited to a predetermined size of the constellation but can accommodate a variable number of satellites.

By way of example, the layout of the new L3OC almanac message is described in [8.43]. Each message has a length of 300 bit including a 20 bit time mark and a 24 bit CRC. A full description of all L3OC navigation messages will be provided as part of the GLONASS open service signal ICD.

## 8.3 Satellites

The constellation of GLONASS satellites is a key element of the entire GLONASS system. Throughout the more than 30 years of its history, three generations of GLONASS satellites have been built and operated:

- The initial generation of *GLONASS* satellites first launched in 1982
- The subsequent *GLONASS-M* satellites launched since 2003
- The *GLONASS-K* series introduced in 2011.

Each new generation of GLONASS satellites extended the satellite capabilities and improved the overall system performance. In parallel to technical improvements, the in-orbit lifetime was also continuously increased. Key characteristics of each satellite type are summarized in Table 8.8. All GLONASS satellites were developed by the Academician Reshetnev

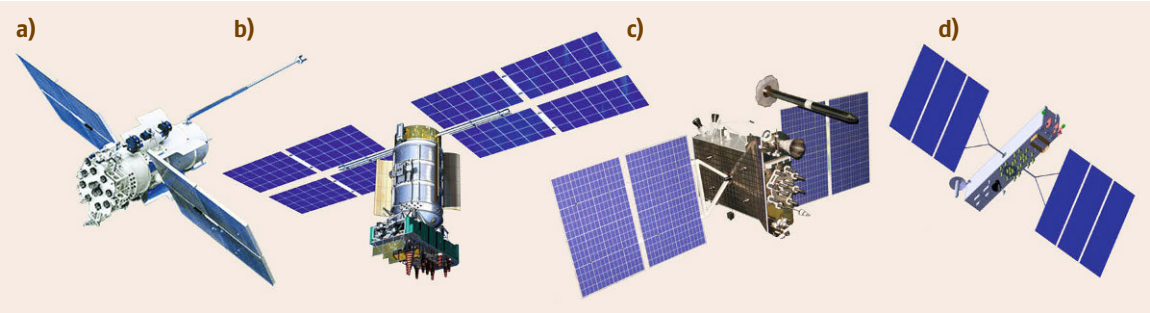

**Fig. 8.15a–d** The GLONASS satellites family: **(a)** *GLONASS IIv*, **(b)** *GLONASS-M*, **(c)** *GLONASS-K1* **(d)** *GLONASS-K2*. Artist's drawings (courtesy of ISS Reshetnev)

Research and Production Association of Applied Mechanics (NPO PM), which is now part of the joint stock company Information Satellite Systems (ISS)-Reshetnev Company.

While not part of the actual radionavigation system, it is worthwhile to note that the GLONASS constellation is complemented by two geodetic satellites named Etalon (measuring gauge). The ball-shaped satellites of 1.2 m diameter are completely passive and covered with corner cube reflectors for satellite laser ranging (SLR). The Etalon-1 and -2 satellites were launched in 1989 and injected into a typical GLONASS orbit along with two pairs of regular GLONASS navigation satellites. While initially used to study the orbital dynamics of satellites in medium altitude orbit, they still serve the international community today for fundamental studies of geodesy and dynamics of the Earth [8.44].

This section introduces the different spacecraft of the GLONASS family (Fig. 8.15) and describes their characteristic features and performances.

### 8.3.1 GLONASS I/II

The first generation of GLONASS navigation satellites (originally termed Uragan, the Russian word for hurricane) was developed in the late 1970s. Following [8.1], the GLONASS series comprises four subtypes, which are commonly designated as type (or block) I, IIa, IIb, and IIv (or IIc). A first type I satellite was launched in 1982 and the last IIv satellite was in use from 2005 to 2008.

The GLONASS spacecraft have a mass of roughly 1.4 t (including propellant for orbit maintenance) and are made up of a cylindrical structure with a length of about 3.3 m (Fig. 8.16). Two solar panels with a total surface area of about 24 $m^2$ delivered a net system power of about 1 kW. The GLONASS I/II satellites employed a pressurized platform design to protect the payload against the space environment. Heat dissipation was achieved through heat exchangers and four thermal control flaps. The opening angle of these shutters could be varied and allowed the adjustment of the internal temperature with an accuracy of about 5 °C.

Attitude control was achieved through reaction wheels, which were periodically unloaded using magnetorquers. Reference measurements of the magnetic fields were provided by a magnetometer, which was mounted on an external boom (Fig. 8.16) to avoid magnetic disturbances by the satellite body. The GLONASS satellites were also equipped with a hydrazine propulsion system. It comprised two 5 N thrusters for orbit correction and 24 0.1 N thrusters for orientation changes and despinning after orbit injection. After reaching their assigned orbital slot, the satellites kept their nominal position within an argument-of-latitude deadband of ±5° throughout their operational lifetime with no need for further correction maneuvers.

The longitudinal $-x$-axis of the cylindrical spacecraft body points towards the Earth and carries the L-band antenna. It is composed of 12 helix elements arranged in an inner ring with four elements and an outer

ring with eight elements. These elements are phase coherently combined to achieve an M-shaped antenna gain pattern with a slightly higher beam intensity towards the rim of the Earth (Chap. 17). In addition, the GLONASS satellites carry a laser retroreflector array (LRA) for satellite laser ranging measurements [8.45]. The LRA comprises almost 400 individual corner cube reflectors accommodated between the L-band antenna elements to center the effective reflection point on the boresight axis.

In the GLONASS I series, two 5 MHz BERYL rubidium clocks with a stability of $5 \cdot 10^{-12}$ over one day served as the primary atomic frequency standard (AFS). The subsequent type II spacecraft were equipped with three GEM cesium clocks (offering a two-fold cold redundancy) that achieved a ten times better performance [8.46, 47]. The average lifetime of these early clocks amounted to only 1.5 years, which notably restricted the overall mission duration.

In total, 87 GLONASS I and II satellites were launched from 1982 to 2005. This includes six satellites that did not reach their final target orbit. Typical operations periods ranged from about one year for the early satellites to five years for the latest units. The first fully operational GLONASS constellation completed in 1995 was exclusively made up of IIv spacecraft.

### 8.3.2 GLONASS-M

From 2003 onwards, the first-generation GLONASS satellites were replaced by the modernized GLONASS-M series. These spacecraft share the same core structure and exhibit a similar mass as the GLONASS I/II series but are easily distinguished by the different placement of the solar panel rotation axis and a larger antenna panel on their front side (Fig. 8.17). Also, the satellites no longer carry a magnetometer boom on the zenith-facing side of the spacecraft body.

Like GLONASS I and II, the GLONASS-M satellites make use of a pressurized container and exhibit the characteristic thermal control flaps, but offer better mission and operational performances as well a longer design lifetime (seven years) than their predecessors. The GLONASS-M satellites achieve an 0.5° accuracy for the nadir pointing attitude control and a 2° pointing accuracy for the solar panels. The use of larger solar panels (34 $m^2$) provides a higher overall system power of 1.5 kW.

The laser retroreflector array uses a more compact design than on GLONASS I/II and is accommodated next to the L-band navigation antenna on the front panel with a small lateral offset from the principal body axis of the spacecraft (Fig. 8.18).

As a novel feature, GLONASS-M satellites include a radio-based intersatellite link [8.48], which is undergoing flight validation and will help to mitigate the limited geographical coverage of the GLONASS ground segment. It provides distance measurements between spacecraft based on dual one-way pseudoranges and can thus contribute to an improved ephemeris and clock accuracy [8.49].

The latest GLONASS-M satellites are also equipped with a prototype Inter-Satellite Laser Navigation and Communication System (ISLNCS, Fig. 8.18). Early in-flight experiments have demonstrated the capability to measure the distance between two satellites with a precision of about 3 cm and to synchronize the onboard clocks to each other with a corresponding error of less than 0.1 cm [8.50, 51].

**Fig. 8.17** GLONASS-M spacecraft (courtesy of ISS Reshetnev)

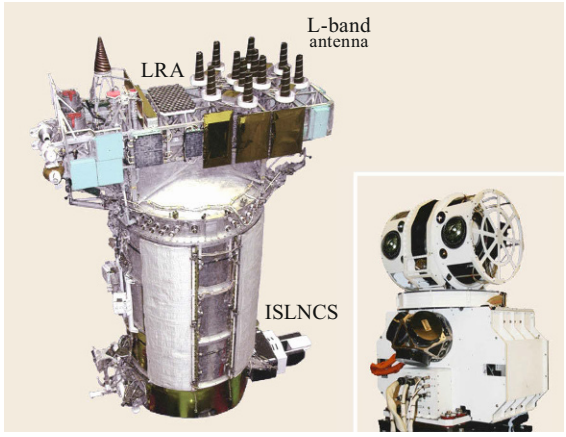

**Fig. 8.18** GLONASS-M spacecraft with laser retroreflector array (LRA) and intersatellite laser navigation and communication system (ISLNCS). The *insert* shows the ISLNCS design in use since 2013 (courtesy of Science-Industry Corporation of Precise Device Engineering Systems (NPK SPP))

Besides the modernization of the spacecraft platform, the GLONASS-M satellites introduced various changes to the radio navigation signals [8.52]. The transmitted frequencies were shifted to a lower range ((1598.0625 ... 1605.375) ± 5.11 MHz for L1 and L2 = (1242.9375 ... 11248.625) ± 5.11 MHz for L2) and filters were installed to reduce out-of-band emission in the frequency bands 1610.6–1613.8 MHz and 1660.0–1670.0 MHz down to the level provided in ITU recommendation 769 [8.31]. Furthermore, the transmission power in the L2 band was doubled and the civil navigation signal was added to L2, thus offering the first fully open dual-frequency navigation service. Along with these changes, various improvements to the navigation message were made. Available spare bytes in the original design were populated with new parameters such as the GPS-GLONASS time difference, leap second announcements or the age of orbit and clock data. Starting with spacecraft No. 55 in 2014, transmission of the L3OC was, furthermore, added to the GLONASS-M satellites.

Like their predecessors, the GLONASS-M satellites employ three cesium clocks as the primary frequency standard. According to the technical requirements the frequency stability amounts $1 \cdot 10^{-13}$ over one day, which directly contributes to a better overall navigation performance.

As of early 2015, the operational GLONASS constellation is entirely composed of GLONASS-M satellites.

### 8.3.3 GLONASS-K

The GLONASS-K series represents the latest generation of spacecraft in the GLONASS constellation. It comprises two subseries, namely the lighter K1 satellites (Fig. 8.19) and the more heavy K2 type with full capabilities. Two GLONASS-K1 satellites were launched in 2011 and 2014. In February 2016, the second GLONASS-K1 satellite was introduced into the constellation for nominal operation, while the first GLONASS-K1 satellite remains reserved for test purposes. Construction and deployment of the GLONASS-K2 satellites is planned for the second half of the decade.

GLONASS-K satellites are the first to use an unpressurized payload and service module. They build upon the Express-1000K spacecraft bus developed by ISS Reshetnev (formerly NPO PM) for various geostationary communication and relay satellites. The box-shaped structure is made up of lightweight honeycomb panels and heat pipes are used for thermal control [8.48]. With a mass of 935 kg, the K1 satellites have only two thirds of the mass of their predecessors, which offers greater flexibility in the launcher selection. The use of advanced Ga-As solar cells enables a high electrical power (1.6 kW) despite a smaller size of the solar panels (17 $m^2$) than all previous satellites. The design lifetime of ten years is substantially longer than that of the earlier generations and will assist a smooth and interruption-free GLONASS service.

**Fig. 8.19** GLONASS-K1 spacecraft (courtesy of ISS Reshetnev)

Similar to the GLONASS I/II spacecraft, the laser retroreflector of the GLONASS-K1 satellite is integrated into the L-band antenna structure to align both phase centers with the nadir-pointing axis through the center of mass. In this way, the phase center location is invariant under yaw rotations that are continuously performed to keep the solar panels perpendicular to the Sun (Sect. 3.4). The atomic frequency standards of the GLONASS-K1 satellites comprise two cesium and two rubidium clocks with a specified performance of $(0.5 - 1.0) \cdot 10^{-13}$. All GLONASS-K1 satellites transmit the CDMA L3 open service signal (L3OC) in addition to the legacy FDMA signals of the open and authorized services on L1 and L2. Support of L2 and, subsequently, L1 CDMA signals is foreseen for an enhanced version of K1+ satellites and the larger K2 satellites.

Aside from the core navigation payload, the GLONASS-K satellites are equipped with a radio cross link for data exchange and ranging, an optical cross link, a Cospas-Sarsat [8.53] distress alert detection and routing system, as well as an optical onboard system for simultaneous two-way and one-way laser ranging measurements intended for calibration and remote clock synchronization.

## 8.4 Launch Vehicles

The buildup and sustainment of the GLONASS constellation is provided through triple launches with the Proton launch vehicle or single launches with the Soyuz rocket (Fig. 8.20). Launches of the Soyuz rocket are performed from the Plesetsk Cosmodrome [8.54] in northern Russia (62.9° N, 40.6° E) and maintained by the Russian Air and Space Defence Forces. Proton launches, in contrast, are conducted from the rocket and space complex in Baikonur [8.55]. The latter site is located in the Republic of Kazakhstan (45.6° N, 63.3° E) and leased by the Russian Federation for its national space program.

The Proton-K rocket and its stronger and modernized M version are heavy-lift launch vehicles with a long flight heritage. The 3(+1)-stage rockets with a height of 53–58 m serve a wide range of missions in different orbits. They can carry up to 22 t into a low Earth orbit (LEO) or about 6 t into geostationary transfer orbit (GTO).

The first stage comprises six RD-275 engines with a common central oxidizer tank and six permanently attached strap-on fuel tanks. The stage provides a total thrust of 10 MN over a burn duration of 2 min and accelerates the rocket to $\approx 1.6$ km/s before burnout at an altitude of about 40 km. The second stage combines four RD-0210/0211 engines with a total thrust of roughly 2 MN. It completes its firing approximately 5 min after liftoff near an altitude of 120 km. The third and final stage combines a single RD-0212 engine and a RD-0214 steering engine for fine control of the injection vector and velocity. All of the aforementioned engines use unsymmetrical dimethyl hydrazine (UDMH, $C_2H_8N_2$) and nitrogen tetroxide ($N_2O_4$) as fuel and oxidizer, which are known to be highly toxic but do not require cooling for storage.

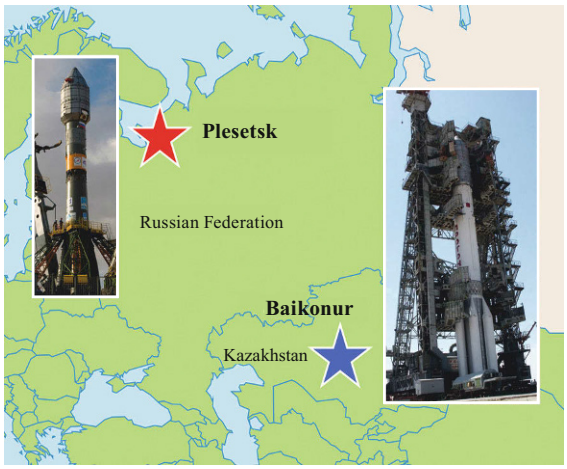

**Fig. 8.20** Launch sites and vehicles for the GLONASS navigation satellites (courtesy of ISS Reshetnev)

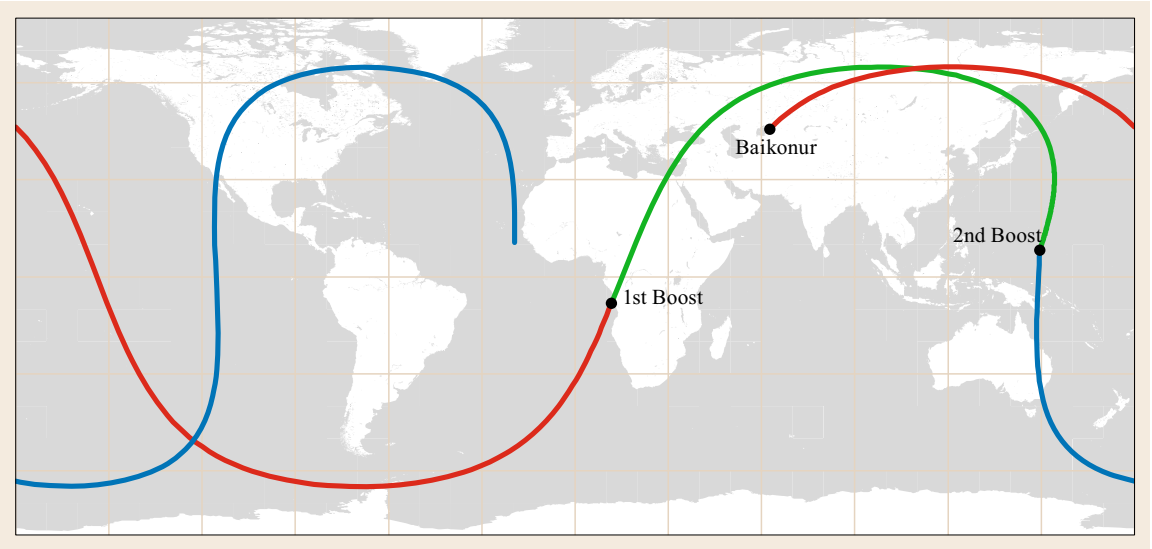

**Fig. 8.21** Representative example of the ground track during orbit injection of GLONASS satellites with a Proton rocket. The low Earth parking orbit and the elliptical transfer orbit are marked by *red* and *green lines* respectively, with *gray dots* indicating the approximate location of the upper stage burns. The *blue line* describes the first orbital revolution of the GLONASS spacecraft after separation. The illustration is based on patched Keplerian orbits and does not take into account the actual boost durations

**Fig. 8.22** Integration of three GLONASS-M satellites with a Block-DM upper stage (courtesy of ISS Reshetnev)

Aside from the three main stages, the Proton rocket typically employs a reignitable upper stage to realize more complex mission profiles. For GLONASS launches, either the *DM* or *Breeze-M* upper stage are employed, which offer a thrust level of 80 and 20 kN respectively. A typical missions scenario for GLONASS orbit injection is illustrated in Fig. 8.21 based on [8.1, 56]. After ascent of the launcher and burnout of the third stage (roughly 10 min after launch), the upper stage with the attached GLONASS satellites is separated and moves around the Earth at an altitude of about 200 km. This parking orbit has an inclination of $\approx 64.8°$ in accord with the orbit planes of the GLONASS constellation. A first boost of the upper stage raises the apogee to the desired target altitude of 19 130 km. The highly elliptical transfer orbit has an eccentricity of $e \approx 0.6$ and it takes about 3 h to proceed from perigee to apogee. Here, a second burn is performed, which circularizes the orbit. Thereafter, the GLONASS satellites are deployed into their target orbit. Following the separation from the upper stage, the solar panel deployment and the checkout of all onboard systems, the satellites are ultimately moved to their desired position in the orbital plane in a series of small orbit correction maneuvers using their own thruster system.

The large payload capacity of the Proton rocket enables triple launches of GLONASS I/II or GLONASS-M satellites, which was particularly helpful during the buildup and rebuild phase of the constellation. To fit three satellites under the Proton fairing, the solar panels are folded around the satellites in a rhombic shape that enables a tight packing of the triplet on the launch adapter (Fig. 8.22). Out of 51 launches with a total of 132 GLONASS satellites conducted up to 2015, a wide majority were conducted with Proton-K and -M rockets carrying three GLONASS satellites (with occasional replacements by mass dummies or Etalon satellites) at a time.

Starting with the launch of GLONASS-K1 in 2011, the Soyuz-2b [8.54] was introduced as an alternative launch vehicle for GLONASS satellites. The rocket has a height of about 46 m and can carry a payload of 4–8 t into low Earth orbit (depending on the inclination and actual altitude). The Soyuz rocket carries four RD-107A strap-on boosters that serve as the first stage and and develop a thrust of 3.3 MN over a 2 min boost phase. The central second and third stages are based on a single RD-108 and RD-0124 engine respectively, which provide thrust levels of 0.9 and 0.3 MN. Unlike the Proton rocket, the Soyuz launcher employs kerosene and liquid oxygen as propellant. A Fregat upper stage serves as forth stage and performs the transfer orbit injection as well as the final circularization of the orbit at the target altitude of the GLONASS constellation.

The Soyuz vehicle can carry a single GLONASS-M or -K1 satellite and has typically been used for replacing individual aged satellites in the constellation. As a side note, the Soyuz launcher has also been used for in-orbit delivery of various satellites of the Galileo constellation. Aside from the two precursor satellites Galileo in orbit validation element GIOVE-A and -B, most of these launches were, however, conducted from the European spaceport at Kourou, French Guiana.

## 8.5 Ground Segment

The ground segment is an essential part of the GLONASS architecture providing system operation and ultimate GLONASS performance. There is no formal division between system control and mission control functions. All operational procedures after satellite liftoff are fulfilled by the Air and Space Defense Forces (ASDF). If satellites are launched from the Baikonur launch site, the initial active phase of the launcher trajectory tracking is supported by the Russian Federal Space Agency (RFSA) assets.

The main functions of the GLONASS ground segment comprise:

- Support of operations in the launch and early orbit phase (LEOP)
- Commissioning of satellites and their transfer to dedicated orbit slots (in case of a triple launch or commissioning at an orbital spare position)
- Telemetry monitoring, command and control
- Mission planning and constellation keeping

- Maintenance and decommissioning of satellites at their end of life
- Monitoring of the ground assets status
- Generation of the system timescale and its steering to UTC(SU)
- Generation of orbit and clock data
- Upload of navigation data to the satellites
- Improvement of the satellite dynamics models
- Monitoring of the GLONASS navigation, positioning and timing performance
- Serving of external interfaces with civil institutions.

Core components of the GLONASS ground segment include the GLONASS system control center (SCC) and the central clocks (CCs), the telemetry, tracking and command stations (TT and C) and the uplink stations, as well as one-way monitoring stations and satellite laser ranging (SLR) stations. All major ground segment assets are located within the Russian territory at the ASDF sites shown in Fig. 8.23.

The system control center is located in Krasnoznamensk (formerly known as the closed town of Golitsyno-2) some 40 km southwest of the Moscow city center. It performs the planning and coordinates the work of all ground segment elements. Orbit determination and clock synchronization is implemented through processing of all available sets of data including two-way ranging from TT and C and uplink stations, downloaded radio cross-link ranging data, and one-way ranging data from ASDF monitoring stations. Use of data from the RFSA monitoring stations is planned to improve orbit and clock information as well as the cross-link ranging data.

GLONASS System Time is maintained by the central clock facility. It includes a group of four hydrogen masers, which are continuously steered to the Russian realization of Coordinated Universal time, UTC(SU) [8.27, 28]. The master central clock at Schelkovo near Moscow is complemented by a second facility at Komsomolsk in the far east of Russia.

The telemetry, tracking and control stations are used to receive status information from the GLONASS satellites, to send control commands, and to perform two-way ranging measurements for orbit determination. For maximum coverage, a total of five TT and C stations situated in the western, central and eastern parts of Russia are available. They are complemented by five uplink stations in Schelkovo, Yeniseisk, Komsomolsk, Vorkuta, and Petropavlovsk. Each of these sites is equipped with two antennas, which enables up to three uploads of orbit and clock data to each GLONASS satellite per day.

The monitoring stations collect one-way pseudorange and carrier-phase measurements for orbit and clock determination as well as offline performance and integrity monitoring. Most of them are colo-

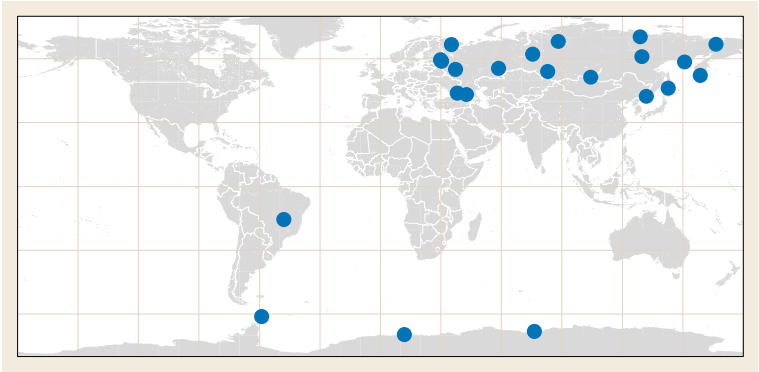

**Fig. 8.25** Network of SDCM monitoring stations (status end-2014)

**Fig. 8.24** Altay Laser Ranging Center near Barnaul (Altay) (courtesy of Science-Industry Corporation of Precise Device Engineering Systems (NPK SPP))

cated with laser ranging stations (Fig. 8.24), which enables complementary optical two-way distance measurements. The SLR observations are used for calibration of radiometric distance measurements as well as orbit determination and accuracy validation. They also contribute to an improved realization of the GLONASS reference frame. The routine use of SLR for GLONASS operations [8.57] is unique among all navigation satellite systems, but forms an integral part of the system architecture. From the very beginning, all GLONASS satellites were equipped with laser retroreflectors and the high-accuracy SLR measurements have helped in coping with the limited geographical distribution and accuracy of conventional radiometric tracking stations. In total, 13 monitoring and nine laser ranging stations distributed over the Russian territory (and neighboring states of the former Soviet Union) are currently included in the GLONASS ground segment.

As part of the ongoing GLONASS modernization and enhancement, the system for differential correction and monitoring (SDCM) [8.58] has been established. SDCM is based on a network of reference stations, which are equipped with combined GPS/GLONASS dual-frequency receivers, hydrogen maser atomic clocks and direct communication links for real-time data transfer. By the end of 2014, a total of 18 station have been deployed in Russian territory as well as four stations in Antarctica and Brazil (Fig. 8.25). Further stations are planned in Cuba and Kazakhstan as well as other countries in South America, Africa and Asia/Oceania to achieve a worldwide coverage. The SDCM network enables a continuous performance and integrity monitoring [8.59] as well as real-time corrections for precise point positioning applications [8.60]. SDCM correction data are provided via the Internet for terrestrial users and through the Luch-5A/B relay and communication satellites. Incorporation of the SDCM reference stations into the GLONASS orbit and clock determination could constitute an important building block for a fully global, high-performance GLONASS navigation service.

For synchronization of the onboard clocks, support of one-way laser ranging is currently under development [8.51]. Using photodetectors on board the GLONASS satellites, the arrival time of laser pulses with precisely known transmission time can be measured relative to the onboard timescale. By comparing these measurements with traditional two-way SLR observations, the difference between the satellite and ground clocks can then be determined [8.61]. Along with the installation of laser time transfer equipment in the future GLONASS satellites, the GLONASS ground segment will be upgraded to support such operations on a routine basis.

## 8.6 GLONASS Open Service Performance

Continuous monitoring of the GLONASS system performance and integrity is presently provided through various institutions and services in Russia. These include the Information and Analysis Centre of the Russian Federal Space Agency (IAC [8.62]), the System for Differential Correction and Monitoring (SDCM [8.59]), and the System for High-accuracy Determination of Ephemeris and Time Corrections (SVOEVP [8.63, 64]). Complementary to Russian reference stations, these monitoring services make use of stations from the International GNSS Service (IGS [8.65]) network to enable a fully global coverage. Unless otherwise noted, the performance results presented in this section are based on analyses and data of the IAC.

In a statistical sense, the positioning performance of a satellite navigation system can be expressed as the product of the position dilution of precision (PDOP) and the user range error (URE). The PDOP depends only on the number of tracked GNSSs and the geometric distribution of their line-of-sight vectors. The URE in contrast describes the root mean square errors of the difference between modeled and observed pseudoranges. Aside from user equipment errors (UEE) such as noise and multipath or uncompensated atmospheric delays, it comprises the signal-in-space range error (SISRE). The latter describes the impact of errors in the broadcast orbit and clock parameters on the range computation.

Since completion of the nominal 24-satellite constellation in 2012, GLONASS provides global daily availability of a better than 99% at a 5° elevation mask angle and a PDOP of less than 6. An example of the instantaneous PDOP map for the current GLONASS constellation is shown in Fig. 8.26. PDOP values amount to 1.5–2.5 for most of the globe and only exceed a value of 3 in very limited geographic regions.

The signal-in-space range error as monitored by the IAC exhibits typical variations in the range of 1–2 m across individual satellites of the constellation (Fig. 8.27). For comparison, a mean SISRE of 1.9 m has been derived from the analysis of broadcast ephemeris data covering a one year interval in 2013/2014 [8.66] while SISRE values of 1–4 m were obtained by [8.67] for individual GLONASS satellites in the 2009–2011 time frame.

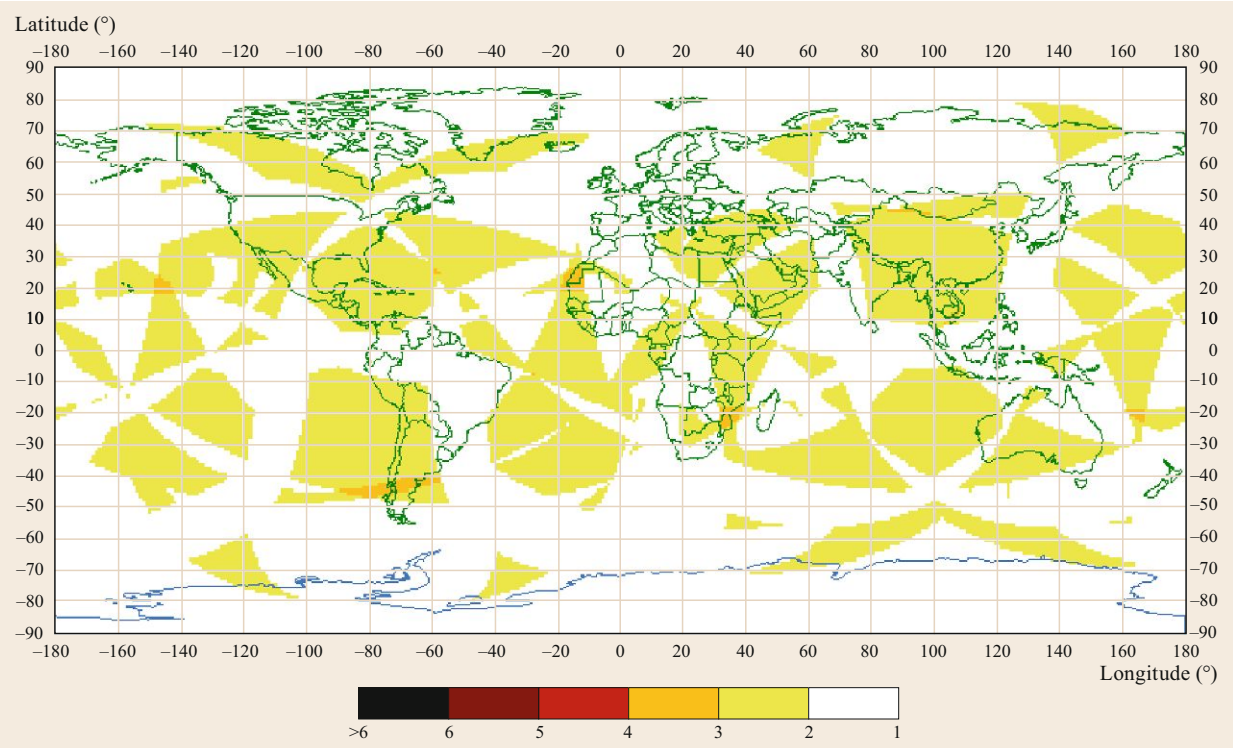

**Fig. 8.26** Instantaneous PDOP map for the GLONASS constellation on 8 March 2015, 10:30 UTC (mask elevation angle 5°) (courtesy of Federal Space Agency-Information Analytical Centre)

**Fig. 8.27** Average GLONASS constellation SISRE for 6–8 March 2015 (RMS, m) (courtesy of Federal Space Agency-Information Analytical Centre)

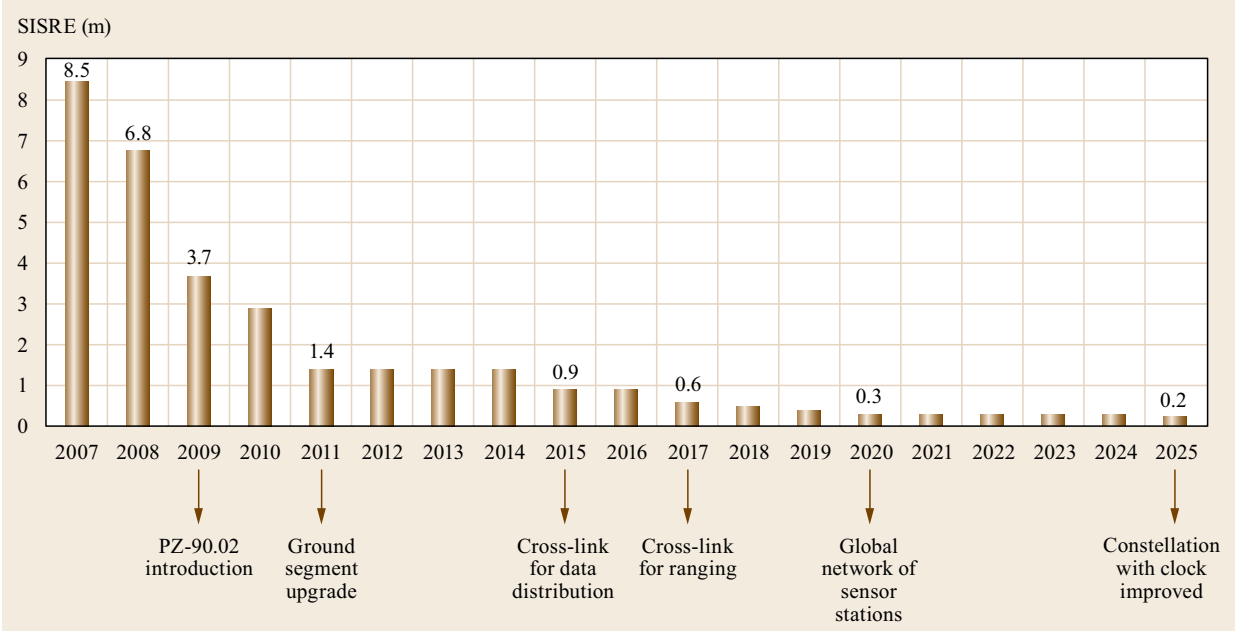

**Fig. 8.28** Mean SISRE of the GLONASS constellation through GPI plan implementation

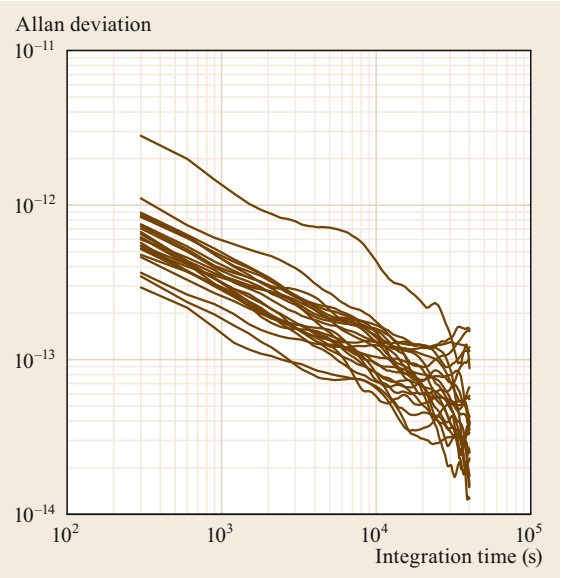

**Fig. 8.29** Allan deviation of GLONASS-M satellites on 5 March 2015 as derived from European Space Agency (ESA) clock products (courtesy of P. Steigenberger (DLR))

One of the key factors contributing to the SISRE is the onboard clock stability. It is commonly characterized by the Allan deviation (ADEV), that is the relative frequency error over a specified time interval (Fig. 8.29). For the current constellation of GLONASS-M satellites, the Allan deviation (ADEV) over a one-day correlation time is typically better than $(0.5-1.0)\cdot 10^{-13}$ [8.62, 68]. Over short timescales of 1–100 s, ADEV values of about $1\cdot 10^{-11}$ have been reported in [8.69, 70]. An overall improvement of the onboard clock stability is expected from new types of atomic frequency standards on the next-generation GLONASS-K satellites.

The GLONASS performance improvement (GPI) plan foresees a continuous SISRE reduction to less than 0.5 m by 2020 (Fig. 8.28). Key steps to achieve this improvement include the processing of carrier-phase measurements in the orbit determination and time synchronization process, the use of intersatellite communication cross links for performing up to 24 navigation data uploads per day, use of intersatellite ranging data for orbit and clock determination in the ground segment facilities, and the global expansion of the monitoring network. Further improvements are expected from the introduction of high-performance CDMA signals and new generations of onboard clocks.

# 9. Galileo

Marco Falcone, Jörg Hahn, Thomas Burger

The European global navigation satellite system Galileo is designed as a self-standing satellite-based positioning system for worldwide service. It is independent from other systems with respect to satellite constellation, ground segment, and operation. Galileo is prepared to be compatible and interoperable with other radio navigation satellite systems, with global positioning system (GPS) as the main example. It uses the same physical principles as GPS, GLONASS, and others, that is radio signal-based ranging measurements from high-precision clocks as sources in orbit. The features of the first generation of Galileo comprise technological advances such as passive maser clock technology in orbit, plus modern system and signal concepts aligned to the planned and ongoing modernization of other systems. To the user, Galileo provides navigation signals on three frequencies E1, E6, and E5. The signals in E1 and E5 are coordinated with GPS L1 and L5, and both systems use equivalent modulation principles. This is expected to result in a benefit with respect to positioning accuracy, and in increased robustness of a positioning service derived from the combined use of multiple independent radio navigation systems. This chapter describes architecture and operations of Galileo.

The enormous potential benefits of satellite navigation for the citizens brought the European Space Agency (ESA) and the European Commission (EC) together in collaboration to develop and deploy a European radio navigation satellite system called Galileo.

Galileo development followed an iterative approach illustrated in Fig. 9.1. It was initiated in late 2003, carried out by the European Space Agency (ESA), and co-funded by ESA and the European Union.

ESA launched two GIOVE (Galileo In-Orbit Validation Element) satellites in 2005 and 2008, with a representative ground segment. These satellites secured the frequencies provisionally set aside for Galileo by the International Telecommunications Union. The satellites served also as a testbed for key technologies such as onboard atomic clocks and navigation signal generation. The GIOVE satellites are no longer active and have been moved to higher altitudes, away from the nominal Galileo orbit.

The following in-orbit validation phase aimed to perform initial validation of the system using a reduced constellation of four Galileo in-orbit validation (IOV) satellites – the minimum number for independent position and timing solutions at test locations – in combination with Galileo's terrestrial network of ground stations. This phase used the first family of Galileo satellites (GSAT010x), launched through dual launches on 21 October 2011 and 12 October 2012. These four satellites served for IOV of the Galileo system, but are also part of the operational Galileo constellation. On 12 March 2013 this ground and space infrastructure came together to perform the very first determination of a ground location through Galileo signals alone. This initial position fix of longitude, latitude and altitude took place at the Navigation Laboratory at ESA's technical heart European Space Research and Technology Centre (ESTEC), in Noordwijk, the Netherlands. From this point onward, Galileo navigation messages have

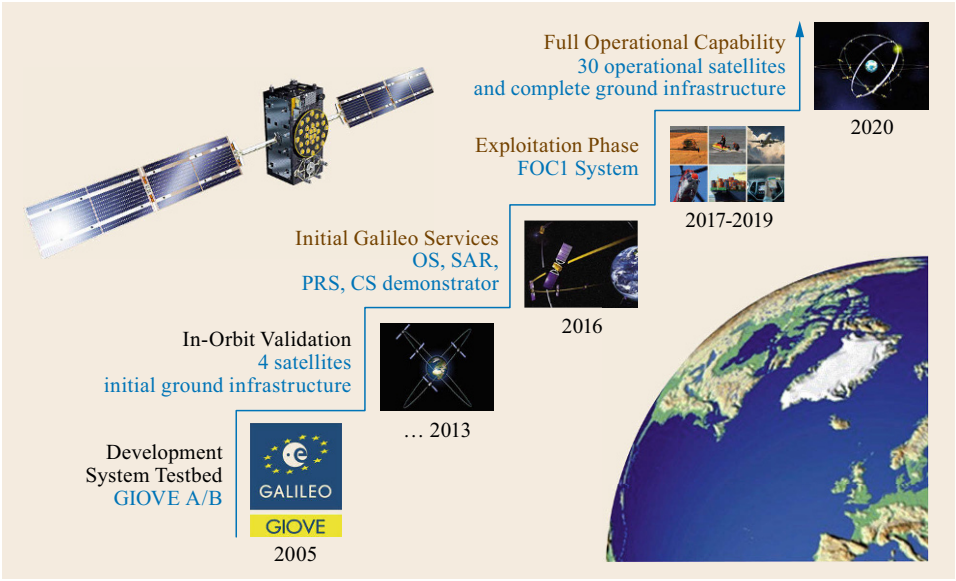

**Fig. 9.1** Galileo incremental deployment (courtesy of M. Pedoussaut, S. Corvaja, Th. Burger, ESA, and pixabay.com)

been broadcast. The IOV campaign was conducted successfully throughout 2013, and the results were used as a reference to predict the expected performance of the completed Galileo constellation.

The deployment of the Galileo system until its full operational capability (FOC) is conducted under a public procurement scheme, entirely financed by the European Union. In 2007 the European Parliament and the European Commission decided to implement the system, and allocated budget for Galileo and for the European geostationary navigation overlay service (EGNOS). In 2008 the first part of the procurement of the Galileo full operational capability was launched, aiming to address full system deployment, long-term operations and replenishment. This phase will consist of the launch of all remaining satellites (up to 30) and deployment of the full operational ground segment, including all required redundancies in order to comply with the full mission requirements in terms of performance and service area. Early Galileo services are set to begin during the year 2016.

Following this, the Exploitation Phase is planned to start during the deployment of the full system, scheduled for 2017, and will consist of routine operations as well as ground segment maintenance and replenishment of the satellite constellation. This phase is planned to last over the design lifetime of the system, nominally 20 years.

## 9.1 Constellation

The Galileo constellation is the result of detailed studies and optimization [9.1, 2]. Table 9.1 summarizes the finally selected basic Galileo reference constellation parameters [9.3, 4].

The nominal satellite positions in space for a given time are defined by the reference Keplerian elements expressed in the Celestial Intermediate Reference System (CIRS) [9.5].

$$
\begin{aligned}
i_{\mathrm{ref}} &= 56^{\circ}\,, \\
\Omega_{\mathrm{ref}} &= \Omega_0 + 120^{\circ}\cdot(k_{\mathrm{plane}}-1) + \dot{\Omega}\cdot(T-T_0)\,, \\
u &= u_0 + 45^{\circ}\cdot(k_{\mathrm{slot}}-1) \\
&\quad + 15^{\circ}\cdot(k_{\mathrm{plane}}-1) + D_{\mathrm{nom}}\cdot(T-T_0)\,. \qquad (9.1)
\end{aligned}
$$

$$
\begin{aligned}
\Omega_0 &= 25^{\circ}\,, \\
\dot{\Omega} &= -0.02764398^{\circ}/\mathrm{d}\,, \\
T_0 &= 21\ \text{March 2010,}\ \ 00{:}00{:}00\ \mathrm{UTC} \\
u_0 &= 338.333^{\circ}\,, \\
D_{\mathrm{nom}} &= 613.72253566^{\circ}/\mathrm{d}\,. \qquad (9.2)
\end{aligned}
$$

In the equations above, the variable $k_{\mathrm{plane}}$ can take the values 1, 2 and 3 for, respectively, planes A, B and C [9.6]. The variable $k_{\mathrm{slot}}$ denotes the slots within the orbital plane and can assume values from 1 to 8. $i_{\mathrm{ref}}$ is the orbit inclination and $\Omega_{\mathrm{ref}}$ the right ascension of ascending node (RAAN). The argument of latitude $u$ is defined as along-track phase angle with respect to the equator.

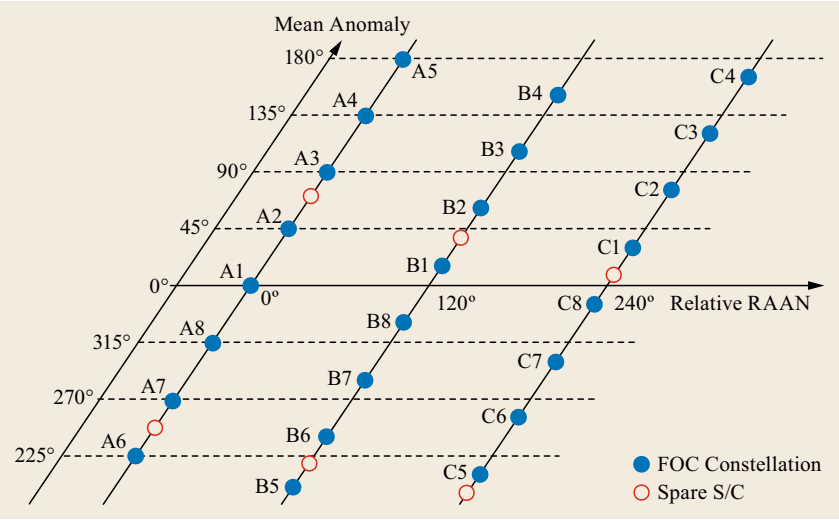

**Fig. 9.2** Galileo FOC constellation slots

**Table 9.1** Galileo reference constellation parameters

| Parameter | Value |
|---|---|
| Reference constellation type | Walker 24/3/1<br>+ 6 in-orbit spares |
| Semimajor axis | 29 600.318 km |
| Inclination | 56° |
| Period | 14h 04m 42s |
| Ground track repeat cycle | 10 sidereal days/17 orbits |

The satellites are generally maintained within orbit slots of $\pm 2°$ in inclination and argument of latitude, and $\pm 1°$ in right ascension of ascending node ($\Omega$) with respect to the reference. $\dot{\Omega}$ reflects both the oblateness of the Earth's gravitational field and the gravitational effect of the Moon and Sun. $D_{\text{nom}}$ is computed taking into account the repeat ground-track pattern of 17 revolutions in ten sidereal days. Figure 9.2 shows a systematic sketch of the resulting constellation geometry and satellite locations.

The position of the spare satellites shown in Fig. 9.2 is indicative, as their actual position will be decided at the time of deployment.

The constellation geometry has been optimized to achieve consistently good geometric conditions on a global scale, leading to a good user position accuracy and availability. The inclination of the orbit planes provides for better coverage in the higher latitudes, for example when compared to GPS.

The above reference constellation of 24 satellites will yield between six to 11 Galileo satellites visible at any user location worldwide. Average visibility is more than eight Galileo satellites above 5° elevation. The reference constellation will be complemented with nominally six spare satellites. This constellation provides good local geometries with a typical vertical dilution of precision (VDOP, [9.7]) of 2.3 and horizontal dilution of precision (HDOP) around 1.3. An additional benefit of the constellation geometry is the limited number of planes, which allows for faster deployment and reduced constellation maintenance costs due to the capability to launch multiple satellites with a single launcher. For example Ariane 5 is capable of launching up to four Galileo satellites, and Soyuz is used to launch sets of two Galileo satellites.

Satellite disposal after the end of their operational life is to be considered and planned appropriately, for reasons of space debris control but also because debris avoidance maneuvers will impact the availability of operational satellites for service provision. Galileo satellites are removed from the nominal Galileo orbits after they have reached the end of their operational life. The same applies for remaining launcher stages after injection of new satellites into their orbits. The strategy followed in Galileo is to move those satellites and launcher stages to a *graveyard* orbit that is at least 300 km higher than the operational Galileo orbits.

## 9.2 Signals and Services

Each Galileo satellite provides coherent navigation signals on three different frequencies. Each signal contains several components, comprising always at least one pair of pilot and data components. Figure 9.3 summarizes the transmission plan.

The signals and components are assigned to three types of positioning services:

1. The Open Service (OS) comprising the data-pilot pairs E1-B/C, E5a-I/Q and E5b-I/Q, representing the publicly accessible positioning service
2. The Public Regulated Service (PRS) on E1-A and E6-A, a restricted access positioning service for government-authorized users
3. The Commercial Service (CS) through the data-pilot pair E6-B/C, a navigation signal on a third frequency, optionally encrypted, for the provision of future added value services.

As a fourth service, Galileo satellites support Cospas-Sarsat [9.8–10], an international satellite-based search and rescue system established by the US, Russia, Canada and France, capable of locating emergency radio beacons. This support is provided through a forward search-and-rescue repeater as part of the payload, and through an associated data return link embedded into the navigation message of the E1 OS data component.

E1 and E6 each provide one publicly accessible pair of pilot and data components, and E5 offers two pilot-data pairs in sidebands 15.345 MHz above (E5b) and below (E5a) the E5 carrier frequency. The sidebands E5a and E5b are foreseen for individual tracking and use, offering the equivalent of two coherent carrier frequencies within the E5 band. The overall E5 carrier including both sidebands is defined and generated coherently as an alternative BOC (AltBOC) signal [9.11]. This composite AltBOC signal can also be tracked as a single signal, offering a very large signal bandwidth of at least 51.15 MHz (50·1.023 MHz), and thus providing excellent Gabor bandwidth (Chap. 4) and multipath rejection.

Table 9.2 gives the overview of available Galileo signals and associated carrier and subcarrier frequencies.

Galileo and GPS, as the system with the longest heritage and current most wide use, are considered compatible (sharing of resources without degrading the performance of the other radio navigation satellite system) and interoperable (allowing the user to successfully combine pseudorange measurements from more than one global navigation satellite system (GNSS) into position/velocity/time solutions):

1. Two carrier frequencies are shared (E5a/L5 and E1/L1), with equivalent modulations

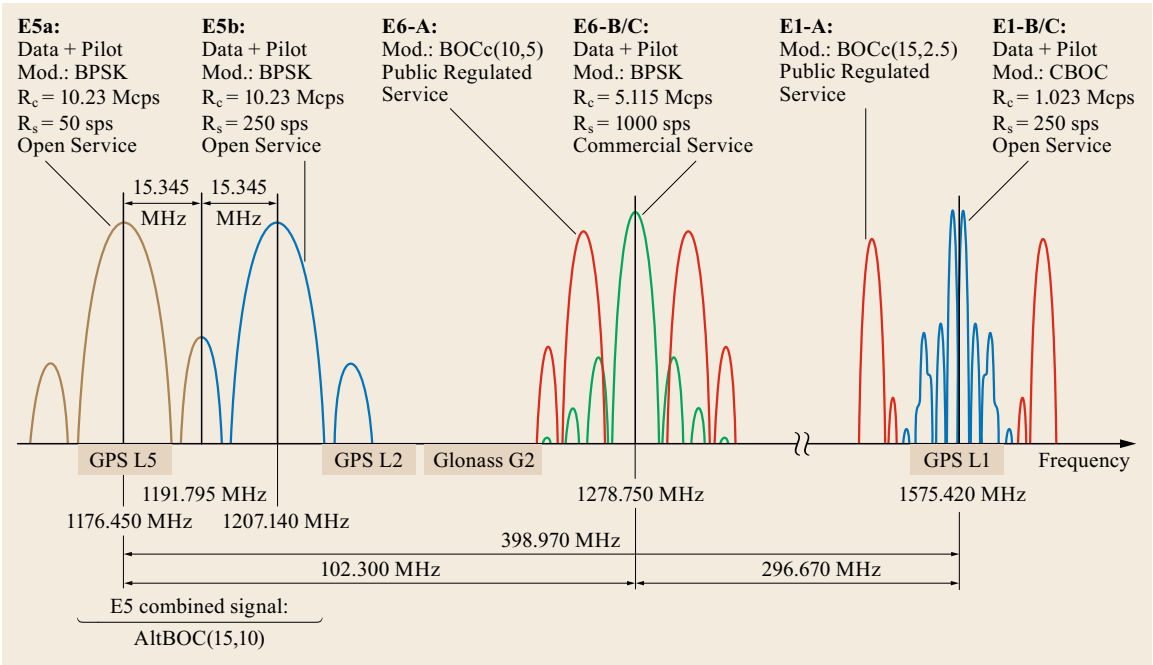

**Fig. 9.3** Galileo frequency bands, signals and components

**Table 9.2** Overview of Galileo signals

| Galileo signal | Carrier frequency (MHz) | Subband | Subband frequency (MHz) | Carrier aligned with |
|---|---|---|---|---|
| E1 | 1575.420 | n/a | n/a | GPS L1 C/A, L1C |
| E6 | 1278.750 | n/a | n/a | |
| E5 | 1191.795 | E5b | 1207.140 | |
| | | E5a | 1176.450 | GPS L5 |

2. Fundamental message concepts are comparable, such as ephemeris, almanac, clock correction, GST-UTC (Galileo System Time - Universal Time Coordinated), and bias group delay
3. Terrestrial reference frames and reference time systems are aligned, as indicated in the following sections of this chapter.

These concepts and measures are intended to simplify and optimize user receiver hardware implementation (radio frequency front-end design and digital preprocessing), but also receiver software and algorithms.

### 9.2.1 Signal Components and Modulations

All Galileo signals and their signal components are derived from the same onboard master clock, and are thus coherent. Table 9.3 provides a summary of the modulation schemes and component parameters. Four pairs of pilot and data components are provided for public use: E1-B/C, E6-B/C, E5a-I/Q and E5b-I/Q. All pilot/data pairs use a 50% power sharing.

The modulation-specific recommendations for receiver bandwidths are driven by the components to be tracked. Recommended receiver bandwidths are as listed in Table 9.4.

When choosing a receiver bandwidth, manufacturers are recommended to carefully consider the interference situation in each band. Some selected examples follow (the list is not complete). In E6 the presence of terrestrial pulsed interference, for example from radar systems, is to be expected, and the band is shared with amateur radio users that use it for audio and video transmitters and relays (HAM TV). Often also other unidentified low-power sources have been observed, especially in urban areas. Receivers will need to be resistant against high-power radio frequency (RF) pulses

**Table 9.3** Overview of Galileo public signal components and modulations. Legend: $R_c$ = primary code chip rate (in multiples of 1.023 MHz), $R_{sc}$ = subcarrier frequency (in multiples of 1.023 MHz), $R_d$ = symbol rate (symbols/s), $R_{sec}$ = secondary code chip rate (chips/s)

| Signal | Component | Modulation | $R_c$ | $R_{sc}$ | $R_d$, $R_{sec}$ | Message | Service | Multiplex | Min received Power |
|---|---|---|---|---|---|---|---|---|---|
| E1 | E1-B Data | Composite binary offset carrier (CBOC) 1/11 | 1 | 1&6 | 250 | I/NAV | OS | in | −160 dBW |
| 1575.420 MHz | E1-C Pilot | CBOC 1/11 | 1 | 1&6 | 250 | – | OS | phase | −160 dBW |
| E6 | E6-B Data | Binary phase-shift keying (BPSK) | 5 | – | 1000 | C/NAV | CS | in | −158 dBW |
| 1278.750 MHz | E6-C Pilot | BPSK | 5 | – | 1000 | – | CS | phase | −158 dBW |
| E5b | E5b-I Data | BPSK | 10 | – | 250, 1000 | [I/NAV] | OS | 0° | −158 dBW |
| 1207.140 MHz | E5b-Q Pilot | BPSK | 10 | – | 1000 | – | OS | 90° | −158 dBW |
| E5a | E5a-I Data | BPSK | 10 | – | 50, 1000 | F/NAV | OS | 0° | −158 dBW |
| 1176.450 MHz | E5a-Q Pilot | BPSK | 10 | – | 1000 | – | OS | 90° | −158 dBW |

**Table 9.4** Recommended receiver bandwidths for Galileo navigation signals

| Component | Rx Bandwidth (double sided) | | | |
|---|---|---|---|---|
| | Min | Recommended | Max | Note |
| E1-B/C tracked as BOC(1,1) | 2.0 MHz | 2.0...24.6 MHz | ≈31 MHz | In steps of 2.023 MHz |
| E1-B/C tracked as CBOC | 14.3 MHz | 14.3...30.7 MHz | ≈31 MHz | Good multipath robustness already at 14.3 MHz |
| E6-B/C BPSK(5) | 10.2 MHz | 10.2...20.5 MHz | ≈41 MHz | In steps of 10.23 MHz |
| E5a-I/Q BPSK(10) | 20.5 MHz | 20.5 MHz | ≈41 MHz | In steps of 20.46 MHz |
| E5b-I/Q BPSK(10) | 20.5 MHz | 20.5 MHz | ≈41 MHz | In steps of 20.46 MHz |
| E5 as AltBOC | 51.2 MHz | 51.2 MHz | ≈72 MHz | Center frequency 1191.795 MHz |

in-band, and against continuous transmitters close to band. The E5 band is mainly shared with air traffic control and positioning systems like DME (Distance Measuring Equipment, primary user), where the DME ground stations transmit within the E5 navigation band. DME transmissions are pulse pairs, each pair a few tens of μs long, transmitted at average rates up to several kHz and pulse powers in the range of 1 kW.

### Selected Galileo Modulation Details

Galileo uses CBOC (Composite Binary Offset Carrier) modulation in E1 and AltBOC (alternative binary offset carrier) modulation in E5. These modulations are specific for Galileo and are shortly explained below. The Galileo E6 public signal uses conventional BPSK (binary phase shift keying) modulation as described in Chap. 4, and is thus not elaborated here. A full description of the public Galileo modulations is published in the Galileo public Open Service Signal in Space Interface Control Document (OS SIS ICD) [9.11].

CBOC as used for the Galileo E1 public signal is a composition of a 1.023 Mcps spreading sequence combined with a two-component spreading symbol. The spreading symbol comprises the sum of a BOC(1,1) subcarrier at 10/11 power and a BOC(6,1) subcarrier at 1/11 power. The spreading symbol of the data channel combines the two subcarriers in-phase and the spreading symbol of the pilot channel combines them in antiphase, as illustrated in Figs. 9.4 and 9.5. As a result of the additive combination of the two binary offset carrier (BOC) subcarriers with nonequal amplitude, the time domain CBOC spreading symbols are four-level pulses. The spreading pulses of the CBOC data and pilot components differ with respect to the phase of their BOC(6,1) subcarriers.

When tracking using a conventional dual-level BOC(1,1) despreading is possible with minor losses (≈ 0.4 dB) that are also a function of the receiver bandwidth. Direct CBOC tracking requires a four-level correlator with amplitude stages of $\{\pm 1.25, \pm 0.65\}$. An approximation of the replica levels using two bit representations of the replica is possible, but not optimum. Alternative techniques, for example combing separate binary correlators for the BOC(6,1) and BOC(1,1) parts are increasingly becoming subject to publications and patents [9.12–14], demonstrating the feasibility of efficient tracking of CBOC modulated signals.

The phase of the BOC(6,1) components in the data and pilot spreading symbols is inverted. Thus the com-

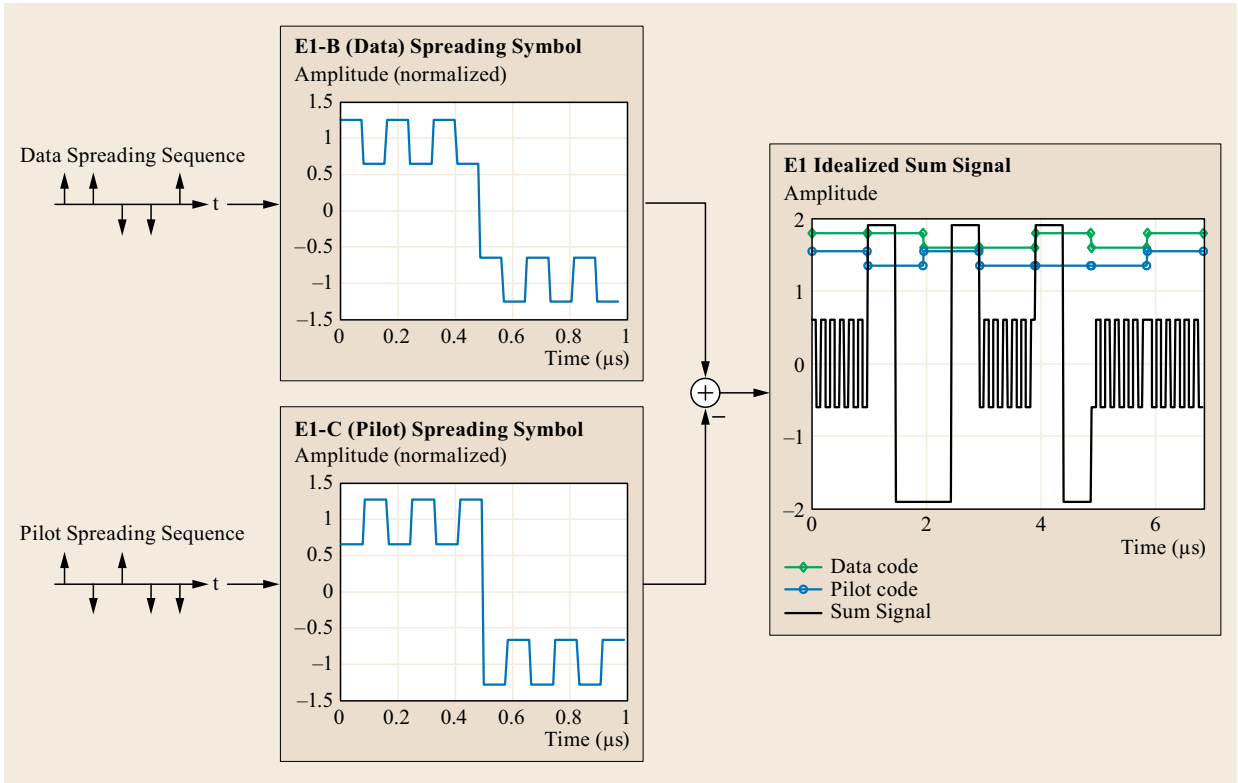

**Fig. 9.4** Galileo CBOC principle

bined signal of pilot and data channel, as the in-phase addition of the pilot and data baseband signals, has only four levels in total. The combined signal has the interesting property that always only either BOC(1,1) or BOC(6,1) is transmitted, in time multiplex. The subcarrier phase is set according to the combination of the spreading chips from pilot and data channels. This opens a range of possible highly efficient correlation mechanisms for tracking the combination signal, using time multiplex techniques.

AltBOC modulation was proposed in 2002/2003 [9.15, 16] as wideband complex sideband modulation. AltBOC can be understood in baseband representation as the sum signal of coherently generated and individually quadrature modulated complex upper (E5b) and lower (E5a) subcarriers, then adding an intermodulation function (IM) to achieve a constant envelope on the transmit side [9.17]. The OS SIS ICD [9.11] baseband representation

$$
\begin{aligned}
s_{\mathrm{E5}}(t) = \\
\sqrt{1/8}\cdot\Bigg[
&\left.\begin{aligned}
&\left[e_{\mathrm{E5a\text{-}I}}(t)+je_{\mathrm{E5a\text{-}Q}}(t)\right]\cdot\\
&\left[sc_{\mathrm{S}}(t)-jsc_{\mathrm{S}}\left(t-\frac{T_{\mathrm{s}}}{4}\right)\right]\\
+&\left[e_{\mathrm{E5b\text{-}I}}(t)+je_{\mathrm{E5b\text{-}Q}}(t)\right]\cdot\\
&\left[sc_{\mathrm{S}}(t)+jsc_{\mathrm{S}}\left(t-\frac{T_{\mathrm{s}}}{4}\right)\right]
\end{aligned}\right\} \quad \text{Signal Part}\\
&\left.\begin{aligned}
&\left[\bar{e}_{\mathrm{E5a\text{-}I}}(t)+j\bar{e}_{\mathrm{E5a\text{-}Q}}(t)\right]\cdot\\
&\left[sc_{\mathrm{P}}(t)-jsc_{\mathrm{P}}\left(t-\frac{T_{\mathrm{s}}}{4}\right)\right]\\
+&\left[\bar{e}_{\mathrm{E5b\text{-}I}}(t)+j\bar{e}_{\mathrm{E5b\text{-}Q}}(t)\right]\cdot\\
&\left[sc_{\mathrm{P}}(t)+jsc_{\mathrm{P}}\left(t-\frac{T_{\mathrm{s}}}{4}\right)\right]
\end{aligned}\right\} \quad \begin{array}{l}\text{Inter-}\\ \text{modu-}\\ \text{lation}\\ \text{Part}\end{array}
\Bigg]
\end{aligned}
\tag{9.3}
$$

contains in its first two lines the four independent bipolar $\{-1,+1\}$ spreading sequences $e_{\mathrm{E5\{a,b\}\text{-}\{I,Q\}}}(t)$ (spreading code, secondary code and data modulation) in sideband modulation with their subcarrier $sc_{\mathrm{S}}(t)$, and in the last two lines the IM consisting of the bipolar sequences $\bar{e}_{\mathrm{E5\{a,b\}\text{-}\{I,Q\}}}(t)$ with their IM subcarrier $sc_{\mathrm{P}}(t)$. All IM sequences are triple-product terms of the nominal spreading sequences $e_{\mathrm{E5\{a,b\}\text{-}\{I,Q\}}}(t)$, for example

$$\bar{e}_{\mathrm{E5a\text{-}I}}(t) = e_{\mathrm{E5a\text{-}Q}}(t)e_{\mathrm{E5b\text{-}I}}(t)e_{\mathrm{E5b\text{-}Q}}(t)\ .$$

The subcarriers before band limitation are discrete multilevel signals with period $T_{\mathrm{S}} = (15.345\,\mathrm{MHz})^{-1}$ and are defined as shown in Fig. 9.6.

The description provided in [9.11] is ideal wideband and yields a final signal constellation diagram (signal

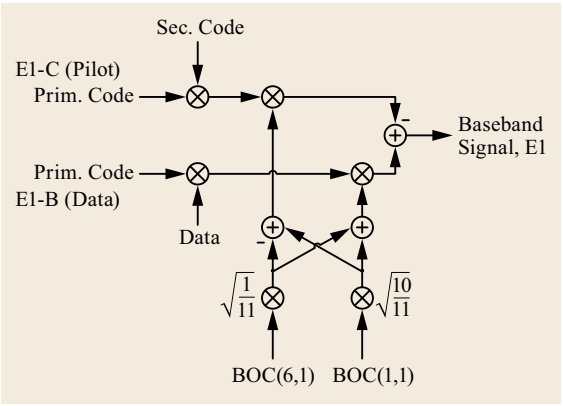

**Fig. 9.5** CBOC generation block diagram

part combined with intermodulation function) that represents an eight PSK-type modulation (Fig. 9.7a). The main energy content of the IM is located around and beyond ±46 MHz offset from the E5 carrier (Fig. 9.7b), and lies outside the recommended AltBOC receive bandwidth (51.2 MHz). Receivers will see only a small fraction of the theoretical IM power and may thus safely decide to neglect the IM for the purpose of AltBOC tracking.

Various alternative AltBOC tracking concepts have already been published, and all require an AltBOC replica generation. One fundamental concept to generate the replica using a lookup table approach appears suitable for receiver implementation and is provided in [9.11], together with the direct mathematical description. This concept represents a baseline; it is to be expected that actual receiver implementations will use optimized forms, for example of combined replica generation and correlation computation.

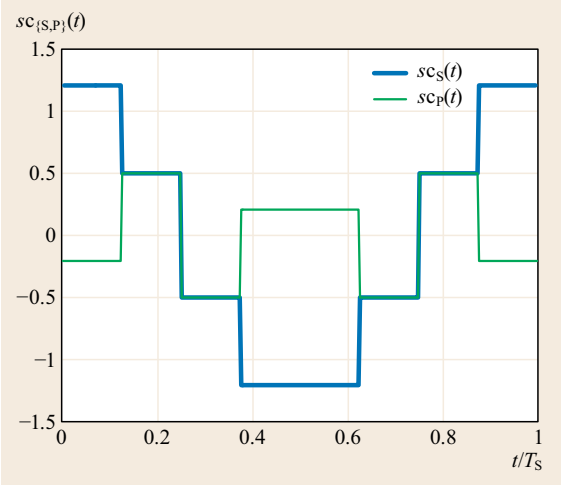

**Fig. 9.6** AltBOC subcarrier functions

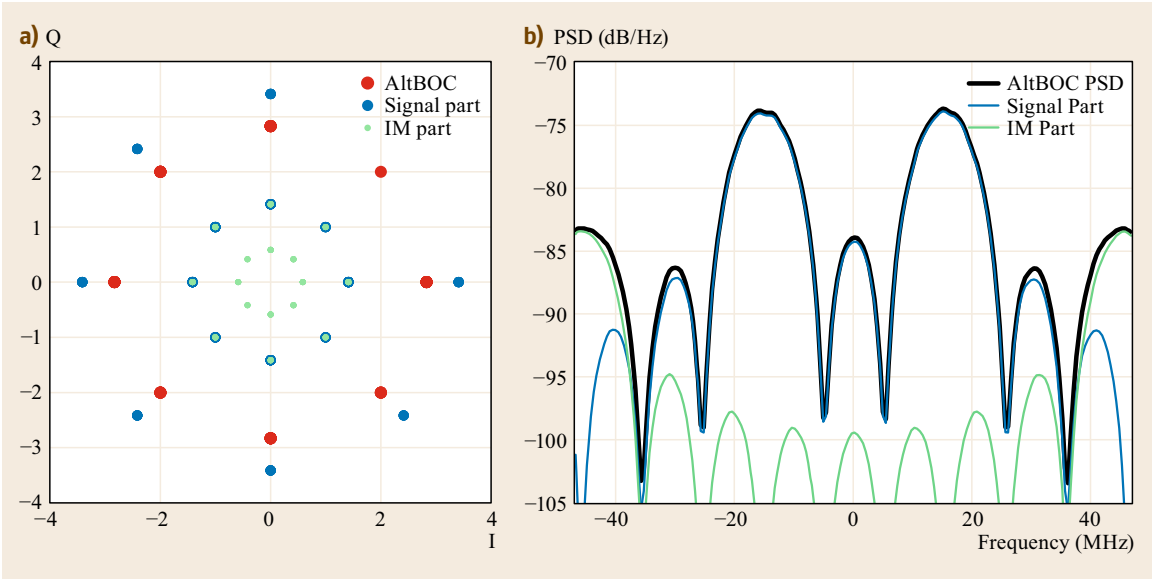

**Fig. 9.7a,b** AltBOC wideband signal vector diagram **(a)** and example power spectral density **(b)**

It is to be recalled that the Galileo navigation messages do not formally provide a direct message for use with AltBOC. The ephemeris information is unproblematic; any of the ephemeris sets provided in the Galileo navigation messages may be used. The clock correction is more critical, since the clock corrections as provided in the two public Galileo navigation messages are individual for specific frequency pairs (Sect. 9.2.2). If needed, either of these clock corrections and broadcast group delays (BGDs), or an average of them, may be used as good approximations.

In the case where only sidebands are to be tracked, then each of the four signal components $e_{\mathrm{E5\{a,b\}\text{-}\{I,Q\}}}(t)$ can be acquired and tracked individually, as BPSK(10)-type navigation signal components. The two components on each sideband are configured as pairs of pilot and data. The two sidebands E5a and E5b of an AltBOC signal are fully coherent, thus any crosstalk between those sidebands is stationary. Tracking accuracy can suffer nonnegligible side effects from this crosstalk. Individual components $e_{\mathrm{E5\{a,b\}\text{-}\{I,Q\}}}(t)$ should thus be tracked using a receive bandwidth centered on the desired sideband E5a or E5b, and narrow enough to suppress the other sideband. For this reason Table 9.4 recommends component tracking bandwidths of 20.46 MHz.

### Galileo Spreading Codes and Sequences

Each unencrypted signal component from each satellite is using individual, unique periodic spreading sequences (Table 9.5). The length (period) of the spreading sequences of data components is chosen such as to span full symbols of the data channel. If this requires more than 10230 chips, a two-tiered construction of a primary spreading code overlaid with a slower secondary code is used. The spreading sequences of pilot components generally use the two-tiered construction, with the length of the primary code equaling the primary code of the corresponding data channel, and the length of the secondary code chosen such as to pro-

**Table 9.5** Overview of Galileo spreading codes (LFSR = linear feedback shift register)

| Signal component | | Primary code | | | | Secondary code | | |
|---|---|---|---|---|---|---|---|---|
| | | Type | Chips | Period (ms) | # | Chips | Period (ms) | # |
| E1-B | Data, CBOC(1,6,1/11), 250 sps | Memory | 4092 | 4 | 50 | – | – | – |
| E1-C | Pilot, CBOC(1,6,1/11) | Memory | 4092 | 4 | 50 | 25 | 100 | 1 |
| E6-B | Data, BPSK(5), 1000 sps | Memory | 5115 | 1 | 50 | – | – | – |
| E6-C | Pilot BPSK(5) | Memory | 5115 | 1 | 50 | 100 | 100 | 50 |
| E5b-I | Data, BPSK(10), 250 sps | LFSR | 10230 | 1 | 50 | 4 | 4 | 1 |
| -Q | Pilot, BPSK(10) | LFSR | 10230 | 1 | 50 | 100 | 100 | 50 |
| E5a-I | Data, BPSK(10), 50 sps | LFSR | 10230 | 1 | 50 | 20 | 20 | 1 |
| -Q | Pilot, BPSK(10) | LFSR | 10230 | 1 | 50 | 100 | 100 | 50 |

vide a total of 100 ms nonrepetitive length of the pilot spreading sequence.

The two-tiered spreading sequence generation works comparably to a pseudodata modulation, where the secondary code represents the (a priori) symbol modulation. Accordingly, the secondary code clocks with one chip per period of the primary code, and is modulo-2 combined with the primary code. Figure 9.8 illustrates this principle.

The design objective was to limit the length of the primary code to less than or equal to 10230 chips, to avoid excessive code search space during acquisition, but also to provide a nonrepetitive sequence length of either one symbol for data components or 100 ms for pilot components. Primary spreading sequences have been carefully selected and optimized for good orthogonality across each family, and are responsible for ensuring sufficient isolation between signal sources. Secondary codes have been mainly tuned for low autocorrelation sidelobes, and as a consequence, a flat power spectrum in the frequency domain.

The two-tiered construction cannot reach the correlation quality of an optimized single-stage spreading sequence with the same length as the combination of primary and secondary code. Instead, for coherent integration covering multiple primary code lengths, or over the full period of the tiered code, the correlation result will repeat the primary code autocorrelation modulated with the shape of the secondary code (partial) autocorrelation. This means there will be repeating correlation peaks every period of the primary code, not with the full amplitude of the main correlation peak, but still with significant levels. Receivers using coherent integration times longer than the primary code period will need to consider this behavior through appropriate hypothesis tests during acquisition to find the correct main peak and secondary code phase. But once the phase of the secondary code is identified, this resolves the code phase unambiguously up to the length of the tiered code. The two-tiered code concept with its pseudodata modulation in the form of the secondary code is also intended to reduce the sensitivity to narrowband interference, compared to repetitive primary codes without secondary code, while maintaining a reasonably length-limited primary code.

The secondary code on pilot components allows the resolution of the code phase relative to Galileo System Time (GST) with an ambiguity interval of 100 ms. This approximately equals the maximum propagation delay between any visible Galileo satellite of the nominal constellation and terrestrial users, and is more than four times the difference between the propagation delay to the closest and the farthest user on Earth. It is therefore considered possible to derive time-free position solutions for users on the surface of Earth, using only code phase measurements including the secondary code of any pilot signal, and provided the receiver already has ephemeris and clock correction information available.

The Galileo primary and secondary spreading codes for public use are provided in the OS SIS ICD [9.11]. Note that the memory codes are provided only in the downloadable electronic (PDF) version of that document. The occasionally available paper printed version

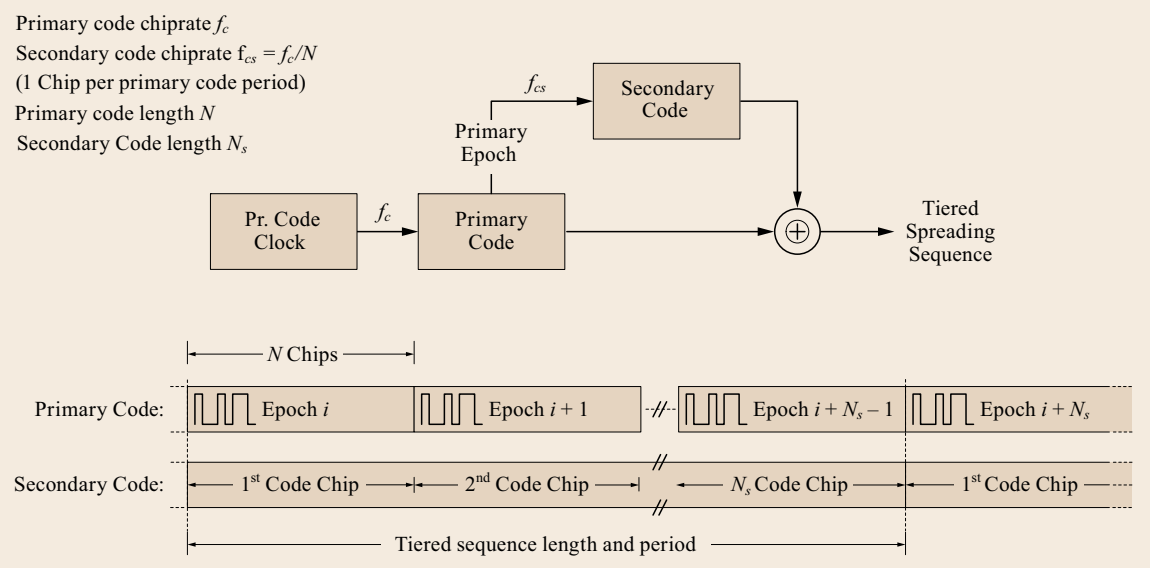

**Fig. 9.8** Principle of the tiered code construction

may not contain hexadecimal representations of the memory codes.

### 9.2.2 Navigation Message and Services

Three different types of public navigation messages are provided through the Galileo navigation signals: the high data rate and short page length I/NAV (historically derived from Integrity NAVigation message), the low data rate F/NAV (Free NAVigation message) and the fast C/NAV Commercial channel NAVigation message. The message types are assigned to signal components as described in Table 9.6. The OS SIS ICD [9.11] and its annexes and associated support documents serve as reference documentation for these message types. OS SIS ICD [9.11] will be gradually extended and amended with new content, following service deployment and the progress of system validation. This section will thus reference to [9.11] and otherwise focus on receiver relevant differences and specifics.

The content of the navigation messages can be roughly differentiated into position/velocity/time (PVT) relevant content, which is mostly repetitive, and nonrepetitive low latency message elements.

Both I/NAV and F/NAV provide direct support to PVT determination, through provision of GST in the form of week number (WN) and time of week (TOW), and of ephemeris and clock correction for the transmitting satellite, but also through ionosphere model parameters, bias group delay information needed for single-frequency users, data validity and signal health flags, almanac and other supplementary information. The fundamentals of ephemeris, clock correction, GST-UTC, almanacs and usage algorithms are consistent with GPS legacy definitions, with format adjustments to Galileo. The ionosphere correction message uses a Galileo-adapted version of the more recent NeQuick model. The detailed user algorithm reference model will be published as annex [9.18] to [9.11].

For low-latency content, I/NAV on E1 includes the return link channel supporting the Cospas-Sarsat search-and-rescue (SAR) system [9.8–10]. This return link is a near-real-time channel for short messages to SAR beacons equipped with a Galileo navigation receiver. Further low latency channels are embedded into the I/NAV message but are not yet formally published, being considered a functional reserve of the Galileo navigation message for future development. In case such low-latency channels are influencing and altering the flow of the message data stream, these changes need to be known to receivers and to be considered already now. One example is I/NAV on E1 and on E5b, which includes capabilities to replace nominal transmissions on a per second basis with one-time low-latency short message pages [9.11]. Despite these messages not being brought into use yet, receivers will need to be robust against such insertions as they may appear in future.

The C/NAV data stream on E6 is also implemented as a near-real-time message stream with short latency. At the time of writing C/NAV applications are under development [9.19] and no content is published yet.

All low-latency data channels are served only from satellites with active uplink from the Galileo ground segment. Their data content can differ between different satellites.

The content of I/NAV and F/NAV messages is compatible with almanac, ephemeris information, GST-UTC and GST-GPS time conversions. Clock correction parameters of I/NAV and F/NAV messages are specific per message type, and are expected to be very similar but are not guaranteed to be identical. This difference is the result of Galileo being a native multifrequency system, where both I/NAV and F/NAV messages are being optimized for specific pairs of frequencies. The I/NAV message, especially its clock correction, is calculated for dual-frequency reception of E1 and E5b, and F/NAV is optimized for the dual-frequency reception of E1 and E5a. As a result the ephemeris and clock corrections provided in F/NAV and I/NAV messages are directly applicable for dual-frequency receivers of the above frequency pairs. Any single-frequency receiver needs to use the bias group delay correction provided within the assigned message type to adjust the clock correction for the single frequency to be measured. Figure 9.9 illustrates this rule.

None of the messages published so far supports PVT using E6 measurements or triple-carrier measurements. Such content could be envisaged to be provided in the C/NAV message as future services or through external sources and communication channels.

**Table 9.6** Message content coverage

| Message type | Component | Content | | |
|---|---|---|---|---|
| | | Positioning | Search and Rescue | Supplementary |
| F/NAV | E5a-I | ✓ | | |
| I/NAV | E1-B | ✓ | ✓ | Individual low latency content |
| | E5b-I | ✓ | | Individual low latency content |
| C/NAV | E6-B | | | C/NAV low latency content |

### Message Timeline and Structure

All Galileo message streams are structured in *pages* as the smallest interpretable data blocks. For F/NAV and C/NAV each page consists of a predefined set of synchronization symbols followed by the rate-1/2 convolutional encoded and cyclic redundancy check (CRC)-protected block of information. One F/NAV page lasts for 10 sec and provides 238 bits of effective information, exclusive of sync and tail symbols. I/NAV transmits data pages in two consecutive blocks, namely the *odd* and *even* words. Each word starts with the I/NAV synchronization symbols followed by a block-encoded data field, and lasts one second. A full I/NAV page (*odd* and *even* words combined) takes two seconds for transmission and provides a usable capacity of 245 bits, exclusive of sync and tail symbols.

The sequence of pages as transmitted from each satellite is organized such that the information required for PVT is provided within a well-defined maximum interval of time. Parts of information with less or no direct relevance for PVT and with longer validity, for example almanacs, are distributed over longer intervals. Figure 9.10 illustrates the concept for F/NAV.

It needs to be noted that [9.11] provides these structures for information with several reservations on possible changes and evolutions, intended to preserve some space for possible future improvement and extensions of the navigation message. Modulation up to symbol level will not change, and existing pages will not disappear. Backward compatibility for legacy receivers will be maintained. But new features may be gradually introduced, using the available degrees of freedom and spare room of parameters like page type identifiers. User receiver designers are asked to consider these reservations appropriately. Some examples are:

1. The nominal sequence of pages as described in [9.11] is not to be relied upon, but may change in the future. This implies that the page sequence may not be the same for all active satellites within a Galileo constellation. The receivers need instead to identify received pages by their page type identifier.
2. The relative timing between I/NAV pages in E1 and in E5b may change, for example through the above changes of page sequences.
3. New page types may be introduced. This will not degrade the PVT quality achievable with legacy data content. However, receivers are expected to react to page types not known to them in a well-controlled manner. Similarly, other spare space in identifier value ranges may be explored and combined with new definitions of data content, for example almanacs for space vehicle identifiers (SVIDs) outside the currently defined range.

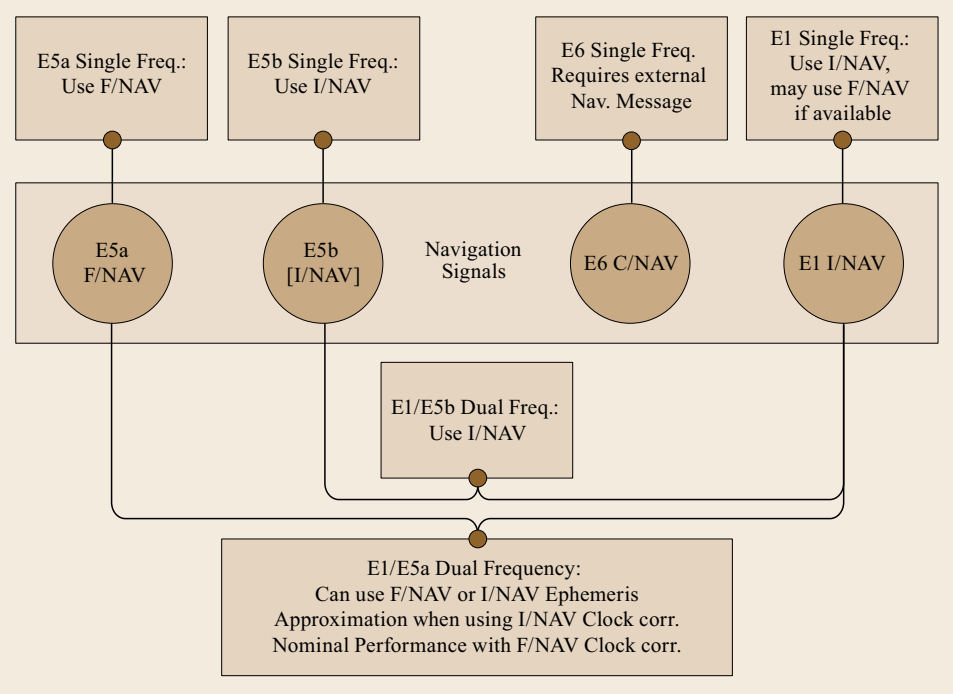

**Fig. 9.9** Rules of use of Galileo navigation messages for PVT

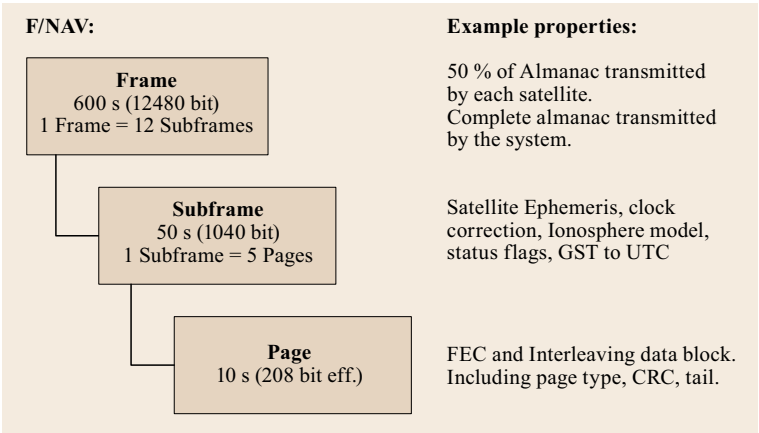

**Fig. 9.10** F/NAV page transmission planning

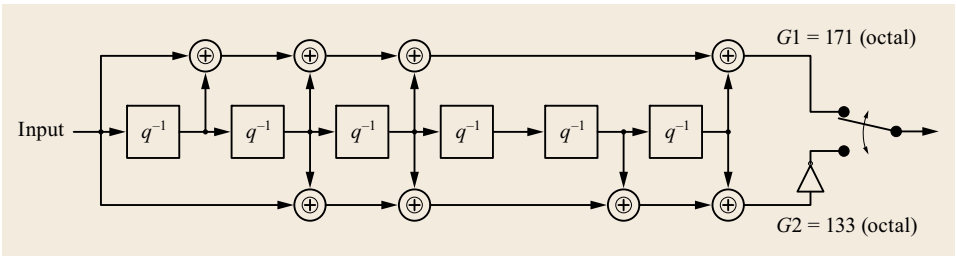

**Fig. 9.11** Galileo FEC encoder

4. There will always be studies and discussions on more caveats to be considered, to reserve further headroom for message evolution. As an example, receivers can be expected to be robust against segments of unknown symbol sequences and failing standard forward error correction (FEC) decoding, as would follow from special page formats, for example with modified effective symbol rates and FEC. It can be assumed that such evolutions will be limited to symbol-level encoding up to message level. Unquestioned baselines of all such discussions is always that modulations are not changed, and existing message content will continue to be provided, such that legacy receivers are not disabled.

#### Forward Error Correction Coding (FEC) and Block Interleaving

Galileo data components employ a well-established low computational effort rate-1/2 Viterbi forward error correcting coding with constraint length 7 to improve message transmission robustness. The encoder polynomials are identical to the GPS L5 civil navigation message (CNAV) encoder, but Galileo applies an additional inversion to the output of the G2 polynomial, to ensure that continuous zero inputs do not create a constant symbol output (Fig. 9.11). Encoding comprises always pages or half pages of the navigation message as independent data blocks without overlaps with earlier or later blocks.

The combination of convolutional encoding with a blockwise concept requires the consideration of *constraint length − 1* predefined tail bits to provide FEC protection for the complete information content of each navigation page; tail-free convolutional encoding, for example tail biting, was not implemented due to potential patent or infliction of intellectual property rights.

Each block is subject to block interleaving using blocks with eight rows and a number of columns according to the page size in symbols (Fig. 9.12), supporting the textual representation in [9.11].

This ensures that burst errors of the channel are deinterleaved to at least eight symbols distance between single symbol errors at the decoder input, supporting the FEC decoder to correct such errors.

### 9.2.3 Ranging Performance

The Galileo ranging performance and consequently also positioning performance is driven by three groups of error contributions originating from the Galileo system, the environment and the user receiver.

The Galileo user equivalent range error (UERE) budget considers all key contributors as a function of satellite elevation:

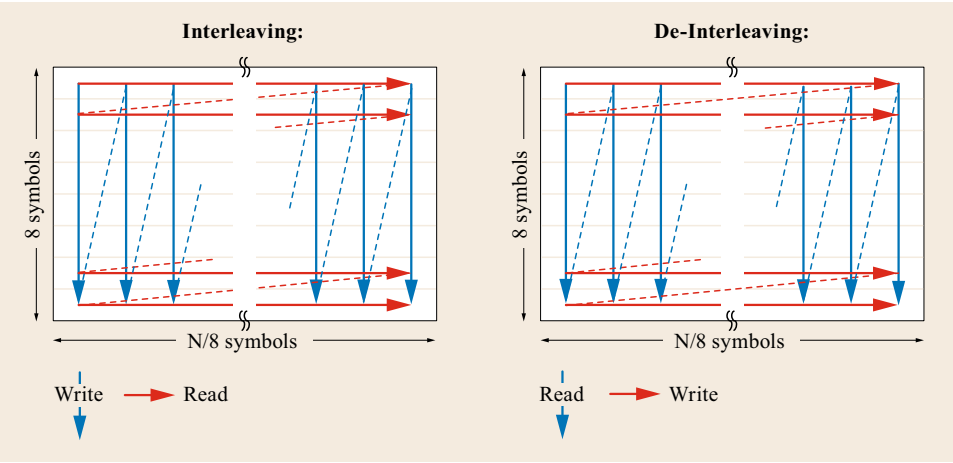

**Fig. 9.12** Galileo message interleaving and de-interleaving

1. Ionospheric error: residual error due to the imperfection of the ionosphere model as provided in the navigation message, used to correct for ionospheric delays (only for single-frequency users)
2. Tropospheric error: residual error due to the imperfection of the model used to estimate the tropospheric delays. Models like Saastamoinen [9.20] combined with International Telecommunication Union (ITU)-R P.835-3, -4 will easily fulfill the assumptions reflected in Table 9.7
3. Interference, multipath, receiver thermal noise error: errors in the user receiver equipment due to *local* effects on code error, such as thermal noise, radio frequency interference and multipath
4. Orbit determination and time synchronization error: error caused by imperfections in the system-provided reference data (ephemeris and clock correction) for the computation of the satellite orbits and clocks at user level
5. Broadcast group delay (BGD) error: residual error due to the imperfection of the correction for transmitter delay differences between carriers (only relevant for single-frequency users).

Table 9.7 provides indicative root mean square (RMS) magnitudes of the error contributions expected to be achieved for the Galileo Open Service (OS) once the system has reached full operational capability. The values are valid for satellites at medium elevations around 45 degrees, at the maximum operational age of data.

The total UERE for a specific user and its environment combined with the local reception geometry, expressed for example through the dilution of precision (DOP), can be used to estimate the user position accuracy.

**Table 9.7** Indicative root mean square (RMS) magnitudes of the Galileo user equivalent range error (UERE) contributions

| UERE Contributor | Single Frequency user | Dual Frequency user |
|---|---|---|
| Residual ionosphere error | < 500 cm | ≈ 5 cm |
| Residual troposphere error | < 50 cm | < 50 cm |
| Thermal noise, interference, random multipath and multipath bias error | < 70 cm | < 100 cm |
| Orbit determination and time synchronization error | ≈ 65 cm | ≈ 65 cm |
| Satellite broadcast group delay | ≈ 35 cm | 0 |
| **Total (RMS)** | **< 513 cm** | **< 130 cm** |

Galileo comprises a worldwide network of initially 16 sensor stations to collect the ranging measurements required to generate the navigation message. The number of stations and their distribution accounts for eventual temporary sensor station and network outages. This ensures the required level of ground network robustness and performance as needed for the provision of nominal ranging, position and timing accuracy.

The Galileo system has been designed with position accuracy targets for E1/E5 dual-frequency Open Service users set to 4 m (95%) horizontal and 8 m (95%) vertical. The ranging accuracy considered necessary to reach these accuracy targets is 130 cm (95%). These targets are used to benchmark the performance predictions and to determine the expected availability of the service accuracy. Figure 9.13 provides global-scale simulated *expected performance* for an Open Service dual-frequency Galileo-only users in the vertical and horizontal position domain with 99.5% availability according to the above benchmark thresholds.

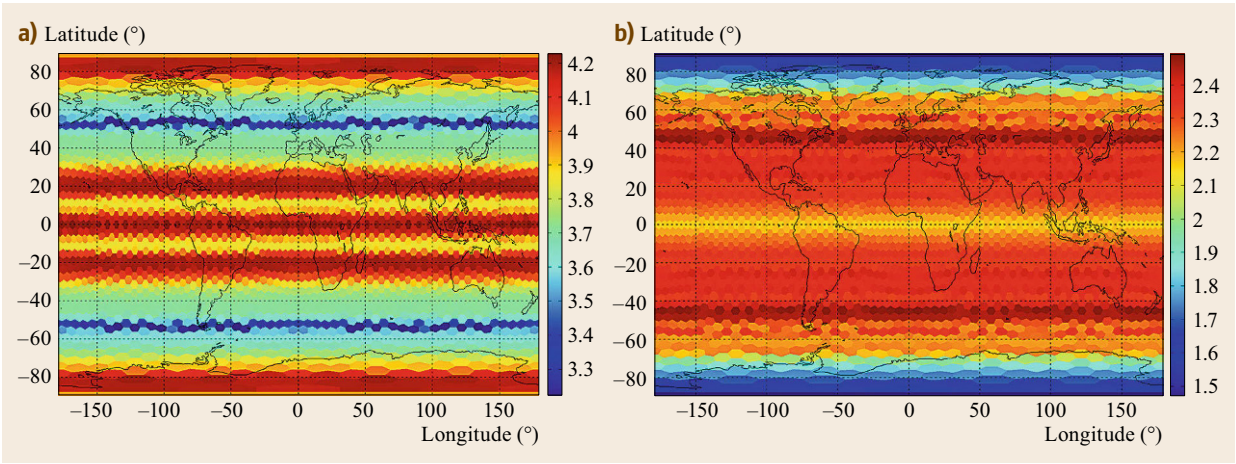

**Fig. 9.13a,b** Simulation of expected performance (color-coded positioning error in meters) for an Open Service dual-frequency Galileo-only user in the vertical **(a)** and horizontal **(b)** position domain with 99.5% availability

### Orbit and Clock Errors

As for most radio navigation satellite systems, the basic information generated by the Galileo system for provision to users are orbit and clock correction for each satellite. The mission ground segment *estimates*, *predicts* and *parametrizes* this information into the navigation message. The message is then *uplinked* to the satellites and *disseminated* to the user through the navigation signals.

Clock and orbits are *estimated* by the orbit determination and time synchronization (ODTS) process, which operates as a least-squares estimator on data batches, operationally running every 10 min. Observation data used for this estimation process are always dual-frequency pairs of measurements:

- E1-E5a observables for F/NAV products
- E1-E5b observables for I/NAV products
- E1-E6 observables for PRS products.

Once estimated, clocks and orbits are *predicted* for the time interval for which the navigation message is to be generated. The reference time of these predictions is located at the beginning of each prediction interval. The result is subsequently *parameterized* and formatted into navigation messages, and finally disseminated to the user. Users will observe a difference (*age of data*) between reference time and time of use of the message. The signal-in-space error (SISE) at the user age of data, that is the imperfection of clock and orbit parameters when applied by the user, determines the ranging performance.

Stability and predictability of the satellite payload implementation, and especially the onboard clock system, is a major contribution to SISE. For this reason the quality of clock and orbit estimations is validated systematically. A specifically interesting time for such measurements are the in-orbit tests (IOTs) following each satellite launch. During these periods all clocks on board can be operated, even if only for a limited time, and can be observed.

A selection of typical results for RMS clock prediction errors (clock predictability) is shown in Fig. 9.14, as a function of the prediction interval. The prediction model used is a second-order polynomial, equivalent to the clock correction within the navigation message, but in high numerical resolution and therefore without parameter quantization effects. Figure 9.14 is intended to show clock quality as much as possible isolated from other contributions. Therefore the clock estima-

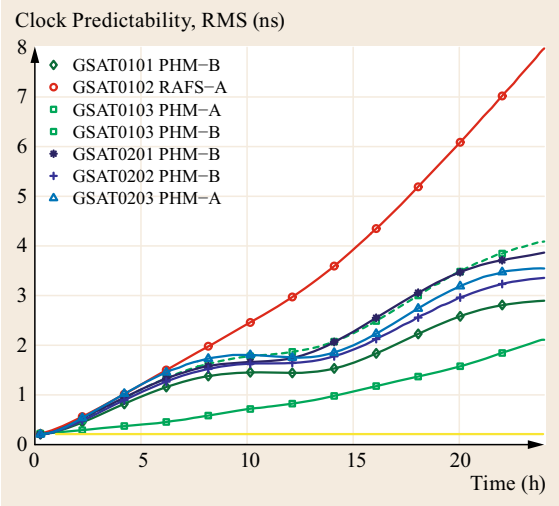

**Fig. 9.14** RMS clock predictability for typical Galileo passive hydrogen maser (PHM) and RAFS

tion used originates from an independent verification system based not only on Galileo sensor stations but also including other project internal sensor stations, otherwise used for verification purposes, and sensor stations of the Multi-GNSS Experiment (MGEX), which is maintained by the International GNSS Service (IGS). A highly stable active maser independent of the Galileo system is used as ground time reference. The vertical bias for very short prediction intervals indicates the measurement noise of the input data as used for the analysis and the resulting model fitting error. Only one rubidium atomic frequency standard (RAFS) is shown, but its behavior is quite representative for the typical predictability of the GSAT010x and GSAT02xx RAFS. The difference between RAFS and passive hydrogen maser (PHM) predictability is clearly visible, especially for longer prediction intervals. The PHM quality and predictability is such that orbit determination imperfections can still be recognized, despite the offline processing using a larger database than available to the system itself.

Each satellite operates two clocks in parallel, nominally one PHM as a master clock and one RAFS as a hot redundant backup. In normal operation the ground segment commands switches between clocks, for example due to maintenance or, eventually, due to failures. Expectation is that at the time of switching to a backup clock, this clock has been in operation already for a prolonged time as a hot redundant clock. Thus its performance will have stabilized and settled, and the switch can be performed with minimum impact on service provision. Planned switches have meanwhile been exercised seamlessly, that is without interrupting service provision from the affected satellite.

Following established practice the ephemeris and clock correction message is generated with respect to a common reference point (apparent center of phase) geometrically close to the frequency-dependent individual centers of phase of the navigation transmit antenna. The user computes the position of this common reference point as a function of GST [9.11]. The vector from satellite center of mass to antenna reference point will be considered for possible publication, following validation.

Galileo establishes its own Galileo Terrestrial Reference Frame (GTRF), to which the above orbit and clock errors are referring. The GTRF is aligned to the International terrestrial reference frame (ITRF) with respect to origin, scale, orientation and rate, such as to remain within 3 cm (2-sigma) of the ITRF.

### Ionospheric Error and Broadcast Group Delay

The ionospheric model parameters include the broadcast coefficients $a_{i0}$, $a_{i1}$, and $a_{i2}$ used to compute the effective ionisation level Az, and the *ionospheric disturbance flags* (also referred as *storm flags*), provided for five different regions.

The ionospheric algorithm for single-frequency users is based on an adaptation of the three-dimensional (3-D) empirical climatological electron density model NeQuick [9.21–23].

The performance of the Galileo NeQuickG model is regularly evaluated. An early but still valid result was measured during the IOV campaign (March to August 2013) [9.21, 24]. The achieved residual error as measured was already reaching expectations for the full operational constellation of Galileo, and was better than the GPS Klobuchar model especially at equatorial latitudes. The global absolute ionospheric error $(1-\sigma)$ for the reported period was 1.34 m RMS achieved with the NeQuickG model and 1.9 m RMS with Klobuchar model. The absolute difference at equatorial latitudes expands to well beyond 1 m.

An example level of correction and comparison of NeQuickG and Klobuchar model results is provided in Fig. 9.15 for 21 May 2015, close to the vernal equinox and the seasonal ionosphere maximum. The performance was measured with receivers in the marked locations (more than 100 stations). From white to green the achieved ionospheric error correction capability was at least 70% RMS or better. Red color markings indicate a correction performance lower than 70%. This result is computed following the description in [9.25], and is in line with these earlier observations.

Similar to other GNSSs, the Galileo clock corrections are generated for dual-frequency users, and single-frequency users will need to use the broadcast group delay BGD($f_1, f_2$) provided through the Galileo navigation message as an additional correction. BGD($f_1, f_2$) is defined as follows

$$\mathrm{BGD}(f_1, f_2) = \frac{\mathrm{TR}_1 - \mathrm{TR}_2}{1 - \left(\frac{f_1}{f_2}\right)^2}\,, \tag{9.4}$$

where $f_1$ and $f_2$ are the carrier frequencies of the involved Galileo signals 1 and 2, while $\mathrm{TR}_1 - \mathrm{TR}_2$ is the delay difference of the signals as contributed by the satellite payload. This formulation allows for easy translation of the dual-frequency clock correction information from the navigation message when using only a single-frequency receiver [9.11]. BGD accuracy was characterized, for example during the IOV campaign, and was found to be as expected around 30 cm. It is noted that BGD does not distinguish between pilot and data components. The ground segment measures BGD on the pilot components of the associated dual-frequency combination. The data components are

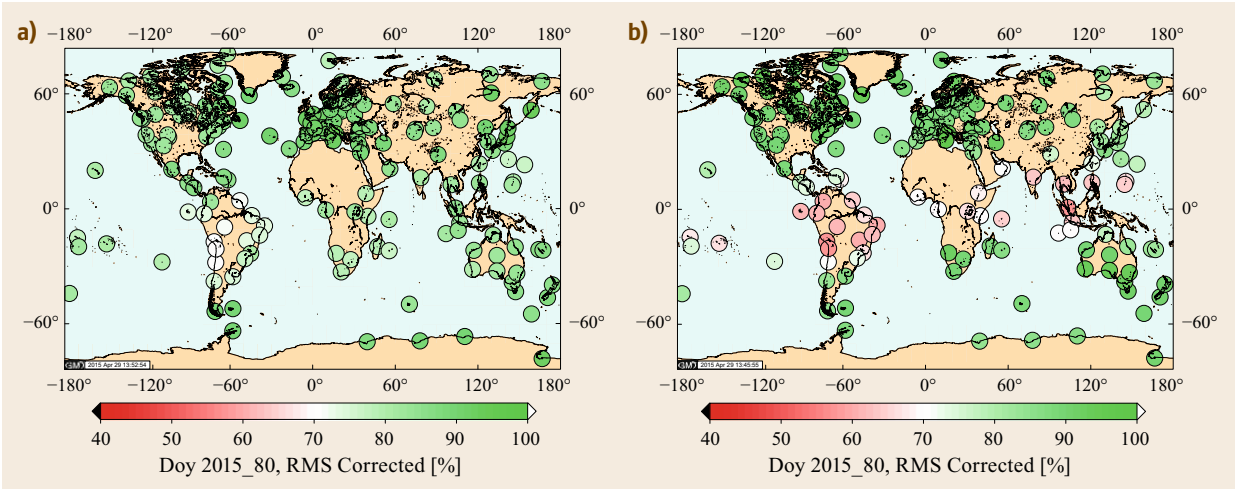

**Fig. 9.15a,b** Level of ionospheric correction and comparison of Galileo NeQuick G model (a) versus GPS Klobuchar model (b) for 21 May 2015

nearly identical to their pilot counterparts, in spectrum and modulation, and the method of signal generation on board ensures that tracking offsets between a data component and its pilot counterpart remain within a few cm, an order of magnitude smaller than BGD accuracy.

### Message Uplink and Dissemination

The navigation message information is routinely generated by the orbitography and synchronization processing facility (OSPF) at intervals of 10 min. To decrease parameterization and quantization errors, the navigation message is generated in sets of eight batches, each batch marked through individual and unique issue of data (IOD) values. Subsets consisting of the first four batches are uploaded through mission uplink contacts and stored on board, using always the latest available sets. During the duration of mission uplink connections to each satellite, the message information broadcast from this satellite will thus also update approximately every 10 min, and the user is provided with the most recent and up-to-date navigation information. Between mission uplinks the satellites operate on the sets stored on board, broadcasting each message batch until it reaches a configured age of, for example, 180 min. Then the satellite selects the next message batch for dissemination, and will so step through the message batches in storage. In this example the broadcast of batches 2, 3, and 4 would start 3, 6, and 9 hours after the last mission uplink.

Navigation message batches can also be uplinked via telemetry, tracking and commanding (TT&C) stations. These uplinks can provide all batches 1–8 of a set, which allows longer operation on stored batches. In the above example, batches 5–8 would become valid 12, 15, 18, 21 hours after the last uplink contact. If there are no uplinks for intervals longer than the example 21 hours, the last message will be continuously transmitted regardless of its age.

In nominal operation the mission uplinks to the Galileo satellites will be scheduled tightly, for example such that the age of the onboard navigation message does not exceed 100 min, in support of using RAFS as master clocks. While using PHM master clocks the time between uplinks can then be extended.

These constraints need to be taken into account for sizing and location of the uplink station network. Accordingly, plans are for at least five uplink stations, where each station can operate up to four uplink antennas. This allows the supply of the complete Galileo constellation with timely navigation message data.

The broadcast of valid Galileo navigation messages started 12 March 2013, using the first four Galileo satellites, and then allowed for the first Galileo autonomous position fix [9.26].

### Open Service Position and Ranging Error Accuracy

Position accuracy is monitored regularly. Receiver determined position solutions at user level, obtained in 2013 during periods with at least four Galileo satellites in visibility, are reported in [9.24], and since then the continuous deployment of the constellation and ground segment has led to the expected improvements. Position solutions collected in February 2016 are shown in Fig. 9.16, covering one 10 day ground track repeat cycle of the Galileo constellation. The position fixes were achieved through a dual-frequency E1b-E5a receiver

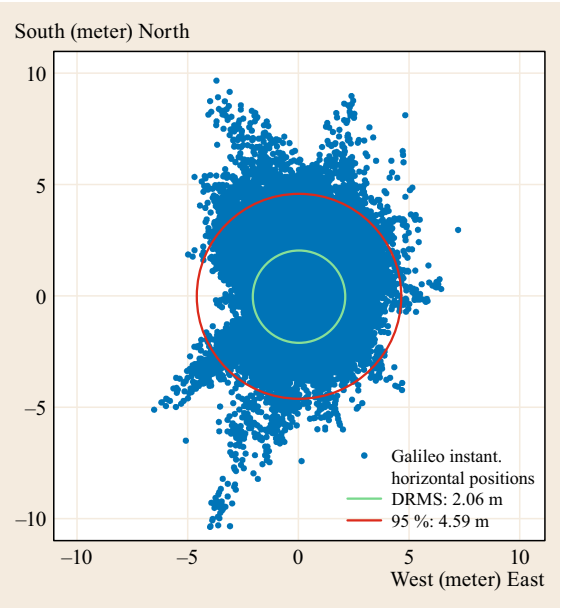

**Fig. 9.16** Horizontal position accuracy at end-user level, Noordwijk, February 2016

where the geometry has been constrained for a geometric dilution of precision (PDOP) better or equal to 5. The measured horizontal accuracy shown in this example is well within expectations, exhibiting here less than 5 m 95% (green circle in Fig. 9.16).

These position results include the effect of dilution of precision, which is still not at nominal level due to the limited number of satellites available at the time of measurement.

The ranging accuracy is a figure of merit describing system performance per signal, before dilution of precision comes into effect. For example, SISE is derived by combining clock and orbit errors projected into the user direction. Its history during the project phases reflects the progress of system deployment and tuning. During IOV in 2013 only four satellites were available, and the ground segment was using only a subset of sensor stations. This initial validation achieved SISE results around 1.3 m 67%. In 2014 the SISE performance was approximately 1.0 m 67%, while in 2015, following the update of the ground segment, a SISE of 0.69 m 67% has been reached.

## 9.2.4 Timing Accuracy

The Galileo internal reference time is the Galileo System Time (GST), and is linked to Universal Time Coordinated (UTC). The navigation message provides GST-UTC information to allow estimation of UTC as an international time reference. To support interoperability with GPS, Galileo also provides the measured GPS-to-Galileo time offset (GGTO).

### System Time Generation

GST is a continuous coordinate time scale in a geocentric reference frame, steered towards UTC modulo 1 second. GST is not subjected to leap seconds.

GST is used as reference time throughout all Galileo system facilities, ground station and satellite clocks.

The broadcast navigation message is time-tagged with GST and provides GST as a 32-bit binary field composed of Galileo week number (WN) and time of week (ToW) [9.11].

The initial epoch of GST is defined to be 00:00 UTC on Sunday 22nd August 1999. This corresponds to the last rollover of the GPS week number. The offset between GST and UTC at the initial epoch is defined as 13 seconds. The GST-UTC offset is changing with the introduction of new leap seconds. This definition is a contribution to GPS-Galileo interoperability insofar as GST has zero integer seconds offset to GPS Time.

The Galileo Time Service Provider (GTSP) links GST to UTC, through selected European timing laboratories, and provides the required frequency steering correction such that GST can be steered to UTC within 50 ns 95% modulo 1 s. The GTSP also provides the GST-UTC offset and the leap second announcements.

GST is generated by the Galileo Ground Mission Segment based on the atomic clocks of the Galileo Precise Time Facility (PTF). Galileo uses two redundant PTFs, one in each of the two control centers in Fucino, Italy and in Oberpfaffenhofen, Germany. Each PTF is equipped with two active hydrogen masers in hot-redundant configuration, and with four high-performance Cesium clocks. The physical realization of GST is defined as the maser output, steered to UTC modulo 1 second according to the GTSP steering corrections.

The quality of GST steering towards UTC is demonstrated for example through a collaboration with several European timing laboratories, comprising Istituto Nazionale di Ricerca Metrologica (Italy), National Physical Laboratory (UK), Observatoire de Paris (France), Physikalisch-Technische Bundesanstalt (Germany), Real Instituto y Observatorio de la Armada (Spain), and Swedish National Testing and Research Institute (Sweden). Already the early verification in 2013 demonstrated very good alignment and stability [9.27]. The subsequent monitoring confirms this steering quality, during all deployment stages of the related subsystems. Figure 9.17 shows an example measurement covering the period from 1 January 2014 to 31 May 2014. In this period the offset UTC – GST be-

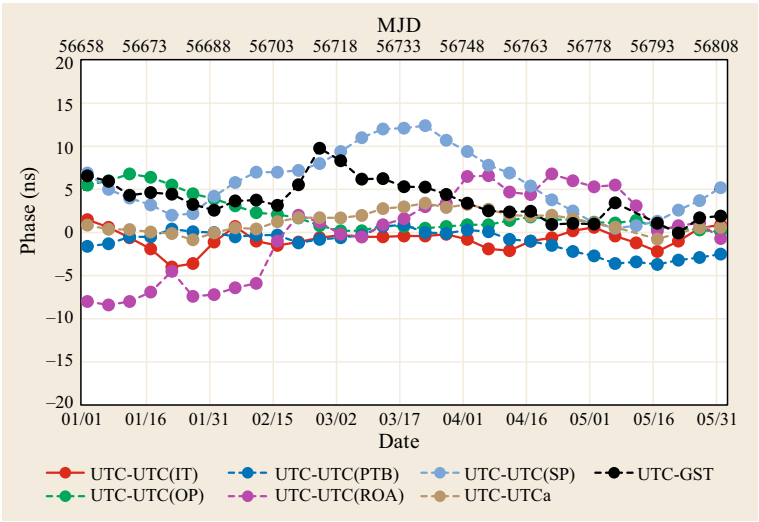

**Fig. 9.17** GST versus UTC offset, relative to European timing laboratories; results from January to May 2014

tween the GST physical realization and UTC remains well within 10 ns, and the behavior of GST relative to UTC is quite similar to the evolution of the UTC offsets of the involved timing laboratories.

### UTC Dissemination

In accordance with ITU Recommendation TF.460-6 [9.28], Galileo disseminates Universal Time Coordinated. For this purpose the Galileo navigation message contains GST-UTC conversion parameters including the total number of leap seconds (i. e., GST-UTC integer offset), announcement of introduction of new leap seconds with the associated date, fractional GST-UTC offset, and slope. Galileo users estimate GST from the broadcast navigation signals, then use the GST-UTC conversion parameters from the navigation message to estimate UTC for their applications. The GST-UTC conversion parameters are generated by the GTSP and updated daily.

The achievable Galileo UTC dissemination performance is being monitored by the Timing Validation Facility, a test and validation facility developed by ESA. Figure 9.18 shows the GST offset to UTC as disseminated by Galileo (UTC(SIS)) versus the rapid UTC solution, an official product of the Bureau International des Poids et Mesures (BIPM) closely approximating UTC. During the reported period May to September 2015 the UTC dissemination error was already well within expectations, but shows minor side effects and improvements in stability and offset due to ongoing calibration and equipment deployment.

### GGTO Dissemination

GPS and Galileo system times are derived independently from each other. Both are kept aligned to UTC

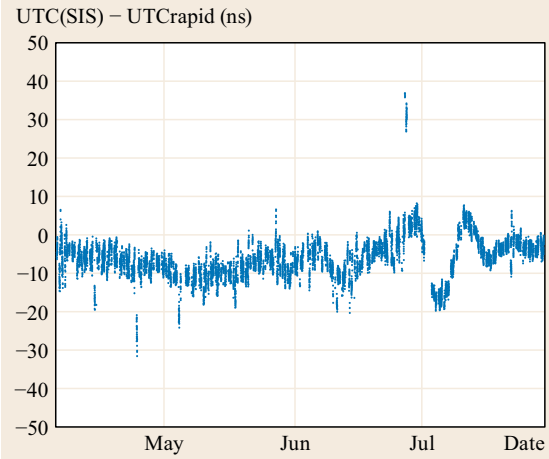

**Fig. 9.18** Offset of UTC as disseminated by Galileo (UTC(SIS)) versus rapid UTC solution in 2015

within their respective GNSS. The Galileo PTF measures the offset between both system times and determines the GPS-to-Galileo time offset (GGTO), defined as the difference between the Galileo and GPS timescales, $\mathrm{GGTO} = t_{\mathrm{Galileo}} - t_{\mathrm{GPS}}$ [9.29–31]. GGTO is then distributed through Galileo's navigation message [9.11] to support combined use of Galileo and GPS systems. The provision of GGTO is expected to benefit user receivers in situations with obstructed field of view and limited numbers of visible satellites from a mixed constellation, can support integrity monitoring, and can support receiver internal calibration.

GPS has been chosen as the reference due to being the best established GNSS at the time. Currently Galileo does not provide offsets to other GNSS than

GPS. If all GNSS would provide their time offset relative to the same common reference, then a receiver could determine all required offsets for using any combination of measurements from mixed constellations for PVT computation. There would be no functional need to provide multiple offsets to different GNSSs within each navigation message. However, if this common reference would fail, all related and derived offsets may degrade or become unavailable. If the approach of a common reference were chosen, at least two independent references are recommended for use and the respective deltas to be provided through the navigation message(s). UTC may be one, and a selected GNSS the other.

Figure 9.19 shows an example measurement of the difference between broadcast GGTO and a posteriori measured GGTO, in August/September 2015.

During the IOV phase, the broadcast GGTO parameters were computed based on time transfer between the Galileo Precise Time Facility and the US Naval Observatory. In the completed Galileo ground segment the GGTO is being measured using calibrated Galileo-GPS receivers, which will improve the accuracy of this parameter.

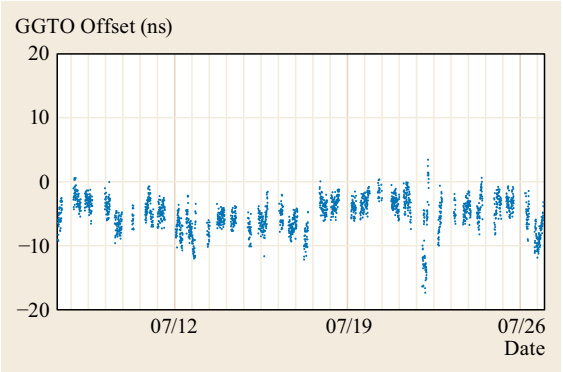

**Fig. 9.19** Deviation of broadcast GGTO from measured GGTO in the period 25 November – 6 December 2013

## 9.3 Spacecraft

Galileo satellites are 700 kg/1500 W class spacecraft (Fig. 9.20, [9.32]). The first Galileo satellites GSAT0101…0104 were manufactured by EADS Astrium GmbH as satellite prime, and launched in pairs: a first dual launch to orbital plane A on 21 October 2011, followed by a dual launch to plane B on 12 October 2012.

The next family of Galileo satellites GSAT02xx is being manufactured by OHB System AG in Bremen, Germany, as prime [9.33]. A total of 22 satellites will be produced under this order. The first dual launch of this family in August 2014 was impaired by a malfunction in the Fregat stage of the Soyuz launcher, and the satellites GSAT0201 and -0202 were placed into a nonnominal elliptic orbit. In 2015 their orbits were corrected as far as possible using the onboard resources. The navigation payloads were then activated and tested, to validate technology and performance, and the satellites since then broadcast navigation signals and are used for clock technology validation. Since nominal orbits were not reached these satellites cannot be accommodated in parts of the navigation message. GSAT0201 and -0202 are however healthy, and ESA is working to incorporate these satellites into the ground processing. The follow-

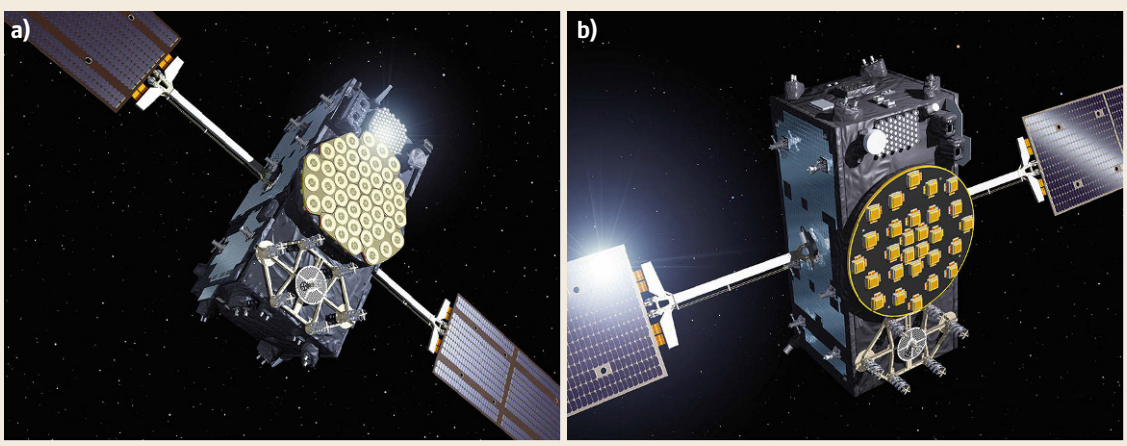

**Fig. 9.20a,b** Galileo satellites (artistic pictures, **(a)** GSAT010x, **(b)** GSAT02xx), (courtesy of ESA/P. Carril)

ing dual launches in March 2015, September 2015 and December 2015 reached the foreseen orbits, and the satellites became part of the nominal constellation.

### 9.3.1 Satellite Platform

A Galileo satellite can be partitioned into the classical components of a satellite design, that is platform (Table 9.8) and payload. The platform then comprises further subsystems for onboard data handling and control, attitude and orbit control including propulsion, power generation and distribution, thermal control, telemetry, and a laser retro reflector.

The attitude and orbit control system (AOCS) of the Galileo satellites is using three-axis attitude control during all phases and maneuvers [9.34] Several operational modes are derived to support the mission sequence of events:

1. During the launch and early orbit phase (LEOP) as well as in contingency situations and safe modes, dedicated acquisition modes are used for Earth or Sun acquisition.
2. Orbit acquisition, station-keeping maneuvers, and end-of-life (EOL) decommissioning can use a dedicated orbit change mode. According to the Galileo orbit design very limited need of station-keeping maneuvers is anticipated [9.1, 6].
3. Normal mode is the nominal operational mode with full nadir pointing performance. This mode uses yaw steering to orient the solar panels towards the Sun, and to support the thermal control of the satellite.

In normal mode, the AOCS sensor/actuator configuration is based on Earth and Sun sensors for keeping the satellite pointed at Earth: the infrared Earth sensors detect the temperature contrast between the cold of deep space and the warmth of Earth's atmosphere, while the Sun sensors are visible-light detectors measuring the angle to the Sun. Angular momentum provided through reaction wheels is used to control attitude and rotational rate. The satellite rotates twice per orbit, to facilitate Sun-pointing of the solar wings. The angular momentum gradually accumulated by the reaction wheels is unloaded through magnetorquers, magnetic coils controlled to deliver the needed torque through interaction with the Earth magnetic field. Gyros are available for additional rate sensing. In operational modes except the nominal mode, thrusters can be used for impulse and attitude control.

The propulsion subsystem is based on monopropellant thrusters. The propulsion subsystem is typically equipped with a set of eight thrusters. Each thruster provides, under beginning of life (BOL) conditions, a nominal thrust of 1 N using monopropellant-grade hydrazine. GSAT010x and -02xx are designed for direct injection into the final orbit, thus their propulsion subsystems need to provide only the delta-velocity capability needed for orbit correction maneuvers.

The power subsystem is responsible for the generation, storage conditioning and distribution of relevant power to the satellite. For the GSAT010x and -02xx families a classical regulated 50V bus architecture has been selected, which consists of

1. A power conditioning and distribution unit providing electrical power to all units on board the spacecraft
2. Two solar array wings supplying electrical power to the spacecraft during sun exposition and in parallel charging the battery after the eclipse phases
3. And a Li-Ion battery, storing the power provided by the solar arrays during the Sun phases and providing it during the eclipse phases.

The TT&C subsystem of GSAT010x and -02xx satellites is the link to the ground control segment by providing redundant command reception and telemetry transmission at S-Band. The TT&C subsystem operates in both ESA standard TT&C mode and spread spectrum mode. Accurate range-rate (Doppler) measurements are possible when the S-Band transponder is operated in coherent mode. S-Band TT&C operations are provided via hemispherical-coverage helix antennas situated on opposite sides of the satellite. Designed for orthogonal circular polarization, together they provide omnidirectional coverage for reception and transmission. Ranging operation is performed simultaneously with telemetry transmission.

The laser retro reflector (LRR) allows the measurement of the satellite's distance to within a few centimeters by reflecting a laser beam emitted from a ground station. The cat's eye reflector array of the LRR can be recognized on the Nadir panels of both Galileo satellite families shown in Fig. 9.20, just aside the navigation transmit antenna of the satellite. Laser ranging campaigns using the LRR are planned to be performed on average about once a year. In between the LRR campaigns, altitude measurements via S-band telemetry and telecommand link are used, which are sufficiently accurate to serve as intermediate measures.

### 9.3.2 Satellite Payload Description

The payload of Galileo satellites comprises a fully redundant triple-band navigation payload, and a SAR repeater [9.35].

The navigation payload can be functionally grouped into the mission uplink data handling system, a tim-

**Table 9.8** Overview of main satellite platform characteristics

| | GSAT010x | GSAT02xx |
|---|---|---|
| Satellites | 4 | 22 |
| Mass at launch | Approx. 700 kg | Approx. 715 kg |
| Size with solar array deployed | 2.7 m × 1.6 m × 14.5 m | 2.5 m × 1.1 m × 14.7 m |
| Design lifetime | 12 years | 12 years |
| Available power | 1.4 kW | 1.9 kW |

ing subsystem, and the signal generation and transmitter subsystem.

The mission uplink data handling system receives the navigation message data and all related support data, through a dedicated code division multiple access (CDMA)-type C-band uplink served by the uplink stations of the Galileo ground segment.

The timing subsystem generates the onboard frequency reference, derived from an atomic clock as reference. Two different types of onboard clock technology are deployed, that is a rubidium atomic frequency standard and a passive hydrogen maser as shown in Fig. 9.21. The navigation payload contains two units of each technology, four clocks in total. Nominally one clock is operated as master clock, and one clock is hot redundant spare. The interface between the four clocks and the navigation signal generator unit is provided by a dedicated clock monitoring and control unit, which is also used for synchronization of master clock and active spare clock [9.36, 37]. This allows the spare to take over seamlessly should the master clock fail.

The navigation payload provides navigation signals on three carriers E1, E6 and E5 in the lower L-band. The generation of all navigation signals and their components is strictly coherent to the common frequency reference from the timing subsystem. E5 offers a wideband AltBOC signal of more than 50 MHz bandwidth containing two BPSK(10) subcarriers 30.69 MHz apart, each providing a pilot/data pair. The open signals on E6 and E1 are BPSK- and BOC-type modulations offering 31–41 MHz usable bandwidth (Table 9.4). The navigation signals are radiated through a dual-band transmit antenna, using a common antenna subsystem for E5 and E6 [9.38, 39].

Stability of the onboard reference frequency is one of the core performance parameters for the quality of the navigation payload. Example Allan deviation (ADEV) measurements from mid-2015 are shown in Fig. 9.22, covering exemplary RAFS and PHM results of GSAT010x and GSAT02xx satellites. The typical performance of the two clock technologies is clearly discernible.

The search-and-rescue repeater provides enhanced distress localization functionality for the provision of a SAR service. It is part of the Cospas-Sarsat MEOSAR System, and is interoperable with other MEOSAR repeaters on Globalnaja Nawigazionnaja Sputnikowaja Sistema (Russian Global Navigation Satellite System) (GLONASS) and future GPS satellites [9.8–10]. The SAR transponder on Galileo satellites receives distress alerts in the 406.0–406.1 MHz band from any Cospas-

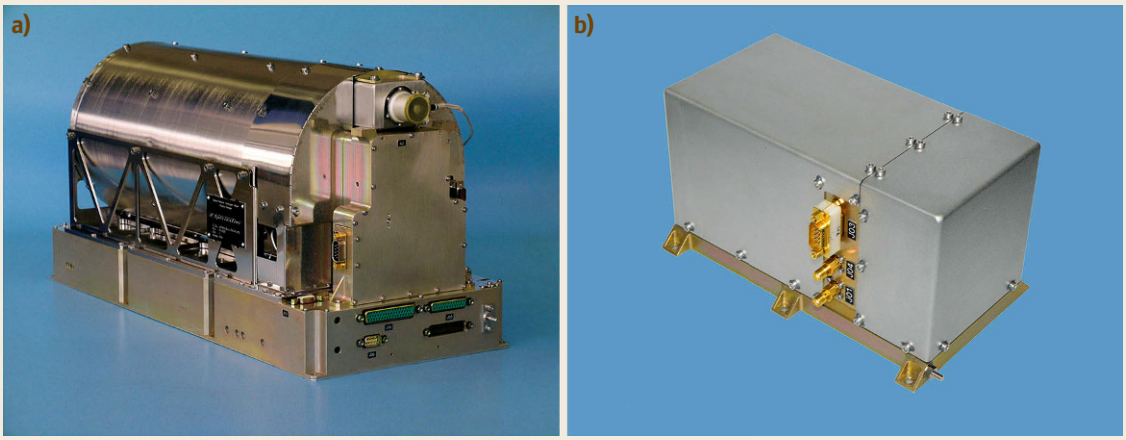

**Fig. 9.21a,b** Galileo passive hydrogen maser clock (a) and rubidium atomic frequency standard (b) (courtesy of Spectratime)

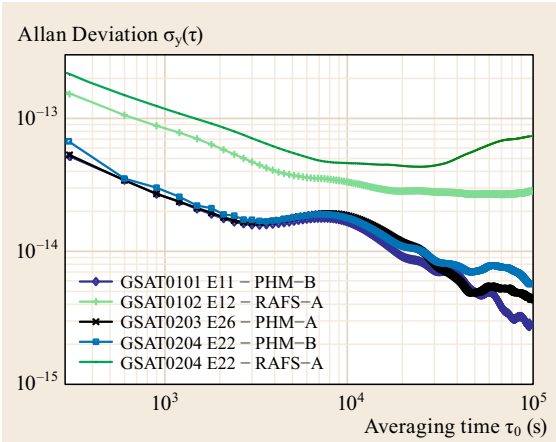

**Fig. 9.22** Galileo PHM and RAFS frequency stability in mid-2015

Sarsat beacon, translates them to the SAR downlink band at 1544 MHz and rebroadcasts this signal to dedicated ground stations, medium altitude Earth orbit (MEO) Local User Terminals, which perform beacon localization in near real time based on difference of arrival (DOS) measurements of time and frequency [9.40].

Galileo also provides a SAR return link service, initially foreseen to inform the alerting beacon and thus the distressed people that the distress message has been received by the Cospas-Sarsat system. This acknowledgment is embedded in the navigation message [9.41].

### 9.3.3 Launch Vehicles

Galileo satellites are launched from the Guiana Space Centre, Europe's Spaceport in French Guiana, using Soyuz and Ariane launchers. The first twelve satellites were using Soyuz launchers, in a series of dual launches on October 2011, October 2012 (Fig. 9.23), August 2014, and March, September and December 2015.

The Soyuz launcher is the workhorse of the Russian space program, in continuous production since the 1960s, and a descendant in design terms of the R-7 rocket that launched Sputnik 1 in 1957, inaugurating the Space Age.

Soyuz has performed more than 1700 manned and unmanned missions. It is designed to extremely high reliability levels for its use in manned missions – today supporting operations of the International Space Station. The launch of GSAT0201 and -0202 in August 2014 ending in a nonnominal orbit will therefore hopefully remain an exception.

For French Guiana launches, this three-stage rocket plus the Fregat upper stage is assembled horizontally in the traditional Russian approach, then moved to the vertical so that its payload can be mated from above in the standard European way. A new mobile launch gantry aids this process, while also protecting the satellites and the launcher from the humid tropical environment.

For Galileo, a specially designed dispenser holds the two IOV satellites in place side by side during launch and then releases them sideways into their final orbits.

**Fig. 9.23** Soyuz Launch Base at the European Space Port (CSG) French Guiana, ©ESA/S. Corvaja

A special version of the Soyuz launcher is also being used: the more powerful Soyuz ST-B variant, including a Fregat-MT upper stage, delivers the Galileo satellites into their final circular 23 222 km orbit.

The re-ignitable Fregat was previously used in its baseline version to deliver ESA's GIOVE-A and -B experimental satellites. Fregat-MT carries an additional 900 kg of propellant.

Alternatively a requalified Ariane 5 ES *Galileo* is available, able to deploy four Galileo satellites into MEO orbit. The first such fourfold launch is foreseen for the last quarter of 2016.

The Ariane 5 ES version is an evolution of the initial Ariane 5 generic launcher that has been upgraded to allow re-ignition and long coast phases. These capabilities are necessary to inject a cluster of four Galileo satellites into their operational orbit. Re-ignition is also required to vacate the injection orbit after releasing the payload, for graveyarding of the last launcher stage outside the nominal Galileo orbit.

## 9.4 Ground Segment

The Galileo ground segment (Fig. 9.24) comprises a Ground Control Segment (GCS) for satellite and constellation control, and a Ground Mission Segment (GMS) for service-related tasks.

The ground control segment performs all functions related to command and control of the satellite constellation. It includes a worldwide network of S-band TT&C stations hosted on Galileo remote sites, to provide global coverage.

The ground mission segment measures and monitors the Galileo navigation signals, computes the navigation message data and distributes it to the satellites. For this purpose the GMS includes two worldwide networks of stations:

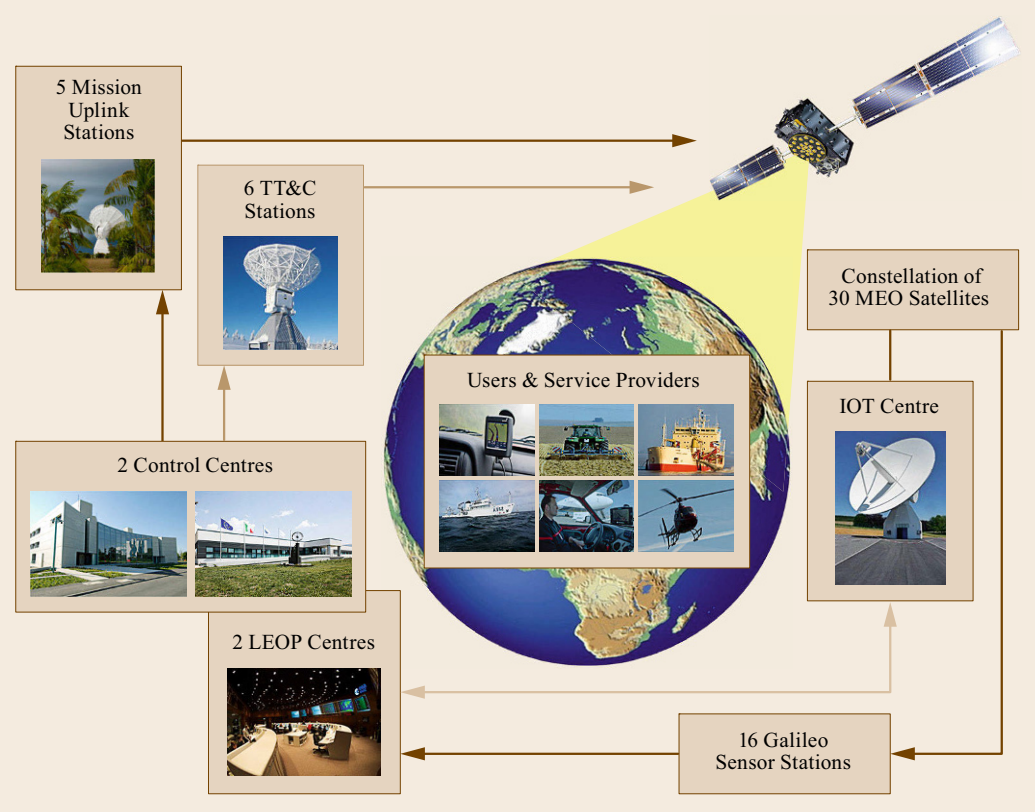

**Fig. 9.24** Galileo system overview (courtesy of ESA/M. Pedoussaut, ESA/S. Corvaja, ESA/J. Mai, ESA/J. Huart, DLR, Telespazio)

1. L-band Galileo sensor stations (GSS) to collect ranging measurements of the Galileo navigation signals, for orbit determination, time synchronization and monitoring of the signal in space
2. C-band uplink stations (ULS) to uplink mission data (e.g., ephemerides and clock prediction, SAR return link and commercial service data).

GCS and the GMS core facilities are deployed in two Galileo control centers (GCC) located in Oberpfaffenhofen (Germany) and Fucino (Italy). A global data dissemination network connects all ground facilities. In their final configuration both control centers and the data dissemination network will be redundant such as to ensure service and operations continuity.

Two additional launch and early operation (LEOP) control centers (LOCC) located in Toulouse (French Space Agency, CNES) and Darmstadt (ESA Operations Centre, ESOC) provide the necessary services to take control of the satellites after their separation from the launch vehicle and until they have reached their position within the assigned orbital slots.

Each LEOP is followed by in-orbit testing (IOT) to verify satellite payload health and survival of the launch. These tests are supported by the designated IOT station in Redu (Belgium), which comprises a calibrated high-gain antenna and measurement system for the L-band navigation signals, and testing equipment and transmitters for the C-band and SAR UHF RF links. A second use of the IOT station Redu is for regular signal characterization during routine operations.

The ground segment manages interfaces to the satellite manufacturers, needed for onboard software maintenance, operations support and telemetry analysis, and in support of eventual troubleshooting of satellite platform and payload units.

Further external interfaces of the Galileo ground segment are installed, to connect to entities contributing to the provision of Galileo services:

1. The GNSS service center (GSC), foreseen as an interface between the Galileo system and external data providers for the Galileo open service (OS) and the Galileo commercial service (CS). The GSC facility is located near Madrid, Spain.
2. The Galileo security monitoring centers (GSMC) providing system security monitoring, management of the public regulated service user segment, and the point of contact platforms (POCP) to interface with national competent PRS authorities (CPA). GSMC facilities are located in France and in the United Kingdom.
3. The time and geodetic reference service providers (TSP, GRSP) to monitor and steer Galileo System Time and Galileo Terrestrial Reference Frame vis-a-vis international meteorological standards.
4. The SAR Galileo data service provider (SAR GDSP) to carry out the position determination of the distress alert emitting beacons once they have been detected by the dedicated ground segment, and to provide SAR return link messages for dissemination through the Galileo navigation signals. The SAR GDSP premises are located in Toulouse, France.
5. The Galileo reference center (GRC) to provide independent performance monitoring of the Galileo services. The GRC facility will be located in Noordwijk, the Netherlands.

These service providers are procured, coordinated and operated by the European GNSS Agency (GSA), an institution of the European Union tasked with the operation of the Galileo system, and in charge of service provision and quality of the operational system.

## 9.5 Summary

Galileo is a joint initiative of ESA and the European Commission (EC), to deploy a highly accurate and independent GNSS under civilian control. Compatibility and interoperability with existing GNSSs and especially with GPS were important requirements during the concept and design studies. The procurement of the Galileo system was launched in 2008, and has since then proceeded with space and ground segment development, manufacturing and deployment. The number of signals from Galileo satellites available for testing and development is increasing with deployment, and this enabled the first Galileo-only position fix to begin 2013 and successful in-orbit validation in the second half of 2013. The simultaneous successful build up of the ground mission and control segments with their worldwide infrastructure is bringing the system into an operational state. Interfaces to external service providers as well as the services themselves are being installed. All these deployments are accompanied by a continuous process of system verification and tuning, visible in the steady improvement of the already good initial results. The sum of these efforts will allow the start of initial services in 2016, with nine nominal satellites plus two satellites in nonnominal orbits, and with the prospect of six more

satellites to be launched in 2016. Successful validation of this system configuration will be the starting point of the exploration phase, planned for 2017, where Galileo will become officially available. The full constellation of 24 satellites plus in-orbit spares and the completion of the ground segment will be reached in 2020.

*Acknowledgments.* The authors would like to thank their colleagues in the Galileo Project Office and all teams at Industry contributing to the European project for the Global Navigation Satellite System Galileo. Without their continuous efforts Galileo would not have come into existence.

# 10. Chinese Navigation Satellite Systems

Yuanxi Yang, Jing Tang, Oliver Montenbruck

This chapter introduces the BeiDou (COMPASS) Navigation Satellite System from its early stage as a demonstration system to its evolution to a global system. First, the development strategy and basic principle of BeiDou Demonstration System are reviewed. Its basic performance is given in details. Second, the basic information of BeiDou (regional) system including constellation, frequency, coordinate reference system, and time datum is described. Its initial performance is evaluated by using single-point positioning, code and carrier phase differential positioning. Some application examples are introduced. Third, the BeiDou (Global) Navigation Satellite System (BDS) is described. Position dilution of precision is analyzed and BeiDou's contribution is summarized. At last, Chinese Area Positioning System is briefly introduced.

The Big Dipper, the Plough or the Saptarishi (in Chinese 北斗, BěiDǒu) are well recognized in many cultures as the most important set of stars giving directions to people in the Northern Hemisphere. Besides telling the north direction, the Big Dipper also indicates the seasons. An ancient Chinese book already states that it is spring when the dipper handle directs east, summer when it directs down, autumn when it directs west, and winter when it directs up.

The Big Dipper can only be used for orientation in clear nights. As the first manmade navigation device, which was not affected by weather and could always identify the cardinal directions during day and night, the ancient compass was invented in China [10.1]. It is composed of a box frame and magnetic needle, or a spoon made from lodestone (Fig. 10.1). This magnetic device is used as a means of orientation, which always points in the northern (or southern) direction.

In Chinese mythology, the army of Huangdi (the *Yellow Emperor*, who was regarded as the initiator of Chinese civilization) lost their direction in a heavy fog around 2697 BC. In a dream, a Fairy clued to Huangdi that the compass could show the south direction. Then the compass was invented. The compass vehicle used in the war helped Huangdi to win the war against Chi You (who was a tribal leader of ancient China). The above story is just one of the many beautiful legends left to Chinese. More than that, the compass was widely

**Fig. 10.1** A Chinese ancient compass (called *Sinan*) made up of a spoon from loadstone and a bronze plate with direction markings. Reproduced with permission of Panorama Media, Inc.

used in ancient China from the Qin Dynasty to Early Ming dynasty. It helped the traders and sailors find the direction during their voyages and expeditions around Southeast Asia and Pacific and Indian Ocean [10.3].

As Chinese scientists and engineers started to implement their own navigation satellite system, *BeiDou* was given as its name which was naturally chosen and recognized by the Chinese people. At the same time, its English name *COMPASS* has been also used for a dozen of years, which is largely used in the system's official frequency filing to the International Telecommunication Union (ITU).

China decided to build an independent navigation satellite system in the 1980s. Three steps for constructing the system were planned (Fig. 10.2). The first step is the BeiDou Navigation Satellite Demonstration System which is called BeiDou-1 or simply BDS-1 [10.2]. In 1994, China started the buildup of the BeiDou Navigation Satellite Demonstration System. In 2000, two BeiDou navigation experiment satellites were launched. In 2003, the third BeiDou satellite was launched, further enhancing the system's performance. Thus, BDS-1 was formally established, which made China the third nation in possession of an independent navigation satellite system following the United States and Russia.

The second step is the regional BeiDou Navigation Satellite System. Implementation of BDS-2 was started in 2004, and the first satellite, a medium Earth orbit (MEO) satellite was launched in 2007. An op-

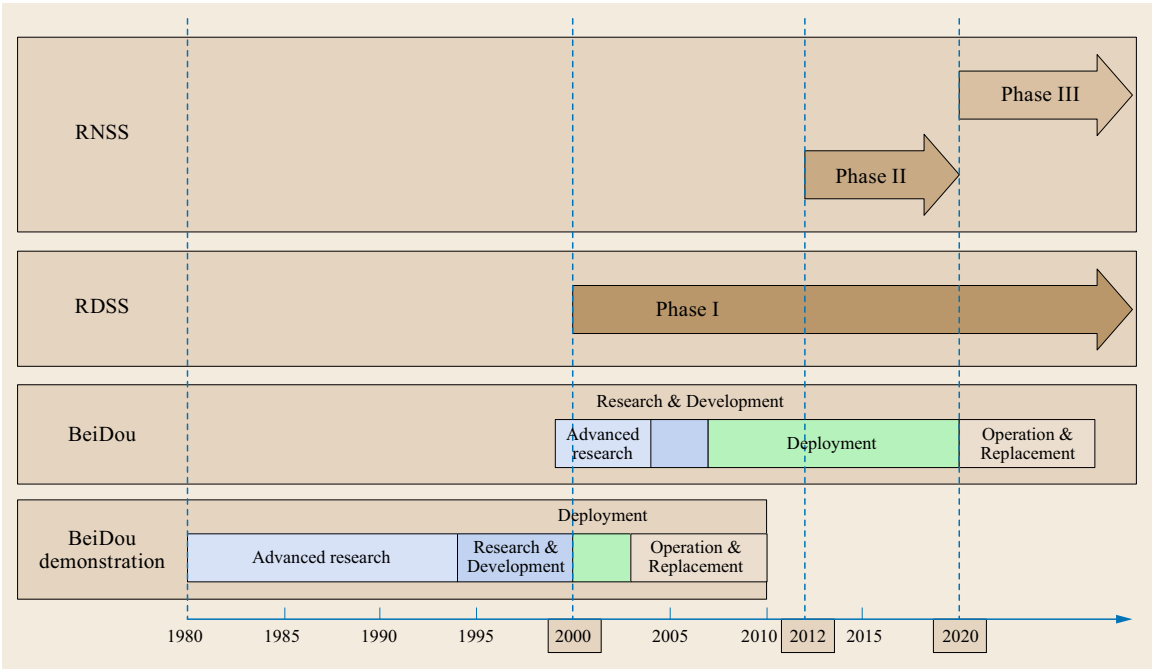

**Fig. 10.2** The three phases in the development of the BeiDou Navigation Satellite System. Following the implementation of a regional radio determination satellite service (RDSS) in the frame of BDS-1, a regional radio navigation satellite service (RNSS) was established by BDS-2 in 2012. This will ultimately be extended to a global service by the third generation BeiDou Navigation Satellite System, BDS-3. After [10.2], reproduced with permission of Beijing Satellite Navigation Center

erational navigation service available for China and large parts of Asia-Pacific region was declared by the end of 2012 [10.4]. It is accomplished through a constellation of 14 satellites, including five satellites in geostationary Earth orbit (GEO), five satellites in inclined geosynchronous orbit (IGSO), and four MEO satellites.

As a third step, the BeiDou Navigation Satellite System with global coverage (BDS-3) is built-up, which will be completed around 2020.

## 10.1 BeiDou Navigation Satellite Demonstration System (BDS-1)

The BeiDou Navigation Satellite Demonstration System (BDS-1; [10.5]) offers a combined localization and communication service through a pair of geostationary satellites. Its main functions comprise:

- Positioning (navigation): quick determination and provision of the user's location.
- Short message communication: provision of two-way message exchange between the users and the master control station (MCS), as well as among the users themselves.
- Timing: broadcast of timing information and provision of time delay corrections for timing users.

All of these functions are achieved through the same channel. The concept is known as *radio determination satellite service* (RDSS, [10.6]) and has first been proposed for the Geostar system. Geostar was developed in the United States throughout the 1980s as a civil localization and communication system [10.7], but soon abandoned in view of the emerging availability of GPS.

Key differences between the BDS-1 RDSS and the RNSS of other constellations such as GPS, GLONASS, and BDS-2/3 are highlighted in Table 10.1.

### 10.1.1 System Architecture and Basic Characteristics

Similar to other satellite navigation systems, the BDS-1 system architecture comprises a space segment, a ground control segment, and the user terminals.

The initial BDS-1 constellation was made up of two geostationary satellites launched in late 2000 and positioned at 80°E and 140°E. According to their position, they are called BeiDou-West and BeiDou-East, simplified as BeiDou 1A and BeiDou 1B (Fig. 10.3). For backup purposes, a third satellite (BeiDou 1C) was added in 2003 at 110.5°E [10.5]. Meanwhile, all of

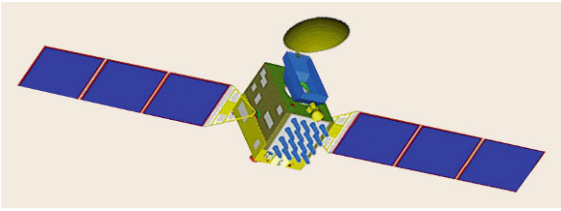

**Fig. 10.3** GEO satellite of the BeiDou Navigation Satellite Demonstration System (BDS-1). Reproduced with permission of Beijing Satellite Navigation Center ►

**Table 10.1** Comparison of the BDS-1 RDSS with the RNSS of other satellite navigation systems

| | BDS-1 RDSS | RNSS |
|---|---|---|
| Basic principles | Determination of the user's location by the master control station | Determination of the user's location and velocity by the user |
| Constellation | GEO | GEOs, MEOs, IGSOs |
| Service type | Positioning, timing, location report, short message communication | Positioning, timing, velocity determination |
| User transmits response signal | Yes | No |
| Observation | Sum pseudorange from the user to the master control station via the satellite | Pseudorange from satellite to user and Doppler measurement |
| Payload complexity | Low | High |
| Coverage | Regional | Regional or global coverage |
| Service frequency | Single service for low- and medium-dynamic users | Continuous service for low, medium and high dynamic users |
| Application | Positioning, location report, communication, rescue | Navigation |

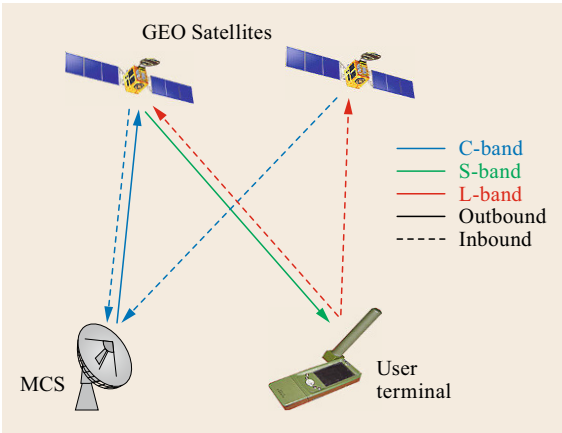

**Fig. 10.4** RDSS links of BeiDou-1. Individual frequencies are distinguished by different *colors*. *Solid lines* refer to output signals (master control station to user), while *dashed lines* refer to inbound (return) signals

**Fig. 10.5** BeiDou master control station at Beijing. Reproduced with permission of Beijing Satellite Navigation Center

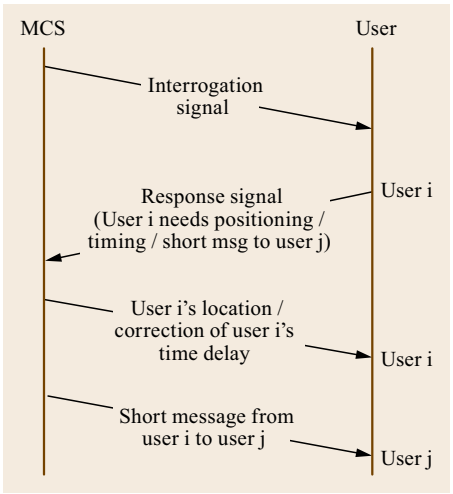

**Fig. 10.6** Information flow of the BDS-1 radio determination satellite service

these spacecraft have reached their end of life and have been substituted by satellites of the second-generation BeiDou system. These hold the same positions in the geostationary belt and continue to provide a BDS-1-type RDSS in addition to their primary RNSS.

Each satellite has two outbound transponders and two inbound transponders. The outbound transponders transfer signals which are emitted from the MCS to the satellites and further to the users. Vice versa, the inbound transponders transfer the signals which are emitted from the user to the satellites and further to the MCS (Fig. 10.4). The feeder link, which includes the uplink from the MCS to the GEO satellite of outbound signals and the downlink of the inbound signal from the GEOs to the MCS, uses the C-band frequency allocation for Fixed Satellite Service. The service link, which includes the uplink of inbound signals from the user to the GEOs and the downlink of the outbound signal from the GEOs to the user, uses the L-band (1610–1626.5 MHz; uplink) and S-band (2483.5–2500 MHz; downlink) frequency allocation for RDSS.

The BDS-1 ground control segment consists of the MCS (Fig. 10.5), at Beijing and more than 20 Calibration Stations. The MCS is responsible for transmitting the outbound signals and for receiving the inbound signals, for performing satellite orbit determination and ionosphere correction, for determining the user location, and for sending the short message to the subscribed users. The calibration stations provide the basic measurements for orbit determination, wide area differential positioning, and user elevation computation from barometric altimeter data.

The information flow of BDS-1 is illustrated in Fig. 10.6. For a positioning request, the MCS determines the user location from the measured signal turn-around time and the user's height. The latter is queried from the digital height database stored in the MCS or provided by the user. The resulting position information is then sent back to the user through the outbound signal. For a short message request, the MCS transmits the message to the addressee through the outbound signal. For timing requests, finally, the MCS calculates the precise correction of the user's time delay and sends it to the user through the outbound signal. The user then adjusts the local clock based on the time delay correction, thus, synchronizing it with the clock of the MCS.

The RDSS user terminals (Fig. 10.7) are capable of sending the requests and receiving location information and short messages. They can work in two modes. One mode is to receive one outbound signal and to transmit inbound signals via two satellites. Another mode is to receive the outbound signals from the two satellites

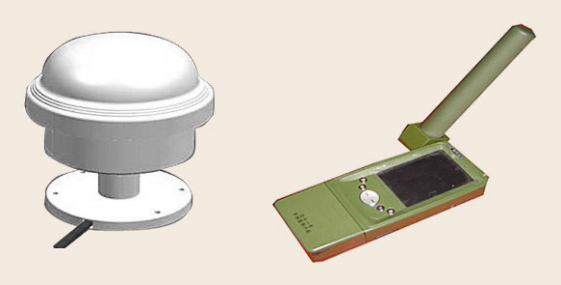

**Fig. 10.7** BeiDou RDSS user terminals. Reproduced with permission of Beijing Satellite Navigation Center

when the user is located in the common coverage area of the two satellites and to transmit the inbound signal via only one satellite. According to the time difference of the two outbound signals received and the service request transmitted by one satellite, the MCS measures the pseudorange from the user to the two satellites and calculates the user position.

Following [10.5], the BDS-1 system is able to handle a total of 540 000 positioning requests per hour. To control the overall system utilization, users are divided into several service classes with update rates of 1–9 s, 10–60 s, and 60–120 s. While the BDS-1 RDSS is free of charges, potential users must register and obtain a card to uniquely identify their terminal for the localization and communication service.

The BDS-1 service area illustrated in Fig. 10.8 is governed by the location of its geostationary satellites as well as the calibration stations. Overall, it comprises China and its surrounding areas, from longitude 70°E to 140°E and from latitude 5°N to 55°N.

The BDS-1 service performance specification is summarized in Table 10.2. A positioning accuracy of about 20 m can be achieved if the terminal locates in the region with calibration stations; otherwise, the positioning accuracy is about 100 m. These specifications are in good accord with practical performance results reported in [10.5]. Here, horizontal positioning errors of about 8 m (2D, 1 $\sigma$) have been obtained both in static tests and a low dynamic test onboard a maritime vessel with BDS-1 receivers in comparison with known positions from a GPS reference receiver.

### 10.1.2 Navigation Principle

The localization of a user terminal in BDS-1 is based on turn-around signal travel time measurements initiated by the MCS. As mentioned before, the MCS first emits an interrogation signal to the two satellites, which is subsequently broadcast to the users in the service area via the outbound transponders of the two satellites. The user receives the interrogation signal and sends its response signal with the user's service request back to the satellite (Figs. 10.6 and 10.4).

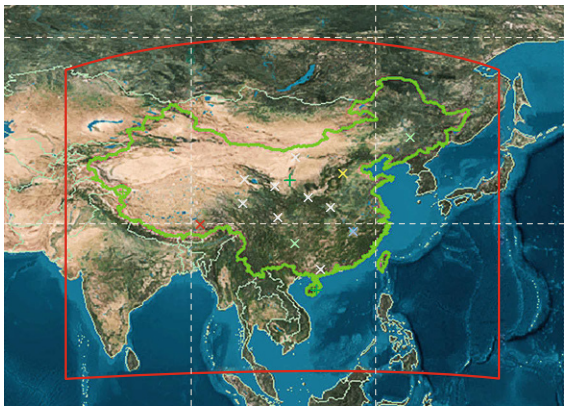

**Fig. 10.8** Service coverage of BDS-1. Reproduced with permission of Beijing Satellite Navigation Center

**Table 10.2** Performance specification for the BDS-1 radio determination satellite service (after [10.5])

| Parameter | Value |
|---|---|
| Horizontal positioning accuracy | 20 m (1$\sigma$) |
| One-way time accuracy | 100 ns |
| Two-way time accuracy | 20 ns |
| Short message communication | 120 Chinese chars./msg. |

A first observation $L_1$ is obtained by measuring the difference between the transmit time $t_t$ and the receive time $t_{r(s,s)}$ of a signal passing through the same satellite s on both the inbound and outbound links. Likewise, a second observation $L_2$ is obtained from the travel time $t_{r(s,s')} - t_t$ of a signal passing through satellite s on the outbound link but through the second satellite s′ on the inbound link.

Denoting the MCS position by $\boldsymbol{r}_m$, the position of the two satellites by $\boldsymbol{r}_s$ and $\boldsymbol{r}_{s'}$, respectively, and the (unknown) user position by $\boldsymbol{r}_u = (x_u, y_u, z_u)$, the two observations can be modeled as

$$\begin{aligned} L_1 &= c \cdot (t_{r(s,s)} - t_t) \\ &= 2||\boldsymbol{r}_s - \boldsymbol{r}_u|| + 2||\boldsymbol{r}_s - \boldsymbol{r}_m|| \end{aligned} \tag{10.1}$$

and

$$\begin{aligned} L_2 &= c \cdot (t_{r(s,s')} - t_t) \\ &= ||\boldsymbol{r}_s - \boldsymbol{r}_u|| + ||\boldsymbol{r}_{s'} - \boldsymbol{r}_u|| \\ &\quad + ||\boldsymbol{r}_s - \boldsymbol{r}_m|| + ||\boldsymbol{r}_{s'} - \boldsymbol{r}_m|| \,, \end{aligned} \tag{10.2}$$

respectively. These relations are likewise applicable for the operation mode in which the user receives signals from the two satellites and transmits them back via only one satellite.

It may be noted that the BDS-1 measurement model does not include explicit clock offset terms as found

in the traditional global navigation satellite system (GNSS) pseudorange model. This is due to the fact that the transmit and receive times are measured by a common clock in the MCS. The control segment (CS) clock offset from the BDS system time is common to the transmit and receive time stamps and cancels when forming the range measurement. As such, the minimum number of independent observations required for a position fix is one less than in other navigation satellite systems using one-way pseudorange observations. However, BDS-1 observations are still affected by equipment delays (transmitter, transponder, and receiver biases) which require proper consideration.

Since the positions of the satellites and the MCS are considered as known quantities, $L_1$ and $L_2$ are in fact equivalent to distance measurements of the user relative to the two satellites s and s′. These are not sufficient, though, to uniquely determine the three-dimensional user position. Information on the user's height $h_u$ above the reference ellipsoid is, therefore, employed as an independent, third observation. $h_u$ can either be provided from a barometric altimeter in the user terminal or provided from a digital elevation model maintained in the MCS for terrestrial users [10.5]. Given the ellipsoid height, a measurement

$$L_3 = h_u + N = \sqrt{x_u^2 + y_u^2 + (z_u + Ne^2 \sin\varphi)^2} \tag{10.3}$$

is formed, which describes the distance of the receiver from the Earth rotation axis along the normal line of the reference ellipsoid. Here,

$$N = \frac{a}{\sqrt{1 - e^2 \sin^2 \varphi}} \tag{10.4}$$

is the radius of curvature in the prime vertical at geodetic latitude $\varphi$, while $a$ and $e$ denote the semimajor axis and eccentricity of the reference ellipsoid (Sect. 2.2.1).

Equations (10.1)–(10.3) cannot be solved directly for the unknown user position, but can be linearized in the vicinity of an approximate a priori value $\boldsymbol{r}_{u,0}$. This yields a three-dimensional set of linear equations from which corrections $\Delta\boldsymbol{r}_u = \boldsymbol{r}_u - \boldsymbol{r}_{u,0}$ are obtained. This process is repeated in an iterative manner until the solution is obtained with the desired accuracy.

For simplicity, atmospheric propagation effects and equipment specific delays have been neglected in the above discussion, but are taken into account in the actual MCS processing. Among others, these corrections are based on a distributed set of calibration stations enabling wide area differential positioning.

### 10.1.3 Orbit Determination

Similar to other satellite navigation systems, positioning with BDS-1 depends on proper knowledge of the satellite positions. In BDS-1, the orbit determination relies on measurements of the calibration stations, which follow the same principle as described in Sect. 10.1.2 for the user positioning. Calibration stations for orbit determination respond to the same frame interrogation signal from the MCS at a certain sample interval. Therefore, the MCS can measure a group of distances related to the individual calibration stations for orbit determination of each satellite.

The basic observation model for satellite orbit determinations matches (10.1) and (10.2) when replacing the user position $\boldsymbol{r}_u$ by the (known) position of a calibration station. However, there are some differences between satellite orbit determination and user positioning. While the number of measurements in the positioning equations of BDS-1 matches with that of the unknown position parameters, the number of measurements in the orbit determination is usually greater than that of the orbit parameters (typically six per satellite). Also, the orbits of both BDS-1 satellites should be determined simultaneously, since the measurement equations for each calibration station depend on the position of two satellites (s and s′) at a time.

### 10.1.4 Timing

Apart from positioning, the BDS-1 RDSS also supports the synchronization of user terminals with the BeiDou system time (BDT) maintained at the MCS. BDT is a continuous time scale without leap seconds [10.8] that is realized by composite clocks with robust data fusion. BDT is aligned to the realization of Coordinated Universal Time UTC(NTSC) maintained by the Chinese National Time Service Center (NTSC). UTC(NTSC) itself is traced to the Coordinated Universal Time (UTC) by satellite common view (CV) links and the offset of BDT with respect to UTC is controlled within 30 ns.

BDS-1 provides two types of timing services: one-way and two-way timings with 100 ns and 20 ns timing accuracies, respectively. Both of these are based on a comparison of transmit and receive times measured relative to the local clock after accounting for the known geometric propagation time and possible correction atmospheric and equipment delays.

Each second, the MCS transmits a total of 32 frames of 31.25 ms duration aligned with the integer second of BDT. Denoting by $\Delta_1$ the time difference between the reception of the $n$-th frame and the receiver's preceding 1-pulse-per-second (1-pps) epoch (Fig. 10.9), the local

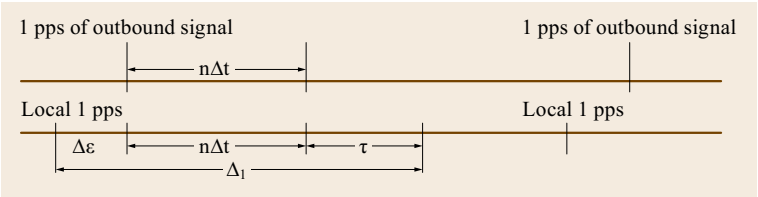

**Fig. 10.9** The principle of BDS-1 one-way timing (after [10.9])

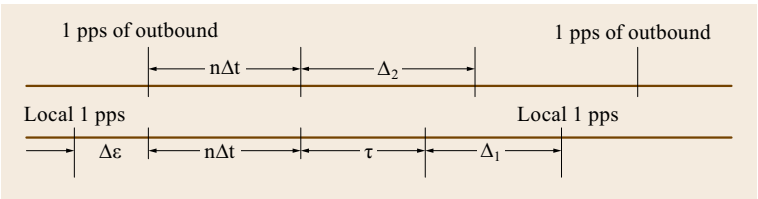

**Fig. 10.10** The principle of BDS-1 two-way timing (after [10.9])

clock offset $\Delta\varepsilon$ is obtained as

$$\Delta\varepsilon = \Delta_1 - (n\Delta t + \tau) \,. \tag{10.5}$$

Here, $\tau$ is the signal travel time, which is modeled from the known MCS-satellite and satellite-user distances as well as atmospheric path delays and equipment delay corrections [10.9].

For two-way timing (Fig. 10.10), the user terminal responds to the inbound interrogation signal and the MCS measures the round trip time $\Delta_2$. From this, the one-way travel time $\tau \approx \Delta_2/2$ is computed in the MCS taking into account various atmospheric and equipment delay corrections. The resulting value of $\tau$ is subsequently sent back to the user. Making use of a local measurement $\Delta_1$ of the time between reception of the interrogation signal and the subsequent 1-pps epoch, the local clock offset is, finally, obtained as

$$\Delta\varepsilon = (1\,\mathrm{s} - \Delta_1) - (n\Delta t + \tau) \,. \tag{10.6}$$

In view of an improved error compensation, the two-way time synchronization achieves an accuracy of 20 ns [10.9], which represents a fivefold improvement over the one-way timing performance.

## 10.2 BeiDou (Regional) Navigation Satellite System (BDS-2)

In September 2004, the construction of BDS-2 was initiated and a first MEO satellite (then known as COMPASS-M1) was successfully launched in April 2007. It served to protect the frequency filings at the ITU and provided a test bed for the validation of indigenous atomic clocks, precise orbit determination, and time synchronization, as well as other key technologies. Starting with the launch of the first GEO satellite in April 2009, a constellation of 14 operational satellites was deployed in only 3.5 years (Table 10.3).

In December 2012, the BDS-2 entered into official operation and declared the start of its regional service covering latitudes 55°S to 55°N and longitudes 70°E to 150°E [10.10]. The initial service announcement was accompanied by the release of the first open service interface control document (ICD) for single frequency users in the B1 band. An updated version covering also the use of dual-frequency (B1/B2) signals was issued after one year in December 2013 [10.11].

### 10.2.1 Constellation

The second-generation BeiDou Navigation Satellite System uses a unique constellation design, which combines elements of global systems (such as GPS, GLONASS, and Galileo) with those of purely regional systems (such as the Quasi-Zenith Satellite System (QZSS) and the Indian Regional Navigation Satellite System (IRNSS/NavIC)). The BDS-2 space segment comprises five satellites in geostationary orbit, five spacecraft in IGSO, and four satellites in medium altitude Earth orbit (Table 10.3).

The GEO satellites are positioned at 58.75°E, 80°E, 110.5°E, 140°E, and 160°E, respectively. At least three of them are continuosly visible above 10° elevation from any point in the service area, thus, enabling a real-time exchange of information between the control center and the BDS-2 users.

The IGSO satellites operate in circular orbits with an altitude of about 36 000 km and an inclination of 55°.

**Table 10.3** Satellites of the regional BeiDou Navigation Satellite System (BDS-2) at the start of operational service. For each satellite, the assigned pseudorandom noise (PRN) code, the international satellite identification number, and the launch date are provided. Satellites in geostationary, inclined geosynchronous and medium altitude Earth orbits are identified by letters "G," "I," and "M," respectively

| Satellite | PRN | Int. Sat. Id | Launch | Notes |
|---|---|---|---|---|
| G1 | C01 | 2010-001A | 2010/01/16 | 140.0°E |
| G2 | – | 2009-018A | 2009/04/14 | Nonoperational |
| G3 | C03 | 2010-024A | 2010/06/02 | 110.5°E |
| G4 | C04 | 2010-057A | 2010/10/31 | 160.0°E |
| G5 | C05 | 2012-008A | 2012/02/24 | 58.75°E |
| G6 | C02 | 2012-059A | 2012/10/25 | 80.0°E |
| I1 | C06 | 2010-036A | 2010/07/31 | ~118°E |
| I2 | C07 | 2010-068A | 2010/12/17 | ~118°E |
| I3 | C08 | 2011-013A | 2011/04/09 | ~118°E |
| I4 | C09 | 2011-038A | 2011/07/26 | ~95°E |
| I5 | C10 | 2011-073A | 2011/12/01 | ~95°E |
| M1 | C30 | 2007-011A | 2007/04/13 | Decommissioned |
| M3 | C11 | 2012-018A | 2012/04/29 | B3 |
| M4 | C12 | 2012-018B | 2012/04/29 | B4 |
| M5 | C13 | 2012-050A | 2012/09/18 | A7 |
| M6 | C14 | 2012-050B | 2012/09/18 | A8 |

Like the GEO satellites, they exhibit an orbital period of one sidereal day (i. e., the duration of the Earth rotation relative to the fixed stars, 23 h 56 m), but exhibit a notable inclination with respect to the Earth equator. This results in continuously repeating ground-tracks with a distinct figure-of-eight shape covering a latitude band of ±55° (Fig. 10.11). The ground-tracks cross the equator from east to west and the northern part is traversed in a clockwise sense, while the southern loop is traversed in a counter-clockwise direction. Three of the BDS-2 IGSO satellites (I1, I2, and I3) describe a ground track with an equator crossing point at 118°E, while I4 and I5 describe a figure-of-eight centered at 95°E. A new satellite (BEIDOU I1-S/2015-019A) for validation of new BDS-3 signal has been launched in March 2015, filling in the third slot in this ground track.

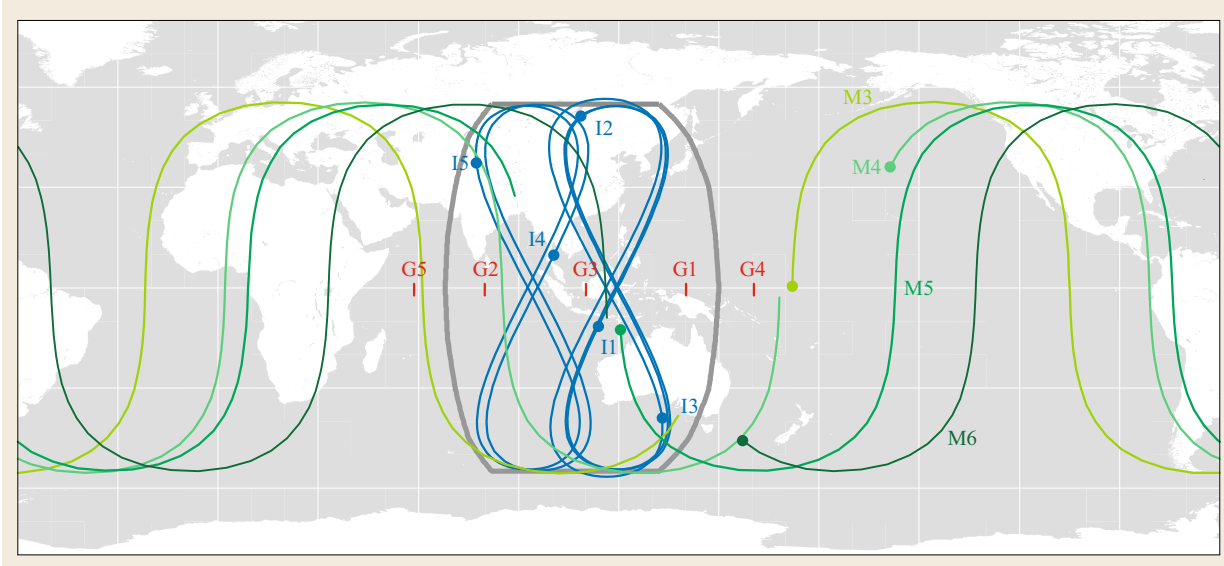

**Fig. 10.11** Groundtrack of GEO (*red*), IGSO (*blue*) and MEO (*green*) satellites of the BeiDou Navigation Satellites System (BDS-2) on 1 July 2014. *Dots* indicate the initial positions at the midnight epoch. The framed region extending roughly from 70°E to 150°E and 55°S to 55°N marks the BDS-2 regional service area as specified in [10.10]

The IGSO satellites in common ground-tracks exhibit a nominal separation of 120° in their arguments of latitude as well as their right ascension of the ascending node (Chap. 3). In this way, they cross the equator at the same geographic longitude with a separation of 8 h.

Even though a combination of GEO and IGSO satellites is commonly considered sufficient and adequate for a purely regional navigation system, the BDS-2 makes complementary use of a small number of MEO satellites. These orbit the Earth at an altitude of 21 530 km (i. e., in between the global positioning system (GPS) and Galileo constellation) and an inclination of 55°. The orbital radius has been chosen such that the satellites complete a total of 13 revolutions within 7 sidereal days, which corresponds to an orbital period of 12h 53m.

The four BDS-2 MEO satellites have been launched in pairs and injected into two different orbital planes, which are separated by 120° in their ascending nodes. In anticipation of a future global extension, the BDS-2 MEO satellite orbits are designed as part of a 24/3/1 Walker constellation [10.12] with 24 satellites evenly distributed in three orbital planes. BeiDou M5 and M6 presently occupy slots 7 and 8 in plane A, while M3 and 4 are placed in slots 3 and 4 of plane B [10.11]. Even though the BDS-2 MEO constellation is still quite limited in size, it increases the average number of visible satellites in the service area and offers additional geometric diversity for improved positioning.

To maintain their nominal position, regular east–west maneuvers with a representative magnitude of about 10 cm/s are conducted by the GEO satellites about once per month [10.13]. North–south corrections, in contrast, are conducted only rarely allowing the buildup of a few degrees of inclination over a period of several years [10.14]. On the IGSO satellites, maneuvers are likewise performed at intervals of about half a year to control the equator crossing longitude [10.15].

## 10.2.2 Signals and Services

The BDS-2 satellites transmit a total of six signals in three distinct frequency bands: B1 at a center frequency of 1561.098 MHz, B2 at a center frequency of 1207.14 MHz, and B3 at a center frequency of 1268.52 MHz. The B1 and B3 frequencies are offset by about 14 MHz and 10 MHz, respectively, from the E1/L1 and E6 bands of Galileo/GPS, while the B2 center frequency matches that of the Galileo E5b (sub-)band. Each carrier frequency is modulated with two signals in phase quadrature using ranging codes of 2.046 MHz or 10.23 MHz chipping rate (Table 10.4). The resulting signal spectra are illustrated in Fig. 10.12.

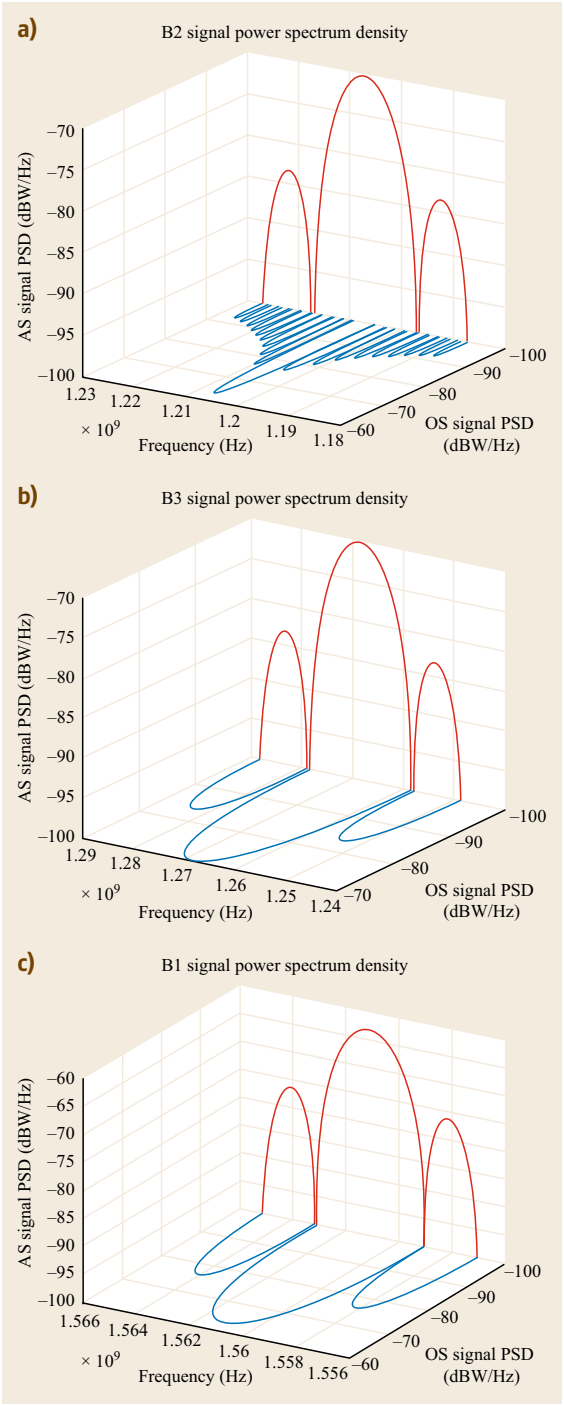

**Fig. 10.12a–c** Spectral characteristics of BeiDou (BDS-2) signals in the B2 (a), B3 (b), and B1 (c) frequency bands. Note the different scales of the individual plots

The in-phase components of the B1 and B2 signals are assigned to the BDS-2 open service [10.11],

**Table 10.4** BDS-2 navigation signals. The BPSK($n$) code chip rate is $n\times1.023$ Mcps

| Band | Frequency (MHz) | Signal | Modulation | Service |
|---|---|---|---|---|
| B1 | 1561.098 | B1-I | BPSK(2) | Open |
| | | B1-Q | BPSK(2) | Authorized |
| B2 | 1207.14 | B2-I | BPSK(2) | Open |
| | | B2-Q | BPSK(10) | Authorized |
| B3 | 1268.52 | B3-I | BPSK(10) | Authorized |
| | | B3-Q | BPSK(10) | Authorized |

while the remaining four signals are reserved for the authorized service. The open service is specified to offer signal-in-space range errors (SISREs) of better than 2.5 m and a horizontal and vertical positioning accuracy of better than 10 m at a 95% confidence level [10.10] within the BDS-2 service area shown in Fig. 10.11. A minimum received signal power of −163 dBW is ensured for the open service signal on each of the two frequencies.

Apart from the standard positioning and timing service available in the entire service area [10.10], the BDS-2 open service signals also support an improved, satellite-based augmentation systems (SBAS)-like positioning service based on near-real-time corrections transmitted through the GEO satellites. This service is freely available to all users, but limited to a smaller service area centered around the Chinese mainland.

The open service signals employ truncated Gold-codes with a length of 2046 chips and a chipping rate of 2 MHz. Similar to the GPS C/A-code, the BDS-2 open service (OS) codes are generated using a pair of 11-bit shift registers and a full family of codes is obtained through configurable selectors (Fig. 10.13). The native code length of the 11-bit registers amounts to $2^{11}-1=2047$ bits, but the sequence is reset after 2046 chips to obtain a pseudo-random noise (PRN) code of exactly 1 ms duration. Within the OS signal ICD, a total of 37 different open service PRN codes are defined, out of which 1–5 PRNs are reserved for the geostationary satellites. On a given satellite, the same PRN sequence is used for both the B1-I and B2-I OS signals.

Next to the primary ranging code, the open service signal of the IGSO and MEO satellites is multiplied with a secondary, or Neuman–Hofman (NH) [10.16] code. Each chip of the NH-code has a duration of 1 ms and is aligned with the start of the primary code. Depending on the sign of the secondary code chip, either the unmodified primary ranging code sequence or a sign-inverted version is transmitted. As discussed in [10.17, 18], the use of NH-codes helps to decrease narrow-band interference, improves the cross- and autocorrelation properties, and offers an increased robustness in the data bit synchronization. The BDS-2 NH-code (00000 10011 01010 01110) matches that of the GPS L5-Q signal. It has a length of 20 chips and repeats after 20 ms.

The B1-I and B2-I signals of all BeiDou-2 satellites are, furthermore, modulated with navigation data. For a given satellite, the same data are transmitted on both frequencies, but different formats and data rates are employed for the various types of spacecraft. In case of the MEO/IGSO satellites, the *D1* navigation message is transmitted with a rate of 50 bps (corresponding to a data bit length of 20 ms). The GEO satellites, in contrast, transmit the *D2* message at a 10 times higher rate of 500 bps. Here, the data bit length amounts to just 2 ms, that is, the duration of two consecutive ranging codes.

The overall modulation scheme for the two classes of BDS-2 satellites is illustrated in Fig. 10.14. While improved signal properties at the expense of a lower data are favored for the MEO/IGSO satellites, the GEO signal is optimized for the transmission of high data volumes. This different tradeoff reflects the specific role of the GEO satellites, which also provide real-time augmentation data to the BeiDou users as part of the navigation message (Sect. 10.2.3).

The choice of different signal structures for satellites of the same constellation is unique to BDS-2 and requires specific care in the receiver implementation. As pointed out in [10.19] and [10.20], inconsistent interpretations of the NH-code sign may result in a half-cycle intersatellite-type biases (ISTB) when forming double-difference carrier-phase observations between GEO and non-GEO BDS-2 satellites using different receiver types. Further aspects of BeiDou receiver design and the impact of the NH-code on acquisition and tracking of the MEO/IGOS signals are discussed in [10.21] and [10.22].

Even though only the B1-I and B2-I signals are officially declared as open service signals, basic properties of the (authorized) B3-I signal have also become public through inspection with high-gain antennas [10.23, 24]. The signal employs a primary ranging code of 10 230 chips with a chipping rate of 10.23 MHz and a resulting length of 1 ms as well as a 20-bit secondary code. Knowledge of the ranging code, which can be generated by linear feed-back shift registers, has enabled various manufacturers to provide geodetic-grade

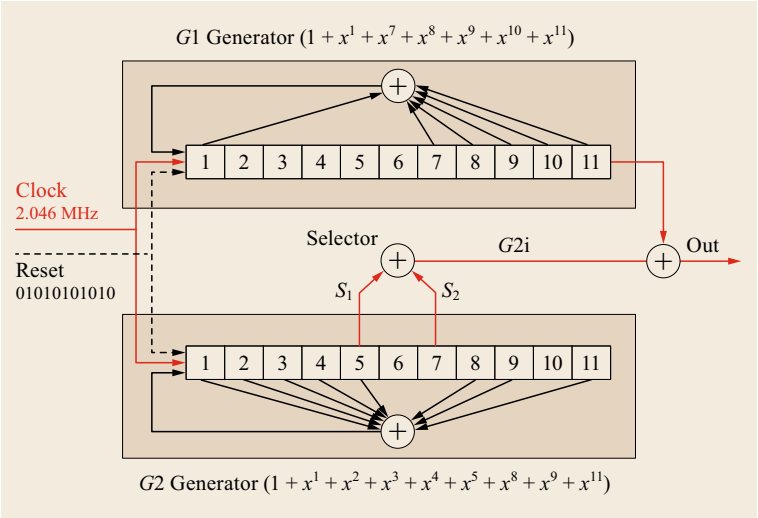

**Fig. 10.13** Code generator for the B1-I and B2-I open service signals (after [10.11])

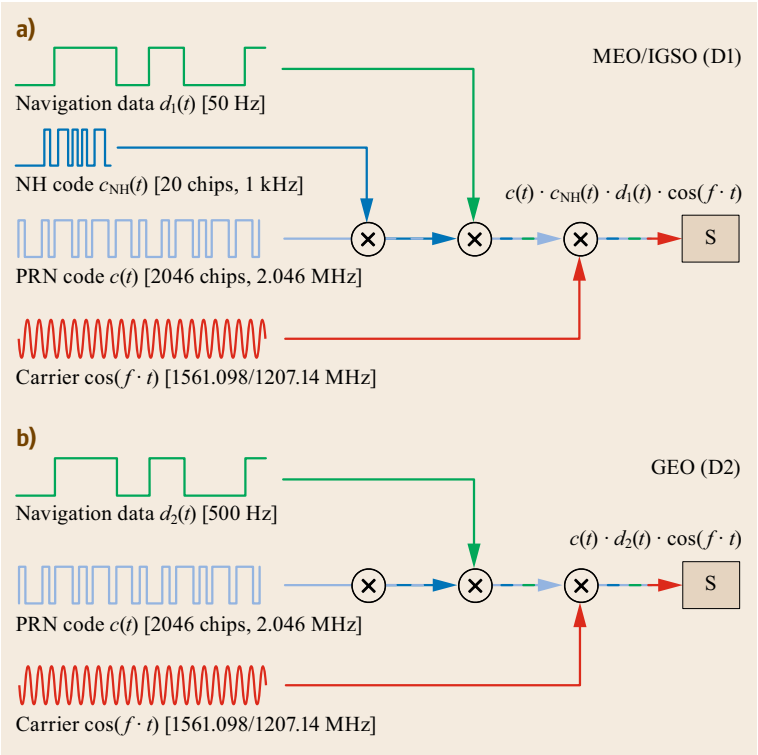

**Fig. 10.14a,b** Signal structure of the BeiDou-2 open service signals for MEO/IGSO **(a)** and GEO satellites **(b)**

triple-frequency BeiDou receivers. Access to more than two frequencies in BeiDou paves the way for various advanced GNSS processing techniques [10.25–28] with applications in surveying, precise point positioning and geodesy. It must be kept in mind, though, that tracking of the B3-I signal is not officially endorsed and may be inhibited at any time using explicit encryption of the B3-I ranging code.

### 10.2.3 Navigation Message

The D1 navigation message broadcast by the MEO and IGSO satellites resembles the legacy navigation message of GPS transmitted with the L1 C/A code signal. It employs the same data rate and provides basic navigation information such as almanac and ephemeris data for acquisition of visible satellites as well as positioning

and timing. On top of these data, the high-rate D2 message of the BeiDou GEO satellites contains additional augmentation service information such as BDS integrity, differential corrections, and ionospheric grid data.

### D1 Message Structure

The D1 navigation message is structured into a superframe made up of individual frames and subframes (Fig. 10.15). Each subframe is composed of 300 bits and takes 6 s to transmit. Five subframes make up a full frame, which is of 30 s duration. The superframe, finally, comprises 24 frames (i. e., one less than GPS) with a total of 36 000 bits transmitted in 12 min. Subframes 1–3 contain fundamental navigation data such as orbit and clock parameters for the transmitting satellite as well as ionospheric model coefficients. This information is updated at the start of each hour and repeated once every 30 s within this period.

Subframes 4 and 5 are commutated, that is, different *pages* are transmitted within consecutive frames. They contain the almanac information for up to 30 satellites (in pages 1–24 of subframe 4 and pages 1–6 of subframe 5) as well as constellation health data, the BDS time offset from UTC as well as the time offsets between BDT and other GNSS time scales (pages 7–10 of subframe 5). The entire information is repeated once every 12 min.

The 300 bits of each subframe are composed of 10 elementary 30-bit words. Each halfword contains 11 data bits as well as 4 parity bits encoded with a Bose–Chaudhuri–Hocquenghem (BCH) [10.29] code enabling single-bit error correction. Furthermore, the data and parity bits from two halfwords with each word are interleaved to protect against possible burst errors during the transmission.

### D2 Message Structure

The D2 message is transmitted at a 10 times higher data (500 bps) than the D1 message and uses a different scheme to transmit the low-rate basic navigation data along with high-rate augmentation data. The superframe is composed of 120 frames, which are divided into five subframes of 300 bits length. A single subframe has a length of 0.6 s and a full frame is broadcast in 3 s. The entire superframe contains a total of 180 000 bits and takes 6 min to transmit (Fig. 10.16).

Subframe 1 provides basis navigation data such as orbit and clock information of the transmitting satellite and ionospheric model parameters in a series of 10 commutated pages. Apart from the different layout, the data are identical to subframes 1 and 3 of the D1 message. As in the case of the non-GEO satellites it, thus, takes a total of 30 s to receive the full ephemeris data of a GEO satellite despite the higher transmission rate. Within a superframe, the same set of 10 pages is repeated 12 times. The ephemeris information is complemented by almanac data (for up to 30 satellites) in pages 37–60 and 95–100 of subframe 5. One full almanac is transmitted per superframe and the information is repeated every 6 min.

Information on the integrity of BDS-2 satellites as well as differential correction data are provided to the users in subframes 2 and 3 of the D2 navigation message. Other than in traditional SBAS systems (Chap. 12), equivalent clock corrections are provided in the BDS-2 augmentation data. The scalar correction values $\Delta t$ account for the combined effects of broadcast orbit and clock offset errors and are intended for users in China and adjacent areas. The user adds the value of $\Delta t$ to the observed pseudorange. Updated values are provided once every 18 s. Within this period, six

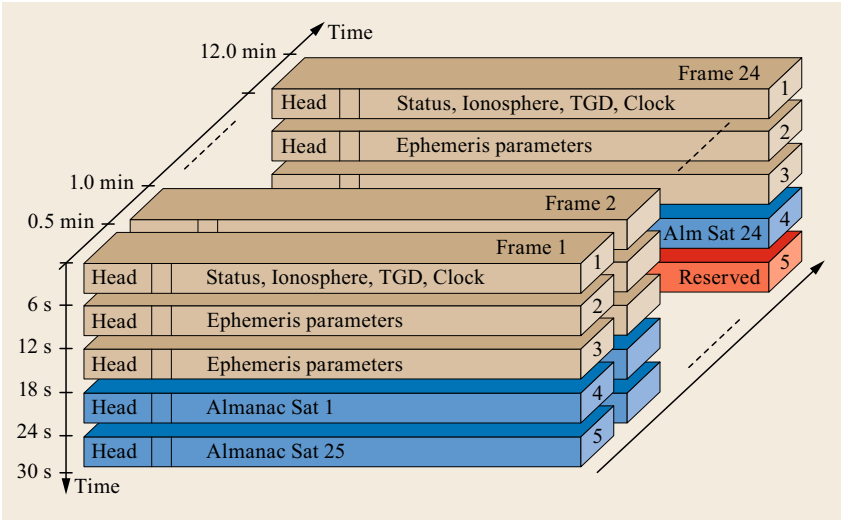

**Fig. 10.15** Structure of the BeiDou D1 navigation message transmitted by the MEO and IGSO satellites. *Arrows* indicate the transmission order of individual subframes

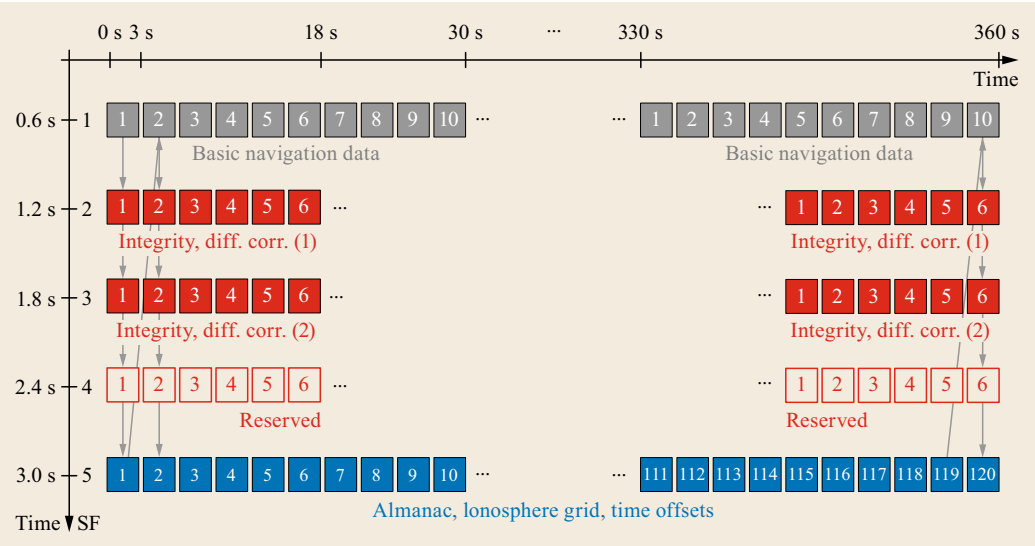

**Fig. 10.16** Structure of the BeiDou D2 navigation message transmitted by the GEO satellites (after [10.30])

commutated pages of subframes 2 and 3 are transmitted, which provide integrity information and equivalent clock corrections for up to 18 different satellites. This covers the expected maximum number of BeiDou satellites jointly visible in the service area for augmentation data.

The differential ephemeris corrections are complemented by low-latency ionospheric corrections for single-frequency users provided in subframe 5. These data cover a service area from 70°E to 145°E longitude and 7.5°E to 55°E latitude and are provided in two subgrids of 5° × 5° resolution which are shifted by 2.5° in latitude (Fig. 10.17). In accord with the length of a superframe, the ionospheric grid data are updated once every 360 s. Depending on the availability and distribution of monitoring stations, the provision of valid correction data may be confined to a subset of points in the overall grid (typically the Chinese mainland).

### Ephemeris Parameters and Models

The broadcast orbit and clock parameters as well as the standard ionospheric correction parameters in BDS-2 have been defined in close correspondence with those of the legacy GPS navigation message. A total of 16 orbit parameters for a perturbed Keplerian model and three parameters of a quadratic clock model are used to describe the satellite motion and clock offset variation within the ephemeris validity interval. Ionospheric path

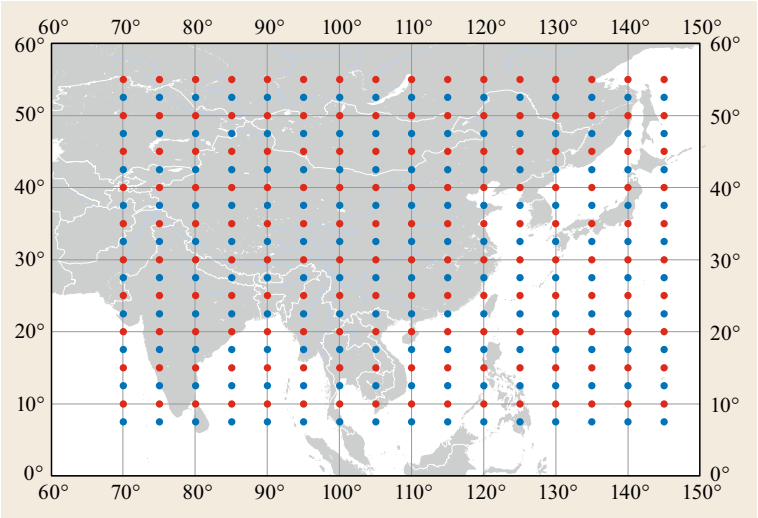

**Fig. 10.17** Ionospheric correction data in the BeiDou-2 D2 navigation message are provided for two interleaved grids of 5° width with a 2.5° offset. The northern grid (*blue*) is transmitted in the first 3 min, followed by the southern grid in the second half of a superframe

delays are described through a Klobuchar-type model with eight parameters.

Despite obvious similarities, the models employed with the BDS-2 broadcast navigation message differ in various aspects from those of GPS [10.11, 30]. All information is referred to BDT (Sect. 10.2.8) and the BeiDou coordinate system (BDC) connected to China Geodetic Coordinate System (CGCS) 2000 (Sect. 10.2.7). Along with that, slightly different values for the gravitational coefficient ($GM_\oplus$) and the Earth rotation rate ($\omega_\oplus$) are employed in BeiDou.

With the above exceptions, the orbit model of BDS-2 matches that of GPS for MEO and IGSO satellites, but a different interpretation of the orbit parameters applies for the GEO satellites (Sect. 3.3.2). Since the geostationary orbits exhibit a very low (and potentially zero) inclination, large residuals and divergence problems may be encountered when determining the broadcast elements. To cope with this situation, a reference plane with a 5° inclination angle to the equator is adopted in the orbit determination of the GEO satellites. A complementary 5° rotation must, therefore, be applied when calculating the position and velocity for these satellites relative to the Earth equator.

Satellite clock offsets from BDT are described through a second order polynomial

$$\Delta T = a_0 + a_1(t - t_{oc}) + a_2(t - t_{oc})^2 + \Delta t_{rel} \qquad (10.7)$$

with coefficients $a_0$, $a_1$, and $a_2$ providing offset, drift, and drift rate at the reference epoch $t_{oc}$, as well as periodic relativistic corrections

$$\Delta t_{rel} = -\frac{2}{c^2}(\boldsymbol{r}^\top \boldsymbol{v}) \qquad (10.8)$$

depending on the spacecraft position $\boldsymbol{r}$ and velocity $\boldsymbol{v}$ in much the same way as for GPS and Galileo. However, the clock offsets are referred to single-frequency B3 observations rather than an ionosphere-free dual-frequency combination. All users of the open service BDS-2 signals must, therefore, account for additional satellite group delay corrections. For processing of single-frequency B1-I observations, a timing group delay parameter $TGD_1$ provided in the navigation message has to be added to the B3 clock offset value, while a linear combination of $TGD_1$ and $TGD_2$ is required for dual-frequency (B1-I/B2-I) observations [10.31].

For ionospheric correction of single-frequency observation users, the BDS-2 broadcast navigation message makes use of a Klobuchar-style thin layer correction model (Sect. 6.3.4). It involves a total of eight coefficients ($\alpha_0, \ldots, \alpha_3$ and $\beta_0, \ldots, \beta_3$) describing the amplitude and period of the daytime vertical total electron content variation. The ionospheric model is constructed in geographic latitude and longitude, rather than geomagnetic coordinates as used in GPS. The coefficients of this model are transmitted by all BDS-2 satellites and updated at hourly intervals. Even though the model is conceptually valid on a global scale, best results are obtained across the Chinese mainland due to currently limited distribution of monitoring stations [10.32].

### 10.2.4 Space Segment

The BeiDou regional navigation satellite system is composed of three groups of spacecraft, namely the GEO, IGSO, and MEO satellites. The satellites have a specified lifetime of eight years. The platform and navigation payload of all three satellites types are essentially similar, but various complementary payloads are accomodated on the GEO spacecraft.

#### Satellite Platform

The BDS-2 MEO/IGSO satellites (Fig. 10.18) adopt the DongFangHong-3 (DFH-3; *The East is Red*) platform, and a slightly modified version (DFH-3A) is employed for the GEO satellites spacecraft [10.14, 33]. The three-axis stabilized DFH-3 bus has been developed by the China Academy of Space Technology (CAST), Beijing, in cooperation with Messerschmitt–Bölkow–Blohm (MBB), Germany, and was used for various geostationary communications satellites since 1994 [10.34]. It is equipped with an apogee boost motor and liquid propulsion system for initial orbit insertion and orbit keeping purposes.

At a size of about $2.4 \times 1.7 \times 1.7\,m^3$ (GEO) and $2.0 \times 1.7 \times 1.7\,m^3$ (MEO/IGSO), the spacecraft have different masses of around 2.5 t at lift-off. The platform comprises subsystems for thermal control, power supply and distribution, tracking, telemetry and commanding (TT&C), as well as attitude and orbit control. The solar arrays with a total area of more than $20\,m^2$ are based on silicon cells (MEO/IGSO satellites) and GaAs/Ge cells (GEOs) providing a minimum power of 2 kW and 2.5 kW, respectively. For power storage, all BDS-2 satellites are equipped with NiMH batteries offering capacities of 40–60 Ah [10.14].

Attitude control is performed through a combination of Earth and Sun sensors as well as four reaction wheels. These wheels are unloaded during station-keeping maneuvers or using magnetorquers to avoid unnecessary orbital perturbations. Outside the eclipse season, a continuous yaw-steering (Sect. 3.4) is performed by the MEO and IGSO satellites to maintain the antennas pointing to the center of the Earth while orienting the solar panels to the Sun [10.35]. The Earth-pointing accuracy is typically better than 0.25° and the nominal solar panel orientation is maintained with an

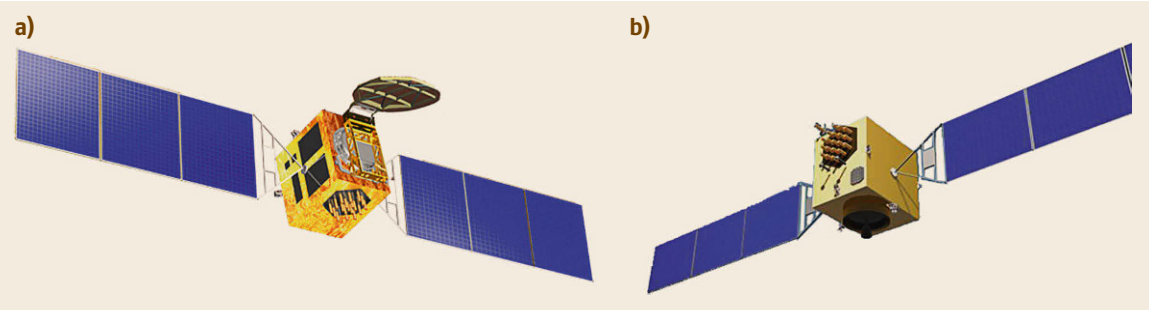

**Fig. 10.18a,b** GEO (a) and MEO/IGSO (b) satellites of the regional BeiDou Navigation Satellite System (BDS-2). Reproduced with permission of Beijing Satellite Navigation Center

uncertainty of less than 5° [10.14]. To avoid the need for rapid yaw-slews near Sun–spacecraft–Earth collinearity, an orbit-normal attitude is employed, whenever the elevation of the Sun above the orbital plane is less than about 4° [10.36, 37]. The orbit-normal mode is also adopted for all BeiDou GEO satellites. Measured yaw angles provided in the onboard telemetry were found to match the nominal attitude at a level better than 0.5–1° [10.38].

### Satellite Payload

The RNSS navigation payload of the BeiDou satellites is mainly composed of the time and frequency subsystem as well as the navigation processor and signal generation unit.

The time and frequency subsystem is used to generate, maintain, and calibrate the primary reference frequency. It consists of Rubidium atomic frequency standards (RAFSs; Fig. 10.19) as well as supporting equipment such as a frequency multiplier, reference frequency synthesizer, and power-division/amplification network. The four clocks on each spacecraft comprise one active clock, a hot backup, and two cold backups. While the majority of clocks employed in the BDS-2 constellation is of indigenous origin, a limited amount of European RAFS has been procured for the BeiDou program and is used alongside the Chinese clocks on the various spacecraft [10.8, 14, 39]. The RAFS performance is further described in Sect. 10.3.2.

Following the modulation of the carrier with the ranging code and navigation message, the navigation signals are filtered and amplified in a traveling wave tube amplifier (TWTA). The phased-arrays antenna used for transmission of the signals covers a total of three frequency bands (B1, B2, and B3). Similar to GPS, a slightly higher gain in the off-boresight direction is used to compensate the increased distance and free-space loss for users at low elevations. The desired shape of the gain pattern is achieved by phase coherent combination of a central part with 6+1 helix antenna elements as well as an outer ring of 12 individual helix antennas.

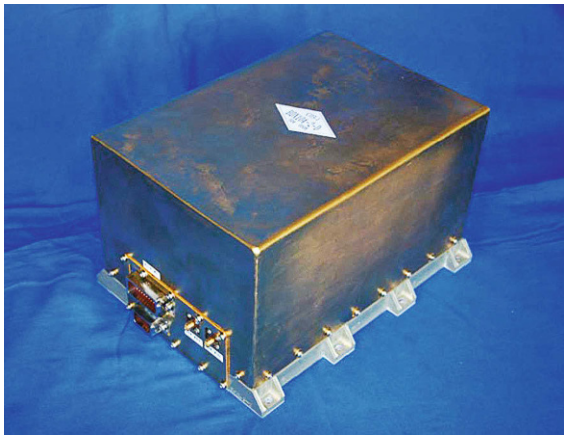

**Fig. 10.19** Rubidium atomic frequency standard for BeiDou-2 satellites (after [10.40]). Reproduced with permission of Beijing Satellite Navigation Center

The upload of navigation information from the ground is handled by the uploading and ranging segment, which comprises an L-band uploading receiver and a spread spectrum ranging receiver for calibration of the two-way time delay.

In addition to the RNSS payload, which is common to all BeiDou-2 spacecraft, the geostationary satellites are equipped with an RDSS payload comprising an L-band/C-band inbound transponder and C-band/S-band outbound transponders for BDS-1-type navigation and short messaging (Sect. 10.1). Furthermore, the GEO satellites host a C-band transponder for time synchronization and data transmission between the ground control center and monitoring stations.

All BDS-2 satellites are equipped with a laser retroreflector array (LRA), which is used for precise orbit determination, and to assist the time comparison between satellites and ground stations. The LRAs were developed by Shanghai Observatory and consist

of a planar array of individual prisms with a diameter of 33 mm. To account for the large distance, an LRA with a size of about $50 \times 40\,cm^2$ and a total of 90 prisms is used onboard of GEO and IGSO satellites, whereas a smaller, 42-prism LRA is sufficient for the MEO spacecraft. Furthermore, the LRAs are slightly tilted on the GEO satellites, to improve the return signal strength for satellite laser ranging stations in China [10.41].

Complementary to satellite laser ranging (SLR), various BeiDou MEO/IGSO satellites support laser time transfer (LTT) through a dedicated onboard detector and timer connected to the atomic clocks [10.42]. The LTT system developed by the Technical University of Prague and Shanghai Astronomical Observatory [10.43] is based on a single photon avalanche diode (SPAD) and enables measurements of the ground-to-satellite signal travel time with subnanosecond (i. e., a few centimeter-level) precision. Independent of GNSS observations or traditional two-way time transfer (TWTT) equipment, LTT enables the precise monitoring and synchronization of the atomic frequency standards of the BeiDou satellites.

### 10.2.5 Operational Control System

The Operational Control System (OCS) of BDS, like that of other GNSSs, is a key segment for BDS operation. The research on the OCS of BDS demonstration system started as early as the 1980s. The OCS of BDS-2 has been in place since 2007, when the first BDS-2 satellite was launched.

The OCS of BDS provides command, control and operation capabilities for the three kinds of satellite constellations. The main functions of BDS OCS are:

- To establish and maintain coordinate reference datum
- To maintain time reference datum
- To measure time synchronization between satellites and ground stations
- To manage precise orbit determination and prediction
- To predict satellite clock offset
- To deal with augmentation data
- To process RDSS information
- To monitor, process, and predict ionospheric delay
- To monitor integrity
- To upload and download navigation message.

The workflow of the OCS can be simply described as collecting data related to the satellites and the ground stations, processing and analyzing the collected data, managing communication between satellites and ground stations, uploading operational commands to satellites, and broadcasting navigation messages to the users.

In the course of the BDS development, the OCS has evolved along with the increased number of satellites and complexity of the constellation. While the OCS in BDS-1 only controlled the two GEO satellites and one backup, the OCS in BDS-2 has to control three different types of satellites (GEO, IGSO, and MEO). The information, which the OCS has to process, has been enlarged dramatically. In addition, the services have been extended from RDSS to RDSS plus RNSS. Finally, the calibration stations have been replaced by the modern monitoring stations. There are high database and calibration stations with barometric altimeter for positioning in the OCS of BDS-1. The OCS of the BDS-2, however, no longer needs high database and some of the new monitoring stations are equipped with laser ranging system.

At present, the OCS of BDS-2 is composed of 1 MCS, 7 monitoring stations of Type A, which are mainly used for orbit and ionospheric delay monitoring, 22 monitoring stations of Type B, which are mainly used for augmentation service and integrity service, and 2 time synchronization/uploading stations (Fig. 10.20).

The frequency bands of the BDS-2 RDSS feeder and service links are the same as in BDS-1. The L-band is used in the BDS-2 RNSS service such as navigation message upload and download (Fig 10.21).

The OCS performance in BDS-2 is reflected by the general accuracy of the satellite orbits, the time datum, and the coordinate datum. The orbit determination accuracy as obtained from the regional monitor network is about 0.2 m, 1.2 m, and 0.6 m in radial, along-track, and orbital normal (N) directions, respectively. Satellite laser range measurements agree with the determined orbits to better than 1 m root-mean-square (rms) [10.38]. The user ranging error (URE) of 2-h orbit prediction is 1 m for GEO satellite, while UREs of IGSO and MEO orbit prediction are about 1 m at 6 h and 5 m at 16 h, respectively. The accuracy of satellite clock prediction ranges from 1.4 ns at 2 h to 12 ns at 10 h. Finally, the accuracy of ionospheric delay corrections by the broadcast Klobuchar model is better than 75%.

The updating strategy of the OCS involves mainly six parts: the least-squares adjustment of a polynomial model for the satellite clock using robust estimation [10.8]; generation of the ephemeris, which is presently updated each hour; adjustment of the coefficients for the Klobuchar ionospheric model, which is based on data from 32 monitoring stations; performance of the RDSS two-way service with a response time of less than 1 s; transfer of RDSS messages of up to 120 Chinese characters of 14 bit each; and issue of integrity warnings with a response time of less than 8 s.

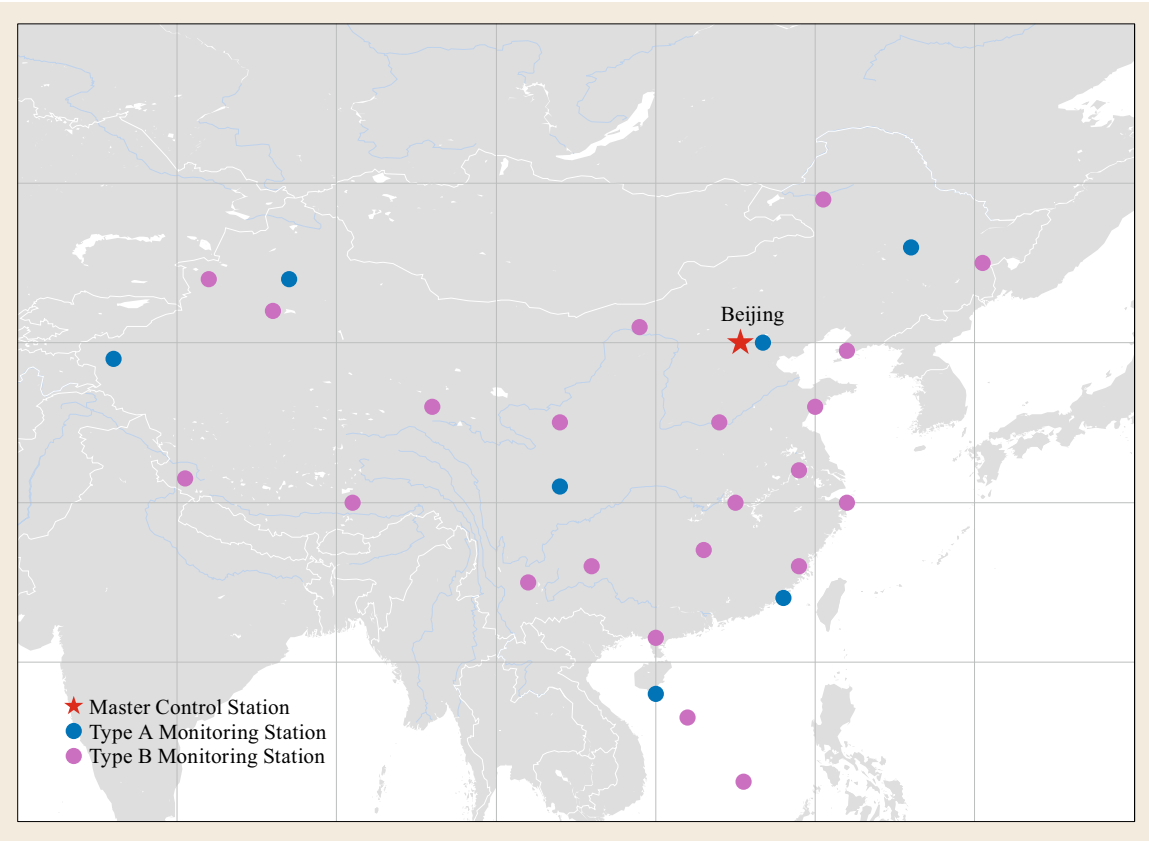

**Fig. 10.20** Location of BeiDou Master Control Station and the type-A/B monitoring stations. Information courtesy of Beijing Satellite Navigation Center

As part of the ongoing BeiDou evolution to a fully global service, the OCS will be adapted to operate the next-generation of BDS satellites (MEO/IGSO/GEO) in an optimal and robust manner. The ground segment will be extended to upload navigation messages for the entire satellite constellation, to maintain an interoperable time datum based on reliable, stable, and accurate clocks, and to maintain the BeiDou coordinate system in real time using multi-GNSS observations.

### 10.2.6 BeiDou Satellite-Based Augmentation System

Unlike other SBASs (Chap. 12), which are separated from the navigation satellite systems, BDS and its OCS include the BeiDou Satellite-based Augmentation Services (BDSBAS, [10.44]) as an integral part.

After the BDS-1 was established, the first-generation of BDSBAS (BDSBAS-1) was embedded in 2003. It broadcasted augmentations for the GPS navigation signal using the GEO satellites. More than 20 monitoring stations were established for tracking and integrity monitoring. In each monitoring station, three receivers and one atomic clock were assembled. All the collected monitoring data were transmitted to the MCS, where the precise satellite orbit, grid ionospheric corrections, and the equivalent satellite clock corrections were processed. The corresponding corrections, the user differential range error (UDRE), and grid ionospheric vertical error (GIVE) were generated.

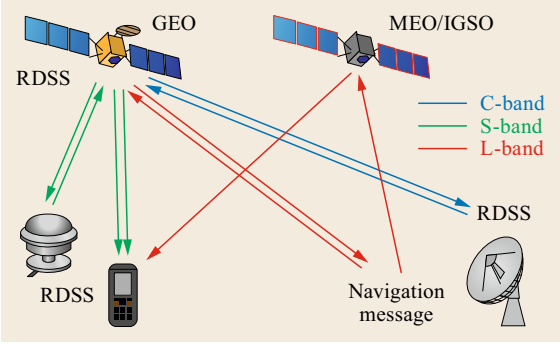

**Fig. 10.21** Signal flow of satellites and monitoring stations

It was shown that the precision of differential positioning based on GPS L1 C/A was about 3 m, and the integrity, continuity, and availability were also improved.

In BDS-2, the basic navigation service and augmentation service have also been integrated [10.11], for which technical tests were started in December 2012. The differences of the BDSBAS-1 and BDSBAS-2 are as follows:

- The augmentation service of only GPS L1 C/A in BDSBAS-1 has been extended to include both GPS L1 C/A and BDS B1I, and possibly Galileo and other GNSSs in the future
- The service coverage area is enlarged in BDSBAS-2, because all five GEO satellites broadcast the augmentation information, as opposed to only two GEO satellites in the BDSBAS-1
- In the BDSBAS-1, the integrity was not included in the augmentation information, but it is included in the BDSBAS-2
- The number of monitoring stations in BDSBAS-2 has been increased to more than 30
- Scalar *equivalent satellite clock errors* were derived and broadcast in BDSBAS-1, while satellite clock errors and satellite orbit errors are handled separately in the BDSBAS-2.

The workflow of calculating the equivalent satellite clock errors is as follows:

- Geometric distances between the satellite and monitoring stations are calculated based on the broadcast ephemeris and the satellite clock corrections as well as the known coordinates of the monitoring stations.
- The differences between the geometric distances and measured pseudoranges which are corrected by the ionospheric influences are calculated; thus, the pseudorange residuals are obtained.
- The equivalent satellite clock correction is obtained as the average of the residuals corresponding to this satellite.

The augmentation data of B1I signal are monitored by the monitoring stations and then the monitored data are transmitted to the MCS and processed there. The corrections of ephemeris, satellite clocks (SCs), and grid ionosphere as well as UDRE/GIVE and integrity information are generated in the MCS and modulated in the navigation message. The augmentation information together with the normal navigation message is uploaded to the GEO satellites through the communication link between the MCS and the GEO satellites, on which the augmentation messages are modulated into the downlink signals and broadcast to the users. In the new test, the precision of differential positioning by B1I of BDS is better than 3 m.

### 10.2.7 Coordinate Reference System

The BDC system is connected to the China Geodetic Coordinate System 2000 (CGCS2000), which itself is aligned to the International Terrestrial Reference System (ITRS) [10.45].

CGCS2000 is realized by the China Terrestrial Reference Frame (CTRF). The definition of this coordinate system follows the criteria outlined in the 1996 conventions [10.46] of the International Earth Rotation and Reference Systems Service (IERS). The next generation of CGCS may be renewed following the new IERS conventions issued in 2010 [10.47].

CGCS2000 is a right-handed, orthogonal system. Its origin is the center of the mass of the Earth including the oceans and the atmosphere. Its scale is that of the local Earth frame, in the meaning of a relativistic theory of gravitation [10.45, 46]. The orientation is initially given by the orientation of the Bureau International de l'Heure (BIH) Terrestrial System at 1984.0, and the time evolution of the orientation is ensured by using a no-net-rotation condition with respect to the horizontal tectonic motions over the whole Earth. The unit of the length is meter. Its $z$-axis is the direction of the IERS Reference Pole (IRP). This direction corresponds to the direction of the BIH conventional terrestrial pole (CTP) at epoch 1984.0. The $x$-axis is the intersection of the IERS reference meridian (IRM) and the plane passing through the origin and normal to the $z$-axis. The IRM is coincident with the BIH Zero Meridian at epoch 1984.0. The $y$-axis, finally, completes a right-handed, Earth-centered Earth-fixed (ECEF) orthogonal coordinate system.

The CGCS2000 origin also serves as the geometric center of the CGCS2000 ellipsoid and the $z$-axis serves as the rotational axis of this ellipsoid of revolution. Parameters of the CGCS2000 reference ellipsoid are listed in Table 10.5.

**Table 10.5** Fundamental parameters of the CGCS2000 system

| Parameter | Value |
|---|---|
| Semimajor axis | $a = 6\,378\,137.0$ m |
| Flattening | $f = 1/298.257222101$ |
| Gravitational coeff. (incl. atmosphere) | $GM_{\oplus} = 398\,600.4418 \cdot 10^9$ m$^3$/s$^2$ |
| Angular velocity | $\omega_{\oplus} = 7.292115 \cdot 10^{-5}$ rad/s |

### 10.2.8 Time System

The time reference for the BeiDou (Regional) Navigation Satellite System is BeiDou Time, BDT [10.8]. BDT is a continuous navigation time scale without leap seconds and with the SI second as its basic unit. BDT is commonly represented by the BeiDou week number (WN) and the seconds of week (SoW), ranging from 0 to 604 799. The zero point of BDT (i. e., WN = 0, SoW = 0) is January 1, 2006 (Sunday) UTC 00h 00m 00s. Similar to GPS and Galileo Time, BDT is aligned to UTC except for an integer second offset caused by the accumulated leapseconds.

The basic tasks of time keeping and timing service of the BeiDou system are to provide time and frequency signals in real time with continuity, stability, high accuracy, and reliability. Here, *continuity* reflects that time (frequency) is differentiable and the ability of the time system to run without interuption; *stability* refers to the variation of frequency over time and is commonly expressed by the Allan deviation (ADEV); *accuracy* means the consistency of the time (frequency) signal with the nominal value, which is often denoted by relative time bias (frequency bias); and *reliability* means the ability to provide the time and frequency signals under given conditions over the envisaged period of operation. In fact, there is no single atomic clock, which can provide time and frequency signals meeting the above criteria. Multiple Hydrogen maser clocks are, therefore, employed to collectively provide the BeiDou system time and frequency with the desired performance and reliability.

BDT is maintained by the Time and Frequency System (TFS) and aligned to the UTC realization UTC(BSNC) of the Beijing Satellite Navigation Center (BSNC). The TFS is mainly composed of five parts shown in Fig. 10.22. The clock ensemble (CE) comprises about 10 Hydrogen masers, which are used to form a *composite clock* in a robust estimation process. The intermeasurement element (IME) provides measurements of the original time and frequency signals from the clock ensemble and outputs the clock differences both in time and frequency in a regular pattern. The outer comparison element (OCE) provides the deviation of BDT from other time scales, especially from UTC and that of NTSC (National Timing Service Center of Chinese Academy of Science). The data processing element (DPE) carries out the calculation with the given algorithm based on all the information from IME and OCE, to give a relative uniform time scale, which is called BDT and works as the time reference for the whole navigation system. The signal generation element (SGE), finally, exerts frequency adjustments to the signals of the master clock (MC), and generates physical time and frequency signals for the MCS.

The algorithm performed in BDT calculation is well designed to form a good composite clock. The frequency offset, drift, and instability of each clock have been taken into account. The weights of clocks are determined by their Allan variances in which the frequency drift is taken off. The equivalent weights are also used based on the robust estimation principle [10.48, 49]. In order to be as consistent as possible with UTC, BDT may be steered with an interposed frequency adjustment after a period of time (more than 30 days) if the bias between the BDT and UTC is beyond the appointed threshold, but the quantity of the interposed frequency adjustment is not allowed to be more than $5 \cdot 10^{-15}$.

In order to align BDT with UTC, a time and frequency transfer chain between the MCS and the NTSC has been established. It makes use of two-way satellite time and frequency transfer (TWSTFT) via the geostationary BeiDou satellites as well as BDS and GPS common view (CV) observations [10.50]. Fiber chains between BSNC and National Institute of Metrology

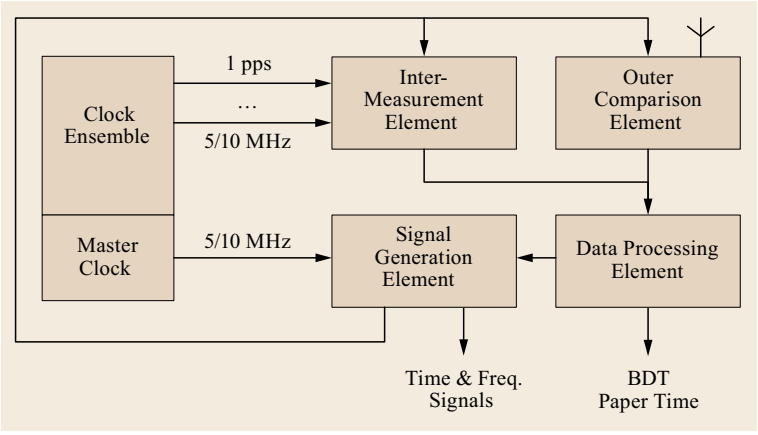

**Fig. 10.22** The composition of the time and frequency systems (after [10.8])

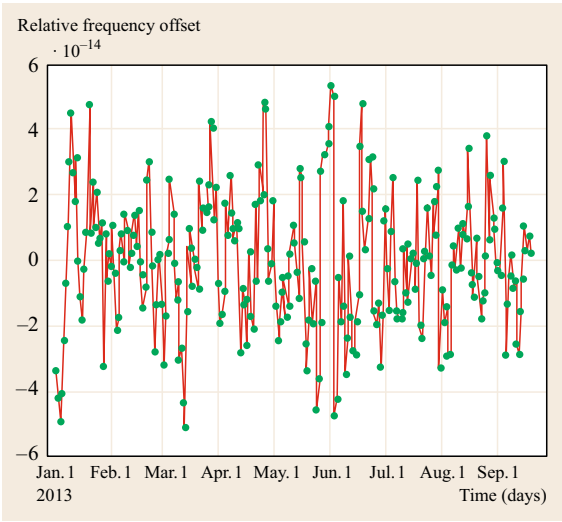

**Fig. 10.23** Frequency bias of BDT relative to UTC(BNSC)

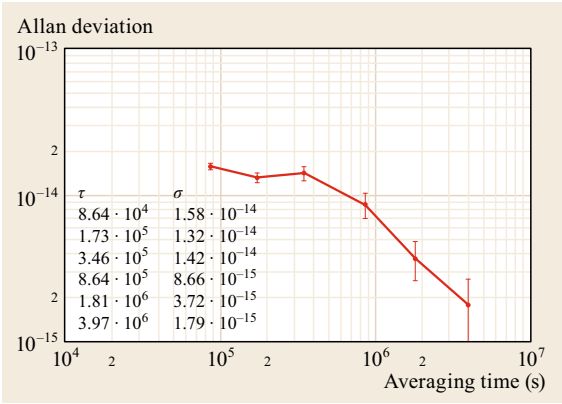

**Fig. 10.24** Frequency stability of BDT shown by ADEV

**Table 10.6** BeiDou system time performance

| Patameter | Value |
|---|---|
| Time (frequency) accuracy | $< 1.0 \cdot 10^{-13}$ |
| Time (frequency) stability | $< 2.0 \cdot 10^{-14}$ /1d |
| | $< 1.0 \cdot 10^{-14}$ /7d |
| Time deviation BDT-UTC | < 100 ns (modulo 1 s) |

(NIM) as well as BSNC and NTSC will be established. Apart from the indirect links, a direct determination of the BDT-UTC time offset through TWTFFT and GNSS CV measurements between the BSNC and the Bureau International des Poids et Mesures (BIPM) is under preparation. For further reference, Figs. 10.23 and 10.24 show the frequency offset and ADEV of BDT in comparison with the realization of UTC provided by the BSNC. The overall offset between BDT and UTC(BSNC) as well as UTC(NTSC) (which is closely aligned with UTC and GPS time) is shown in Figs. 10.25 and 10.26 over a 10-month period in 2013. All graphs are based on data of the BeiDou MCS.

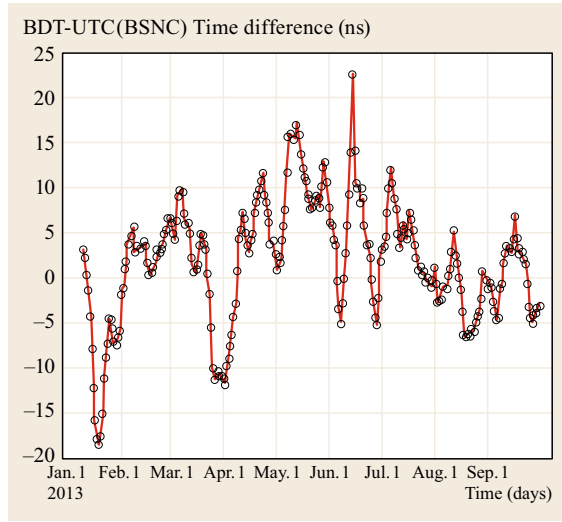

**Fig. 10.25** Difference of BeiDou system time with respect to UTC(BNSC)

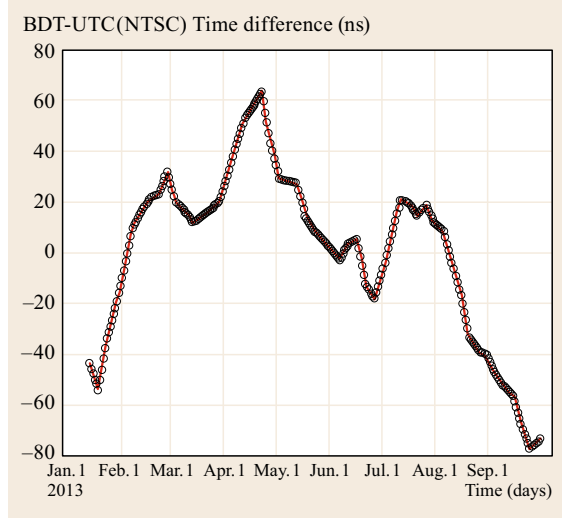

**Fig. 10.26** Difference of BeiDou system time with respect to UTC(NTSC)

The current performance of BDT is summarized in Table 10.6. It may be noted that the performance of BDT after running several years is not as good as its original state shown in [10.8].

## 10.3 Performance of BDS-2

During the construction of BDS-2, the performance of satellite clock, ranging, positioning accuracy, and reliability has been validated gradually. Tests performed by different communities [10.38, 51] demonstrate that the performance of BDS-2 in positioning, navigation, and timing (PNT) has reached or even exceeded the design specification.

### 10.3.1 Service Region

Broadcast ephemeris date for January 22–29, 2013 was used in [10.51] to assess the number of visible satellite and position dilution of precision (PDOP) [10.52, 53] for global users and the Asia-Pacific area shortly after the start of the regional operational service.

For areas between latitude 70°S–70°N and longitude 40°E–180°E, the number of visible satellite is more than five (Fig. 10.27) and the PDOP is smaller than 12 (Fig. 10.28), which satisfies the basic navigation requirements. More reliable navigation is available between latitude 60°S–60°N and longitude 70°E–150°E, where the number of visible satellite is more than seven and the PDOP is less than five. For areas between latitude 50°S–50°N and longitude 85°E–135°E, the number of visible satellite is finally larger than eight and the PDOP is between 2 and 3. Higher accuracy and a more reliable navigation service can be provided in these areas.

The number of visible satellites is above seven in China, and the availability (as defined by a PDOP value of less than <6) exceeds 97.5%. The service region of BeiDou system reaches the design requirement, and the availability of BeiDou system is close to 100% in the designated coverage area (Fig. 10.29).

### 10.3.2 Performance of Satellite Clocks

The performance of BeiDou SCs directly affects the accuracy and reliability of the users' positioning and navigation results. From the measurements between the BeiDou satellites and the ground uplink stations, the onboard clock offsets from BDT and the clock stabilities can be evaluated. In addition, the performance can also be evaluated through the satellite orbit and clock determination process. Results from both approaches are consistent with each other and show that the uncertainties of the measured satellite clock offsets are less than 2 ns.

In order to transmit correct navigation signals, the clock offsets are controlled within 1 ms. Between adjustments, the offset exhibits a dominant linear trend over time (i. e., a frequency offset) and a superimposed quadratic variation (i. e., a frequency drift), which is common for Rubidium atomic frequency standards. By means of an example, Fig. 10.30 shows clock offset variation of a geostationary BeiDou satellite after lin-

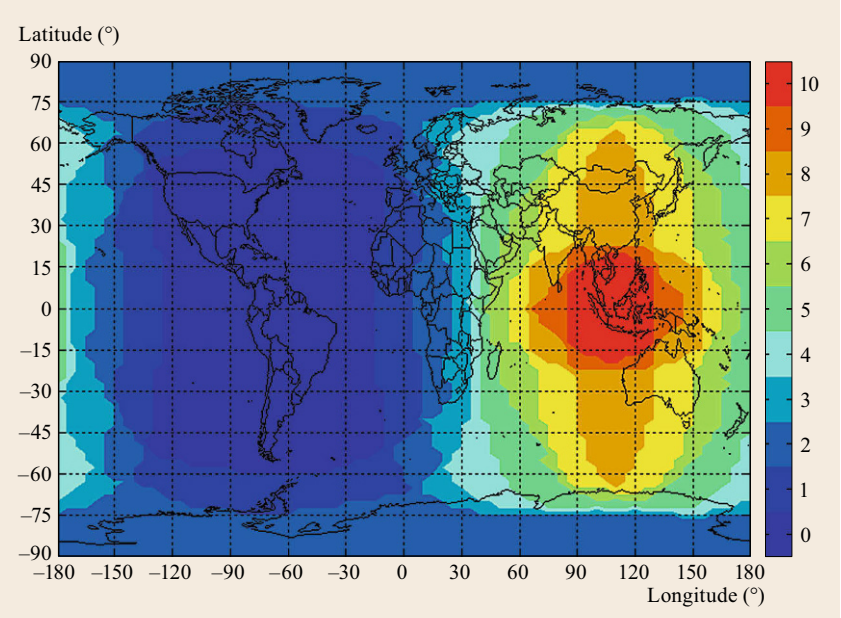

**Fig. 10.27** Number of visible BeiDou satellites (95%) in January 2013 considering a cut-off elevation of 5° (after [10.51])

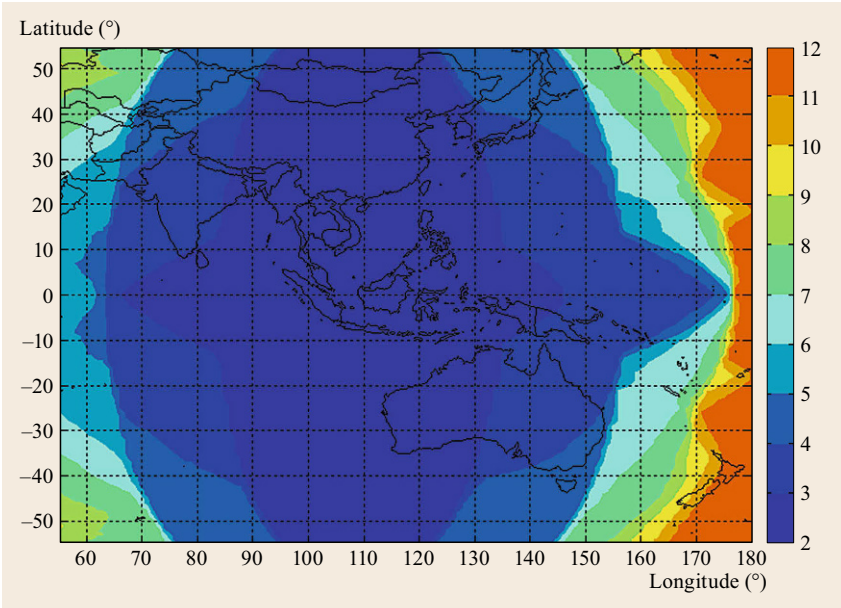

**Fig. 10.28** PDOP value (95%) in Asia-Pacific area (after [10.51])

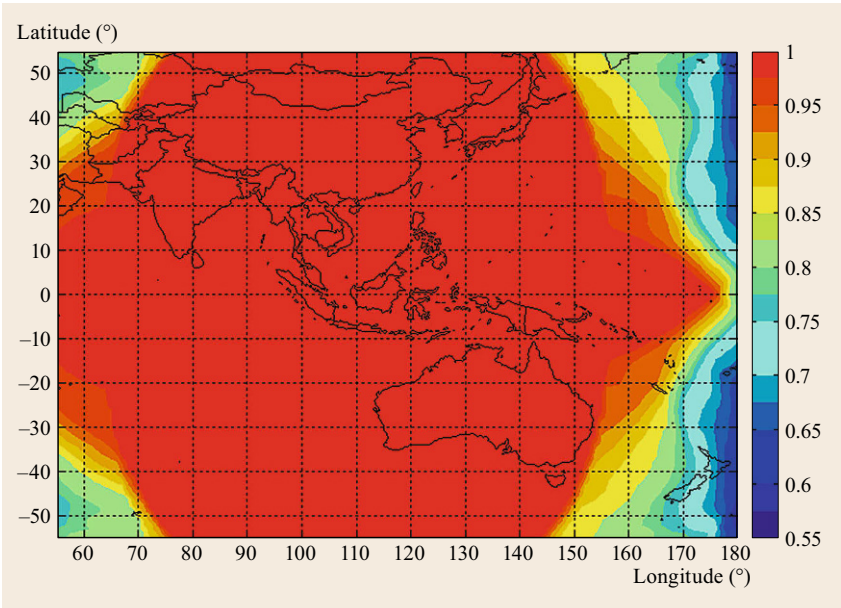

**Fig. 10.29** Availability of BeiDou in Asia-Pacific area (PDOP<6) (after [10.51])

ear and quadratic detrending over a 2-month interval in 2014.

Frequency offsets, drifts, and stabilities (i. e., ADEV for 1 –day intervals) as obtained from TWTT [10.54–56] between the satellites and the seven type-A monitoring stations are summarized in Table 10.7 for all BeiDou-2 satellites. The satellite clocks (SCs) from three different companies are symbolized as SC1, SC2, SC3, and SC4, respectively. As can be seen, the performances of the four clocks are comparable, only the accuracy of SC1 is slightly lower.

The frequency stability as obtained from the TWTT observations over time scales from 1s to several days is illustrated in Fig. 10.31. Here, ADEV values of $2–8 \cdot 10^{-14}$ over one day are obtained for most satellites, while a stability of about $5 \cdot 10^{-11}$ is obtained near 1 s. However, the measured ADEV is dominated by the noise of the employed ranging measurements and

**Table 10.7** Performance of BDS satellite clocks in April 2013. Satellites are identified by their type (*G*, *I*, and *M* for GEO, IGSO, and MEO satellites, respectively) as well as the PRN number of the transmitted signal. The last column indicates, which of the four clocks of each satellite was activated during the analysis period

| Sat | PRN | Frequency offset ($10^{-11}$) | Drift ($10^{-13}$ /d) | Stability (at 1 day) ($10^{-13}$) | Clock |
|---|---|---|---|---|---|
| G1 | C01 | +1.935 | –0.351 | 0.741 | SC3 |
| G6 | C02 | –4.147 | +2.299 | 3.671 | SC2 |
| G3 | C03 | +0.513 | +0.272 | 0.385 | SC2 |
| G4 | C04 | +0.769 | +0.279 | 1.123 | SC4 |
| G5 | C05 | –5.271 | –1.450 | 0.704 | SC1 |
| I1 | C06 | –1.208 | +0.060 | 1.792 | SC1 |
| I2 | C07 | +1.158 | +0.331 | 1.359 | SC3 |
| I3 | C08 | +0.890 | +0.698 | 2.698 | SC4 |
| I4 | C09 | +2.778 | –0.352 | 0.493 | SC1 |
| I5 | C10 | +2.929 | –0.752 | 0.702 | SC3 |
| M3 | C11 | +0.144 | –2.448 | 0.508 | SC1 |
| M4 | C12 | +1.047 | –0.445 | 0.187 | SC2 |
| M5 | C13 | +5.969 | +3.679 | 1.116 | SC1 |
| M6 | C14 | +0.858 | +5.752 | 2.412 | SC2 |

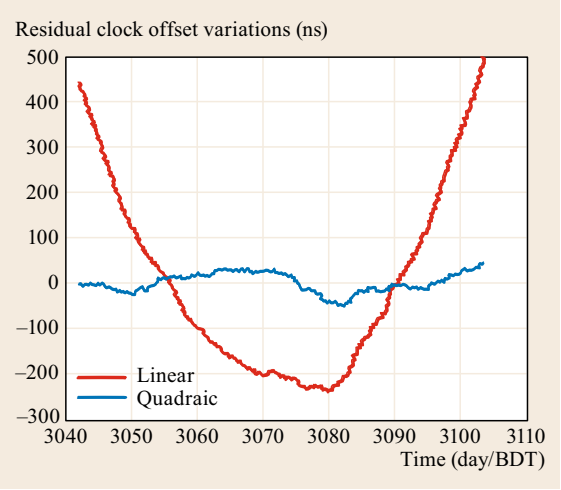

**Fig. 10.30** Residual clock offset variations of GEO-3 satellite clock after linear and quadratic detrending from May 1 to July 1, 2014

does not reflect the actual onboard clock performance below an averaging time of 1000 s [10.55]. Independent analyses of one-way carrier phase observations reported in [10.57] and [10.58] have actually demonstrated a short-term stability of about $0.5 \cdot 10^{-11}$ at 1 s intervals. Modified ADEVs of less than $1 \cdot 10^{-14}$ at daily time scales are reported in [10.59].

### 10.3.3 Positioning Performance

The BDS-2 positioning performance following the start of the regional service has been assessed in [10.51]. Single-point position solutions were obtained from measurements collected with a geodetic receiver in Beijing from December 27, 2012 to March 20, 2013 (including a 13-day unavailability due to receiver update and maintenance). The employed B1I pseudorange observations exhibit a noise level of 0.2–0.4 m and the BeiDou Klobuchar model was used for compensating ionospheric path delays. Observations were limited to a 5° cut-off elevation.

The resulting 95% ($2\sigma$) position errors relative to the surveyed antenna location are illustrated in Fig. 10.32 over the 71-day time interval. Complementary to these, the horizontal, vertical, and PDOP (95% values) of every day are shown in Fig. 10.33. On most days, the 95th percentiles of the horizontal, vertical, and total position error are smaller than 6 m, 10 m, and 12 m, respectively, which is in good accord with the open service performance specification [10.10].

The average single-point positioning accuracy of 10 m at a mean PDOP of 3 indicates a users range error (URE) of about 3.5 m $2\sigma$. This value includes user equipment related contributions (noise, multipath, and uncompensated atmospheric delays) as well as the SISRE, which characterizes the contribution of broadcast orbit and clock errors. Independent comparisons of broadcast ephemerides with postprocessed precise orbit and clock determination results indicate a SISRE value of about 1.5 m (rms) on average over the entire BDS-2 constellations [10.60–62].

Apart from standard positioning applications, BeiDou has found widespread use for precise point positioning in stand-alone or multiconstellation mode. Precise orbit and clock products for BeiDou are rou-

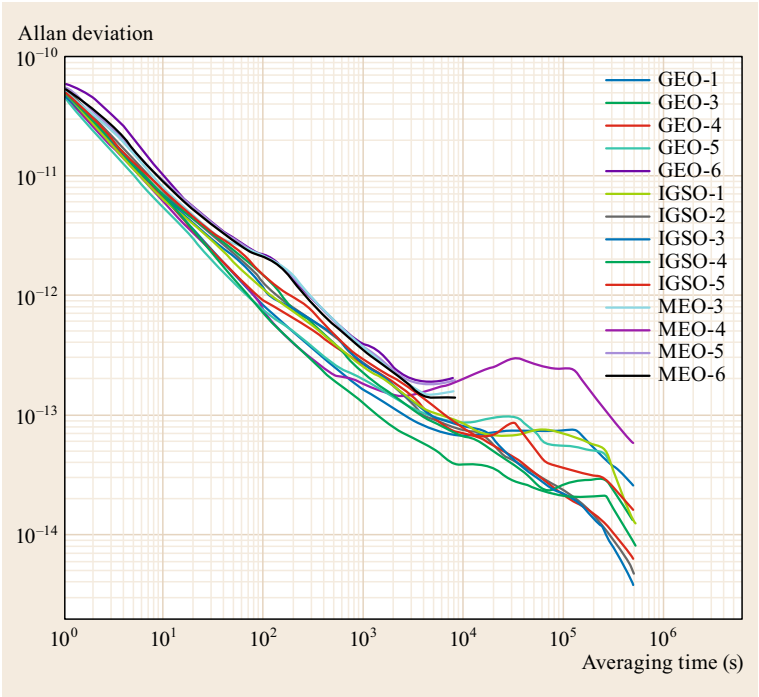

**Fig. 10.31** Frequency stability (ADEV) of BeiDou satellite clocks based on two-way time transfer (after [10.55])

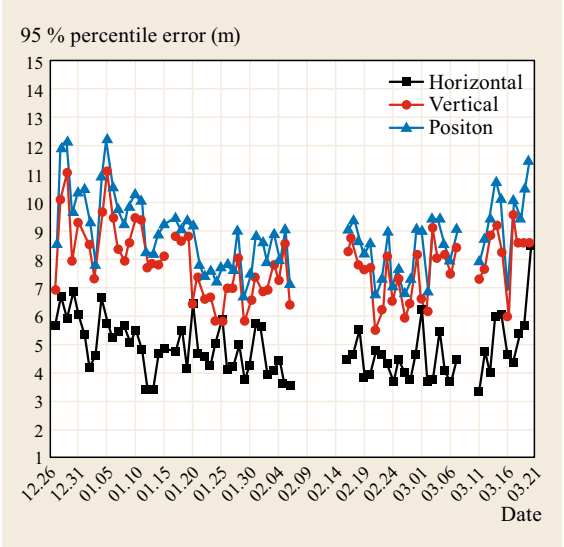

**Fig. 10.32** Positioning performance of BeiDou-only navigation in Beijing after start of the BDS-2 regional service from December 2012 to March 2013 (after [10.51])

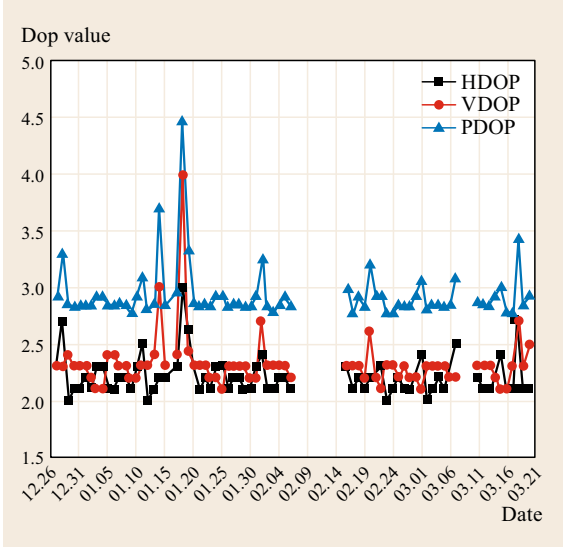

**Fig. 10.33** Horizontal (HDOP), vertical (HDOP) and PDOP of BDS-2 in Beijing between December 2012 and March 2013 (after [10.51])

tinely generated by a variety of analysis centers [10.59, 63, 64] and publicly made available through the International GNSS Service.

A comprehensive assessment of the BeiDou tracking performance and the associated positioning performance conducted in [10.51] is summarized in Fig. 10.34. Using a geodetic grade receiver, code and carrier phase observations with noise levels of about 10 cm and 0.5 mm, respectively, were collected. While the code-only position exhibit rms errors of 6 m and 10 m in horizontal (H) and up (U) directions, respectively, the cancellation of common errors in differential

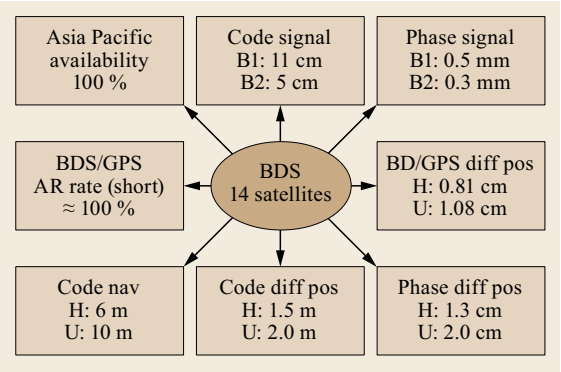

**Fig. 10.34** Performance of BDS-2 service in Beijing area (after [10.51]). See text for further explanations

code positioning enables an accuracy better than 2 m in each direction. Using carrier phase observations, differential positions with centimeter-level accuracy and an ambiguity resolution (AR) rate of about 100% are obtained at short baselines. Combining BDS and GPS, the carrier phase-based differential relative navigation accuracy can further be improved by a factor of 2.

### 10.3.4 Application Examples

Starting with the successful implementation of the BeiDou Navigation Satellite Demonstration System in 2003, BDS has been used for a wide range of applications and created substantial social and economic benefits [10.4]. BeiDou terminals and receivers developed by Chinese industry are employed for land and maritime navigation, provide precise timing for critical infrastructure, contribute to weather services, and are widely employed for emergency services. Prominent examples highlighting the benefits of BeiDou for the Chinese society include the use of BDS navigation during the Beijing Olympic Games and the Shanghai World Expo as well as as BDS navigation and communication in earthquake and snow disaster relief.

Use of the BeiDou Navigation Satellite System in the transportation sector has been promoted through pilot projects such as the Demonstration System of Monitoring Management Services in Priority Transportation, the Highway Infrastructure Safety Monitoring System [10.65, 66], and School Bus Safety Monitoring [10.67]. In the maritime sector, an integrated information service platform has been established to provide vessel localization and monitoring, rescue and information services as well as harbor access management for fishing boats [10.4, 68].

Apart from the navigation related applictaions, BeiDou is an important element for the reliable distribution of precise time information. Key technologies such as long-distance fiber technology and an integrated satellite-based timing system have been developed as part of the BeiDou two-way timing demonstration program [10.69, 70]. Similarly, a pilot project for power system time synchronization provided the basis for monitoring and protection of electric power grids [10.71].

The pilot project for *Monitoring and Warning in Atmospheric, Oceanic and Space* has addressed the automatic data transmission among China's meteorological stations and a real-time hydrological monitoring system has been established to support flood and drought control [10.4]. Further studies in this field include the assessment of precipitable water vapor from ground-based BeiDou observations in a precise point positioning approach [10.72] as well as the estimation of typhoon wind speeds using reflected signals from BeiDou GEO satellites and the transfer of related information using the BeiDou short message mode [10.73].

BeiDou also plays a vital role in diverse forms of emergency and disaster relief services. Among others, forest fire monitoring terminals based on BDS have been designed and produced by Chinese industry [10.74]. They have been successfully used in a forest fire prevention system [10.75], which benefits from the combination of the BeiDou positioning and short message communication services. This unique feature of BeiDou is also utilized within the nationwide disaster relief management system, where BeiDou has greatly improved the efficiency of emergency operations and decision-making processes [10.4, 76, 77].

Finally, with the ongoing proliferation of navigation satellite systems, BeiDou has become an important contributor to multi-GNSS. With the availability of more satellites and signals, precision and reliability of parameter estimation improves, as well as convergence times, position availability and robustness of ambiguity resolution [10.78–80].

## 10.4 BeiDou (Global) Navigation Satellite System

The BeiDou Navigation Satellite System with global coverage (BDS-3) will be completed by 2020. The space constellation will consist of five GEO satellites (positioned at 58.75°E, 80°E, 110.5°E, 140°E, and 160°E) as well as as 27 MEO satellites and three IGSO satellites. The current satellites will be a part of the

constellation that forms the BeiDou global navigation satellite system. Future MEO and IGSO satellites will have the same orbit as the current ones, that is, they will be placed in orbits with an inclination of 55° at altitudes of 21 500 and 36 000 km, respectively. The three IGSO satellites orbit the Earth in three different planes but exhibit a common ground track with its ascending node at 118°E.

BDS-3 will provide an open service and an authorized service in four frequency bands, including B1 (1559–1610 MHz), B2 (1164–1219 MHz), and B3 (1240–1300 MHz) with center frequencies of 1575.42 MHz, 1191.795 MHz, and 1268.52 MHz. A new S-band signal, Bs (2483.5–2500 MHz), is also broadcasted by the newly launched satellites. Compared to the regional BeiDou system, new and advanced signal structures are employed for better performance, compatibility, and interoperability with other GNSSs [10.81]. Key characteristics of these signals as presented in [10.82–84] are summarized in the following.

The B1 frequency has two signals, named B1-A and B1-C. B1-A is an authorized signal and employs a BOC(14,2) binary offset carrier modulation. The open service B1-C signal, in contrast, utilizes a MBOC(6,1,1/11) multiplexed binary offset carrier modulation. It consists of two components, namely the B1-CD data channel and the B1-CP pilot channel, which are transmitted in phase quadrature. The B1-CD component is modulated with a 50 bps (100 sps) binary navigation data stream.

On the B2 frequency, an AltBOC(15,10) modulation is used, which generates two side lobes at 1176.45 MHz (B2a) and 1207.14 MHz (B2b), respectively, and comprises four individual signal components for the open service. B2a consists of a data channel (B2a-D) and a pilot channel (B2a-P) in phase quadrature. The binary navigation data stream on B2a-D is transmitted at a rate of 25 bps (50 sps). Similarly, the upper sideband comprises the B2b-D data channel (with twice the data rate of the B2a-D channel) and a B2b-P pilot channel in phase quadrature.

In the B3-band, two authorized signals (B3 and B3-A) with a total of four individual components are transmitted at a common center frequency of 1268.52 MHz. The B3I and B3Q signals are modulated in quadrature phase shift keying (QPSK) with a 10.23 Mchips/s PRN code and a 500 bps binary navigation data stream. The B3-A signal is modulated in BOC(15,2.5) and consists of two components, B3-AD and B3-AP, in phase quadrature. The B3-AD data channel is modulated with a 50 bps (100 sps) binary navigation message.

The Bs signal, finally, is modulated in BPSK(8) and transmitted at a central frequency of 2492.028 MHz. It consists of two components, designated as Bs-D and Bs-P. The Bs-D component is modulated with a 50 bps (100 sps) binary navigation data stream.

Between March and September 2015, the first four satellites of the third generation BeiDou system (including two IGSO and two MEO satellites) have been launched. Initial test signals transmitted by these satellites for system validation purposes are described in [10.85]. As of December 2015, the final structure of the BDS-3 signals has not officially been published and minor modifications of the aforementioned signal properties might still be performed for further optimization. However, as China had claimed before, the ICD of the global open signal will be published as soon as possible once the new signal system assessment is accomplished [10.81].

## 10.5 Brief Introduction of CAPS

The Chinese Area Positioning System (CAPS) is an alternative, regional radio navigation system that has been developed since the early 2000s under the lead of the Chinese National Astronomical Observatories and the NTSC. It implements the concept of a *transponder satellite communication navigation and positioning system* [10.86] utilizing spare capacities of existing geosynchronous communication satellites. While traditional GNSS concepts are build on a dedicated satellite constellation, which generates and transmits the navigation signals in orbit, CAPS makes use of communication satellites, which relay navigation signals generated on ground to the users. The reuse of existing space infrastructure offers considerable cost savings along with great flexibility and redundancy [10.87–89].

CAPS has been involved in the testing of signals, time synchronization, and orbit determination of the BeiDou system. In the future, CAPS will contribute to the performance monitoring of BeiDou and serve as an experimental platform for the integration of navigation and communication services.

### 10.5.1 CAPS Concept and System Architecture

Similar to other spacebased navigation systems, the CAPS system can be divided into a space segment and a ground segment (Fig. 10.35).

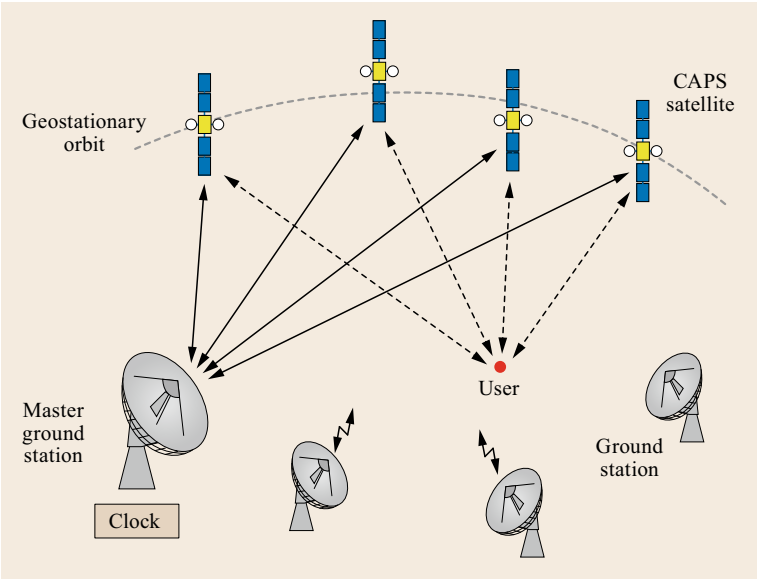

**Fig. 10.35** The CAPS system architecture comprises various satellite in near-geostationary orbit as well as a master ground station and multiple remote stations for orbit determination

The space segment is made up of multiple communications satellites in geosynchronous orbits, which offer continued visibility from the regional service area. Apart from satellites in a tightly controlled GEO, the CAPS includes decommissioned GEO (DGEO) satellites which no longer perform a north–south station keeping and attain a slightly inclined geosynchronous orbit (SIGSO). The use of highly inclined geosynchronous orbits has, furthermore, been suggested to improve the geometric distribution of visible satellites and the overall dilution of precision (DOP) in CAPS-based positioning [10.87]. The satellites do not require a dedicated navigation payload and high performance atomic clock, but merely a standard transponder to relay a signal between a ground based transmitter and a receiver. As such, CAPS offers great flexibility in the choice of satellites for its space segment.

The CAPS ground segment consists of a master ground station and various remote ground stations. All stations are equipped with large dish antennas for transmitting a modulated ranging signal to the satellites and can simultaneously receive signals from other stations returned through the satellites' transponders. The master station hosts the primary time and frequency reference. It generates the CAPS system time, which itself is synchronized to the realization of Universal Coordinated Time provided by the National Time Service Center (UTC(NTSC)) [10.90].

The master station also serves as the ground navigation center, which determines the orbits and transponder delays of the CAPS satellites from the measured measures transmission times between stations, and broadcasts this information to the user as part of the navigation message. In addition to orbit and clock information, the CAPS navigation message includes near real-time temperature and pressure data collected by meteorological stations across China. Along with barometers in the user terminals, this information can be used to infer the altitude of the user and to support a robust three-dimensional positioning.

Users receiving ranging signals from multiple CAPS satellites, can determine their position using the measured signal travel times, and, optionally, barometric height information. Even though, at first sight, CAPS resembles the first-generation BeiDou system (Sect. 10.1), it employs a completely passive navigation technique. No signals need to be returned by the user to the control center and all positions are computed in the end-user equipment rather than a central navigation facility.

CAPS utilizes C-band links for all signals exchanged between ground stations, satellites and users. This choice is partly driven by the wide availability of C-band transponder capacity on geostationary communication satellites, but also motivated by a general interest to avoid the crowded L-band spectrum for new navigation systems. As discussed in [10.91], the higher frequency induces increased free-space losses and a higher attenuation due to rainfall, but is substantially less affected by ionospheric path delays. Also, C-band supports the use of wide-band navigation signals with beneficial noise and multipath properties.

To avoid interference at the satellites, different frequencies need to be employed for the uplink and downlink. For ionospheric correction, the satellites of the CAPS trial system described in Sect. 10.5.3

transmit dual-frequency navigation signals at $f_{C1} = 4143.15\,\text{MHz}$ and $f_{C2} = 3826.02\,\text{MHz}$ to its users. The ground stations, in contrast, use carrier frequencies of $f_{C1} = 6368.15\,\text{MHz}$ and $f_{C2} = 6051.02\,\text{MHz}$ for the uplink. The uplink and downlink signals are separated by a constant offset of 2225 MHz, which is generated by a local oscillator onboard the satellites [10.92]. Since the onboard oscillator exhibits only a moderate stability, an active alignment of the uplink frequency is performed in the master station to compensate the frequency shift of the transponder. In this way, CAPS can also be used to determine the user velocity based on observed Doppler shifts at the receiver.

Through the inherent combination of navigation and communication, CAPS offers unique advantages over traditional navigation-only satellite systems. Possible applications of these features include the provision of differential corrections and integrity information but also various forms of search and rescue or disaster management services. The design and application of a CAPS user-terminal supporting joint navigation and communication functions for land and marine use is, for example, discussed in [10.93].

### 10.5.2 Positioning Principle of CAPS

Navigation as well as orbit determination and time synchronization in the CAPS are performed through measurements of signal travel times between the transmitting ground station and the user receiver. The signal path involves an uplink from the ground station at $\boldsymbol{r}_g$ to the transponding satellite at $\boldsymbol{r}_s$ and a subsequent downlink to the user at $\boldsymbol{r}_u$. Denoting the transmit and receive times by $t_g$ and $t_u$, respectively, the two-leg pseudorange is given by

$$\begin{aligned} p_{gsu} &= c\cdot(t_u + dt_u - t_g) \\ &= ||\boldsymbol{r}_s - \boldsymbol{r}_g|| + ||\boldsymbol{r}_u - \boldsymbol{r}_s|| \\ &\quad + c\tau_s + cdt_u + T_{gs} + T_{su}\,. \end{aligned} \tag{10.9}$$

Here, $\tau_s$ is the satellite transponder delay and $dt_u$ denotes the offset of the receiver clock from CAPS system time, which is defined by the master ground station. The tropospheric delays of the uplink and downlink paths are denoted by $T_{gs}$ and $T_{su}$, respectively. They can be taken into account through meteorological measurements at the ground station and tropospheric models for the receiver location. Ionospheric delays are eliminated through the use of a ionosphere-free dual-frequency combination and have, therefore, been ignored in the pseudorange model.

Equation (10.9) describes the basic relation among the measured signal travel times, the satellite, and station coordinates as well as the user position and clock offset. Depending on the specific application, different alternative formulations can be employed. First, the relations

$$\begin{aligned} p_{gsg} &= 2||\boldsymbol{r}_s - \boldsymbol{r}_g|| + c\tau_s + 2T_{gs} \\ p_{gsg'} &= ||\boldsymbol{r}_s - \boldsymbol{r}_g|| + ||\boldsymbol{r}_{g'} - \boldsymbol{r}_s|| \\ &\quad + c\tau_s + cdt_{g'} + T_{gs} + T_{sg'} \end{aligned} \tag{10.10}$$

are obtained for pseudorange observations collected by the master ground station as well as pseudorange observations between the master station (g) and the remote ground stations (g′). These can essentially be used to measure the instantaneous distance between each station and the satellite, and also to determine the three-dimensional satellite position. They also enable calibration of the satellite transponder delay and (by comparison of $p_{gsg'}$ and $p_{g'sg}$) a clock synchronization of the remote stations with the master ground station.

Second, (10.9) may be rephrased as

$$\begin{aligned} p_{su} &= p_{gsu} - c\cdot\tau_{VCLK} \\ &= ||\boldsymbol{r}_u - \boldsymbol{r}_s|| + cdt_u + T_{su}\,. \end{aligned} \tag{10.11}$$

Within this *virtual clock* (VCLK) concept [10.94]

$$\begin{aligned} c\cdot\tau_{VCLK} &= c\cdot(t_s - t_g) \\ &= ||\boldsymbol{r}_s - \boldsymbol{r}_g|| + c\tau_s + T_{gs}\,. \end{aligned} \tag{10.12}$$

denotes the difference between the uplink time $t_g$ at the ground station and the time $t_s$ of retransmission at the satellite. The VLCK correction is determined at the ground station from the known satellite orbit and calibrated time delays. It is then transmitted to the user via the CAPS navigation message and can be used to remove the uplink contribution from the measured pseudorange. As a result, the measurement model (10.11) attains the well-known form of traditional navigation satellite systems using one-way pseudorange observations. The user position and receiver clock offset can then be determined from a minimum of four corrected pseudorange observations. While a closed-form solution is possible for exactly four observations, the measurement model is commonly linearized with respect to the user coordinates and solved in an iterative manner.

Due to the regional distribution of the ground stations as well as the large distance and small orbital inclinations of the near-geostationary satellites, CAPS suffers from an unfavorable dilution of precision (DOP) as compared to traditional GNSSs. The use of barometric measurements is, therefore, considered as a pseudo-observation to better constrain the user position [10.95].

Making use of a barometer in the user terminal as well as broadcast meteorological data (ground pressure and temperature) for the region of interest, the receiver's height above the reference ellipsoid can be determined with an accuracy ranging from 3–5 m for terrestrial users to 10–20 m for aviation users [10.90].

### 10.5.3 Trial CAPS System

Following the governmental approval in 2005, a trial system was established in the course of two years at a cost of about 20 million USD to validate the working principle and performance of the CAPS.

The trial constellation consists of two GEO satellites (Zhongwei/ChinaStar-1 and Sinosat-1) located at 87.5°E and 110.5°E, as well as two decommissioned GEOs (Apstar-1A and Apstar-1), located at 130°E and 142°E, respectively. The master ground station of the CAPS prototype is located at Lintong in central China and hosts a total of six 7 m antennas for uplink and downlink to/from the geosynchronous satellites [10.89]. Four additional ground stations at Urumqi, Shanghai, Changchun, and Kunming provide the necessary measurements for orbit determination.

Each of the two carriers (C1 and C2) is modulated with two ranging signals namely a coarse-and-acquisition (C/A) with a 1.023 MHz chipping rate and an encrypted precise (P) code at 10.23 MHz [10.90, 96]. The CAPS navigation message is transmitted at a rate of 50 bps and comprises 44 frames with a length of 1500 bits.

Static and dynamic performance tests were performed in various regions throughout the China mainland. In addition to the actual navigation signals, barometric altimetry is employed as a virtual satellite. Following [10.87], horizontal positioning accuracies of 15–25 m and 5–10 m were achieved using the coarse and precise ranging signals, respectively, while the velocity accuracy attained values in the range of 0.1–0.3 m/s.

As of 2015, this system is used as a preliminary operational system, and a complete system with three GEO, three DGEO, and three IGSO is pursued.

*Acknowledgments.* The authors are indebted to Dr. Li LIU, Dr. Zhiwu CAI, Ms. Jinxian ZHAO, and Ms. Xia GE of Beijing Satellite Navigation Center for their valuable assistance.

# 11. Regional Systems

Satoshi Kogure, A.S. Ganeshan, Oliver Montenbruck

Other than global positioning system (GPS), Russian global navigation satellite system (GLONASS), BeiDou, and Galileo, the regional navigation satellite systems (RNSS) aim to provide a regional service using a constellation of satellites in geostationary Earth orbits (GEO) and inclined geosynchronous orbits (IGSO). Two regional systems implemented in Asia will be introduced in this chapter.

The first one is the Japanese Quasi-Zenith Satellite System (QZSS), which was originally planned as an augmentation system to enhance GPS capability and performance in the area surrounding Japan. The other is the Indian Regional Navigation Satellite System (IRNSS, also known as NavIC for Navigation with Indian Constellation), which can provide an independent positioning, navigation, and timing (PNT) service over India and surrounding areas.

In this chapter, the concept of regional navigation satellite systems is first described. The combination of satellites in GEO and IGSO is a common idea to realize such a regional service platform with a low number of satellites. The orbital characteristics and geometry of the proposed RNSS constellations are explained before each RNSS is introduced in detail. Secondly, the detailed characteristics of both systems are described in the following sections. The system architecture, service provision including navigation signal properties and service performance to be provided, as well as the deployment plan or schedule are mentioned for each system. Additionally, initial demonstration results are presented.

Applications of global navigation satellite systems (GNSS) are getting more widespread and deeply penetrated into our daily life and economy. Having their own national space-based positioning, navigation, and timing (PNT) infrastructure has thus become a natural interest of many countries. Independent PNT services are an important aspect of national security and support economical growth through sharing the growing market of GNSS applications. However, it is quite difficult for most countries to deploy a fully global satellite navigation system, since this requires a high level of technologies in a broad variety of fields as well as a huge financial budget.

## 11.1 Concept of Regional Navigation Satellite Systems

As a minimum, a satellite navigation system requires simultaneous observations of four satellites to obtain precise position, velocity, and timing at the user location. If the system covers the entire surface of the Earth, several dozens of satellites are indispensable. One of the solutions for realizing a system with minimum cost thus consists in limiting the service area, that is, to establish not a *Global*, but a *Regional* Satellite Navigation System (RNSS).

The use of geosynchronous orbits (including both geostationary orbits, GEOs, and inclined geosynchronous orbits, IGSOs, as well as high eccentricity Earth orbits (HEOs)), which have the same or orbital period as the Earth's rotation (i. e., one sidereal day) or half this value, is the most effective way to establish an RNSS at the minimum number of satellites. In the early stage of European satellite navigation system studies, that is, prior to the decision for a global medium Earth orbit (MEO) constellation, the combination of GEO and HEO satellites in Molniya or Tundra orbit was considered as a candidate constellation for a regional system, which could later be extended to a fully global system [11.1]. Molniya orbits, which have a half sidereal day orbital period, were designed to provide long duration of visibility for a high latitude area including polar regions [11.2]. The Molniya satellite system has been used in the former Soviet Union as a communication satellite system since mid-1960. The Tundra orbit is a derived orbit, which has a one sidereal day orbital period, approximately 23h 56min. Use of IGSO satellites has also been considered as an alternative to traditional GEO satellites for various types of communication and navigation services over the contiguous United States [11.3, 4].

In Japan, the Communications Research Laboratory (CRL), which is the precursor of the current National Institute of Information and Communications Technology (NICT), proposed *Figure-8 satellites* for mobile communications as well as satellite navigation in the late 1990s. The *Figure-8 satellite* uses a circular IGSO and the footprint of the satellite draws a figure of eight on the Earth's surface [11.5]. Japanese industry made a proposal after the concept study for a Japanese Regional Navigation System (JRANS, [11.6]), and the Japan Aerospace Exploration Agency (JAXA) also investigated extension of the current Quasi-Zenith Satellite System (QZSS) to an RNSS in the early 2000s [11.7].

The performance of a satellite navigation system in terms of accuracy, availability, continuity, and integrity has a strong correlation with the number of satellites as well as the satellite geometry (as described by the so-called geometric dilution of precision, GDOP). The utilization of geosynchronous satellites is an effective choice for providing four or more satellites' visibility with a minimum number of satellites for a limited regional service area, since the satellites have good visibility and can be observed for a longer time period in the respective region.

Assuming that there are only four satellites in the sky, the best GDOP can be obtained under the condition that one satellite is located in the zenith and three others at $-19.47°$ elevation separated by $120°$ in the azimuth plane [11.8]. Obviously, this condition cannot be realized in practice and the designers of an RNSS system are required to allocate satellites in the constellation such as to obtain an optimum GDOP at all times throughout a desired service area [11.9].

In this chapter, two RNSSs are introduced in the following sections. To obtain an ideal satellite geometry throughout Japan, QZSS is using IGSO satellites in order to always put a satellite near the zenith, while GEO satellites are planned to be allocated for lower elevations in the future expansion. IRNSS/NavIC, on the other hand, has a different approach to obtain good geometry over the Indian subcontinent, which is located near the equator. Here, GEO satellites are visible near the zenith, while IGSO satellites cover lower elevations and provide the desired spacing in the azimuth plane.

## 11.2 Quasi-Zenith Satellite System

### 11.2.1 Overview

The QZSS is a regional space-based PNT system, which has been deployed by the Japanese government since 2003 [11.10]. At the beginning of the development, the primary intention was to augment the US GPS in Japan by a three-satellite constellation using IGSOs. The satellites in the constellation have the same orbital period as a satellite, that is, 23h 56min, but a higher orbital inclination and slight eccentricity. These orbital parameters were optimized for maintaining better visibility at high elevation angles in Japan. This is of particular interest for urban canyons and mountainous terrain, where navigation users cannot receive a suffi-

cient number of navigation signals from GPS satellites alone. Each of the three IGSO satellites in the constellation flies over Japan for a period of eight hours and at least one satellite provides navigation signals at more than 60° elevation.

The QZSS was named after these orbital characteristics. The first satellite of QZSS, known as QZS-1 or *Michibiki* (a nickname given in an open call by the public), was launched on September 11, 2010. The technical verification and application demonstrations were conducted successfully by the JAXA and other research institutes. Taking account of the successful results, the Japanese government announced on September 30, 2011 to establish a four-satellite QZSS constellation as a national infrastructure by the late 2010s, as well as to set the future goal of a seven-satellite constellation by around 2023 [11.11] to maintain an independent PNT capability at minimum cost.

The National Space Policy Secretariat (NSPS) within the Cabinet Office took responsibility for the deployment of the operational system. The procurement process for the establishment of the ground control segment and the service provision through 15 years from 2018 to 2033 as a Private Finance Initiative (PFI) project started in 2013. A group led by NEC Corporation was selected as service provider and QZSS Service Corporation (QSS) was established to implement the PFI project. As for the satellite procurement, Mitsubishi Electronic Corporation (MELCO) was awarded the manufacturing contract for three additional spacecraft.

The requirements for the operational QZSS define the following services [11.12, 13]:

- *GPS Complementary Service*: L1 C/A and L1C signals on L1 (1575.42 MHz MHz), L2C signal on L2 (1227.6 MHz), and L5 signal on L5 (1176.45 MHz) will be transmitted. Those signals have the highest interoperability with GPS and other GNSSs by using the same radio frequency as well as the same message structure and format as GPS.
- *GPS Augmentation Service*: Two types of the augmentation service will be provided. One is the submeter level augmentation service (SLAS) for code-phase positioning users and the other is the Centimeter Level Augmentation Service (CLAS) for carrier-phase positioning users.
- *Public Regulated Service*: Authorized users can access the dedicated public signal transmission service, which uses encryption and provides users with more signal security. In case the of GPS jamming or spoofing, the service can provide independent positioning and timing information.
- *Early Warning Service*: Using a special message type defined in the submeter level augmentation signal, short messages are to be transmitted for early warning in the case of natural disasters.
- *Message Communications Service*: A satellite communications link will be made available for safety confirmation among families and employees in companies just after natural disasters such as a huge earthquake. As part of the QZSS Safety Confirmation Service (Q-ANPI), the user-generated messages are relayed to the control center through a geostationary QZSS satellite and subsequently forwarded to their final destination by e-mail.

The above-mentioned services will start in the beginning of April 2018, following the launch of three additional QZSS satellites, which are scheduled for the 2017 time frame [11.11, 12]. At the time of writing (mid-2015), the system definition and total system design study are still ongoing. The following sections, therefore, describe the demonstration system for the first satellite *Michibiki* as a reference.

### 11.2.2 Constellation

The QZSS consists of a combination of IGSO and GEO satellites. For the basic four-satellite constellation, which is to be completed in 2018, three IGSOs and one GEO satellite will be adopted. All of these satellites have a $23^{h}56^{m}$ orbital period synchronized with the Earth's rotation period. Accordingly, the QZSS visibility conditions repeat after one sidereal day.

The three IGSO satellites are placed in three distinct orbital planes with a 120° offset in their respective right ascensions of the ascending node (RAAN). In addition, their arguments of latitude are also separated by 120°. This choice results in an identical groundtrack for all three satellites, while their equator crossing times differ by one-third of an orbital period. Accordingly, the satellites pass over the same region with an 8 h separation and offer a continuous 24/7 availability of one satellite at high elevation angles.

In order to optimize the visibility in the area surrounding Japan, the orbits have an inclination of $i = 43°$ as well as a slight eccentricity ($e = 0.075$). Its apogee is placed in the northern-most point of the orbit, that is, the argument of perigee is $\omega = 270°$. The RAAN and mean anomaly are selected such that the center longitude of the ground track is located at 135° East. Figure 11.1 shows the QZSS orbits in an inertial reference frame and its ground track relative to the surface of the Earth. As a result of the slight eccentricity and the specific choice of the perigee, the figure-of-eight ground track is not fully symmetric with respect to the equator. Due to the lower angular velocity near apogee, the satellites remain in the Northern Hemisphere for more than

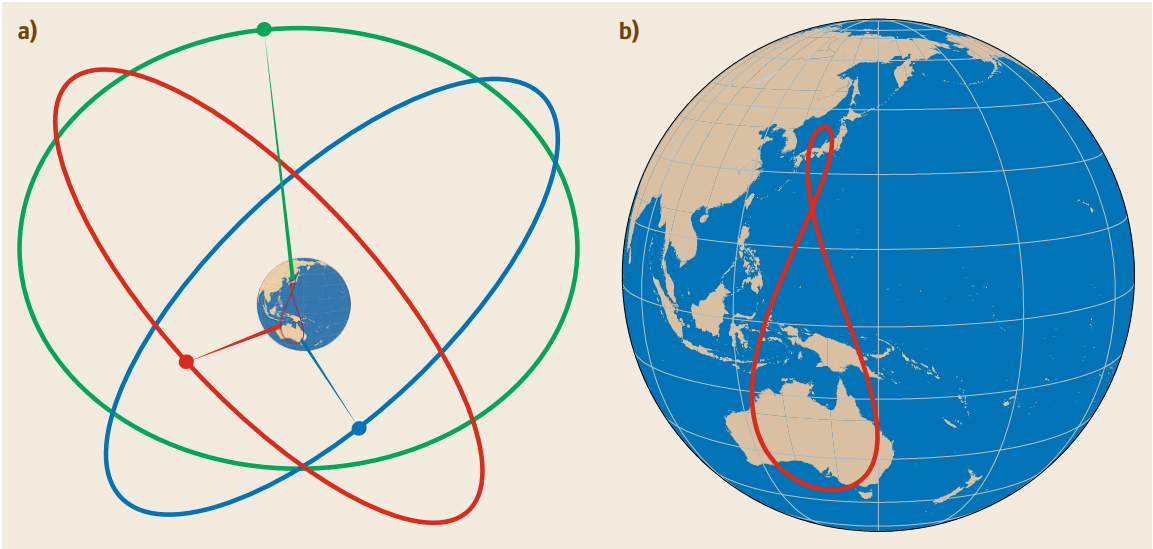

**Fig. 11.1a,b** QZSS IGSO constellation (a) (adapted from [11.14]) and ground track (b)

half of a day but quickly passes the perigee arc over Australia. As discussed in [11.15], this asymmetrical figure-8 orbit provides a good compromise in terms of service availability, link properties, and robustness between a fully symmetric orbit and a *tear-drop* orbit that have been considered as alternatives in the system design studies. The reference orbital elements for the QZSS IGSO constellation as initiated by *Michibiki* (QZS-1) are summarized in Table 11.1.

Due to Earth oblateness, the orbital plane of the QZSS IGSO satellites performs a slow precessional motion and the longitude of the ascending node decreases at an average rate of 3.65°/y. In addition, the orbits are subject to luni-solar perturbations, which induce long-term changes in the orientation of the orbital plane. In order to maintain the center longitude of the ground track within the desired deadband, small orbit correction maneuvers are performed approximately twice per year to adjust the mean motion of the QZSS satellites. Furthermore, out-of-plane maneuvers are required to compensate the secular changes of the orbital inclination [11.16].

**Table 11.1** QZSS orbital parameters (reference values; [11.14])

| Element | Value |
|---|---|
| Semimajor axis $a$ | 42 164 km (average) |
| Eccentricity $e$ | $0.075 \pm 0.015$ |
| Orbital inclination $i$ | $43° \pm 4°$ |
| Argument of perigee $\omega$ | $270° \pm 2°$ |
| Central long. of ground track $\bar{\lambda}$ | $135° \pm 5°$ East |
| RAAN spacing $\Delta\Omega$ | 120° |

Based on simulations of the long-term evolution of the QZS-1 orbit, the initial RAAN of this satellite has been chosen such as to minimize the inclination change over the expected lifetime. This has helped to notably reduce the required fuel for orbital corrections on the *Michibiki* spacecraft, but fixes the RAAN values as well as the total inclination change and fuel demand for the subsequent IGSO satellites.

### 11.2.3 Signals and Services

The QZSS satellites transmit a variety of navigation signals to support the applications and services introduced in Sect. 11.2.1. Four of these signals provide the basis of the GPS complementary service and are fully interoperable with legacy and modernized civil GPS signals in the L1 (1575.42 MHz), L2 (1227.60 MHz), and L5 (1176.45 MHz) frequency bands (Table 11.2). In addition, two augmentation signals for the SLAS and the CLAS are transmitted on L1 and E6 (1278.75 MHz), respectively, which provide error-correction messages for code-phase positioning and high-precision carrier-phase positioning. This subsection briefly summarizes the properties of these navigation signals. Further details of the QZS-1 signals are defined in the interface specification for QZSS users [11.14]. Signals and services launched in 2018 will be defined in a separate document [11.19–21].

Aside from the L-band navigation signals, QZSS GEO satellites will make use of S-band signals (near 2 GHz) for the Q-NAPI Safety Confirmation Service. This service will enable users to forward short safety

**Table 11.2** Overview of QZSS navigation signals [11.14] and planned modifications for the operational services starting in 2018 [11.11, 17–21]

| Signal | Channel | Band | Center frequency (MHz) | Minimum user received power (dBW) | Category | Modifications for operational service |
|---|---|---|---|---|---|---|
| L1-C/A | | L1 | 1575.42 | −158.5 | GPS interoperable signal | |
| L1C | Data channel | L1 | 1575.42 | −163.0 | GPS interoperable signal | |
| | Pilot channel | L1 | 1575.42 | −158.2 | GPS interoperable signal | |
| L2C | Time multiplexed[a] | L2 | 1227.60 | −160.0 (total) | GPS interoperable signal | |
| L5 | I channel | L5 | 1176.45 | −157.9 | GPS interoperable signal | Additional L5S signal for experimental use on separate signal |
| | Q channel | L5 | 1176.45 | −157.9 | GPS interoperable signal | |

Notes:
[a] The L2C and LEX signals employ interleaved bit streams for concurrent transmission of two independent ranging sequences on a common physical channel.
[b] The L5Sb augmentation signal will be made available from QZS-2 onward. The L1Sb signal will be provided from a GEO satellite in the QZSS constellation.

information when other communication links are unavailable in the case of a natural disaster.

### GPS Interoperable Signals

A primary motivation for the QZSS lies in the enhancement of the restricted GDOP of GPS-only navigation in urban-canyons and mountainous areas. The signals serving this *GPS Complementary Service* are designed to minimize any required modifications on the user equipment. Receivers shall be able to seamlessly acquire and track both GPS and QZSS signals, decode their navigation messages, and calculate user position, velocity, and time from the combination of GPS and QZSS observations.

In accord with the current and planned civil navigation signals of GPS, the QZSS transmit the legacy L1 C/A signal, the modernized civil L2C and L5 signals (supported by the GPS Block IIR-M and/or IIF satellites), as well as the L1C signal (to be available from GPS Block III onward). It may be noted that QZSS does not support the transmission of L1/L2 P(Y)-code signals, which are most widely used today for dual-frequency navigation by today's geodetic GPS receivers and serve as a basis for the clock offset determination of GPS satellites. This introduces minor conceptual differences in the handling of GPS and QZSS clock information and requires a proper consideration of intersignal biases by the user.

The technical parameters of these GPS-interoperable signals are intended to be the same as those of the corresponding GPS signals. This includes their radio-frequency (RF) properties as well as their navigation message structure and format as defined in the latest version of the GPS signal specifications (i. e., IS-GPS-200 [11.22] for L1C/A and L2C, IS-GPS-705 [11.23] for L5, and IS-GPS-800 [11.24] for L1C). In the case of the L1 C/A, L2C, and L5 signals, QZSS employs identical modulation schemes and code generators to GPS, but different pseudorandom noise (PRN) sequences. At present, PRN numbers 193–202 have been reserved by the GPS directorate for the transmission of GPS-like navigation signals by the QZSS constellation [11.25].

As a small difference between GPS and QZSS signal structures, QZS-1 uses a pure BOC(1,1) modulation [11.26] for the L1C signal instead of the modified binary offset carrier modulation (MBOC) that has been selected for GPS following the GPS/Galileo signal optimization efforts conducted by the United States and the European Union. Here, the pilot channel of the L1C signal is modulated with a BOC(1,1) subcarrier for 29 out of 33 code chips, whereas the remaining 4 of 33 chips are modulated with a BOC(6,1) waveform (Chap. 7 and [11.27]). In addition to the slightly different choice of the subcarrier, QZS-1 also uses a 90° phase shift between the L1C data and pilot channels [11.14], whereas both channels are phase aligned in GPS. For the new

Block II QZSS satellites a phase alignment fully consistent with GPS will be employed [11.19].

The joint transmission of three distinct L1 signal components (L1 C/A as well as L1C data and pilot) requires a special interplex modulation, which includes a so-called intermodulation (IM) product to achieve a constant signal power envelope irrespective of the individual signal and subcarrier states (Chap. 4). Following [11.28], the resulting signal at time $t$ can be described as

$$S(t) = (A_{\mathrm{L1CA}} S_{\mathrm{L1CA}} + A_{\mathrm{L1CD}} S_{\mathrm{L1CD}}) \cos(\omega t) + (A_{\mathrm{L1CP}} S_{\mathrm{L1CP}} + A_{\mathrm{IM}} S_{\mathrm{L1CP}} S_{\mathrm{L1CA}} S_{\mathrm{L1CAD}}) \sin(\omega t) \quad (11.1)$$

or

$$S(t) = A \sin\left(\omega t + S_{\mathrm{L1CP}} S_{\mathrm{L1CA}} \beta_1 + S_{\mathrm{L1CP}} \frac{\pi}{2} + S_{\mathrm{L1CP}} S_{\mathrm{L1CD}} \beta_2 + \frac{3}{2}\pi\right) \quad (11.2)$$

with

$$\beta_1 = \tan^{-1}\left(\frac{A_{\mathrm{L1CA}}}{A_{\mathrm{L1CP}}}\right) \quad \text{and}$$
$$\beta_2 = \tan^{-1}\left(\frac{A_{\mathrm{L1CD}}}{A_{\mathrm{L1CP}}}\right). \quad (11.3)$$

Here, $S_i = c_i\, s_i\, d_i = \pm 1$ with $i = \mathrm{L1CP}$, L1CD, and L1CP denoting the product of ranging code $c_i$, subcarrier $s_i$ (not on L1 C/A), and navigation data $d_i$ (not on L1C pilot) for the L1C pilot, L1C data, and L1 C/A-code signals. Furthermore, $A_i$ denotes the corresponding signal amplitudes and $\omega$ represents the L1 carrier frequency.

In accord with the relative signal powers given in Table 11.2, values of 44.2° and 30° have been adopted for the angles $\beta_1$ and $\beta_2$ in the QZS-1 interplex signal, respectively. They correspond to almost equal amplitudes of the C/A and L1C pilot component, and an L1 data channel amplitude that is roughly 40% smaller (and almost identical to the amplitude of the intermodulation product). The resulting in-phase/quadrature (IQ) constellation diagram is illustrated in Fig. 11.2.

The LNAV, CNAV, and CNAV2 navigation messages transmitted by QZSS as part of the L1 C/A, L2C/L5, and L1C signals, respectively, are designed for maximum communality with GPS. However, some unavoidable difference arise due to the different purpose and implementation of the QZSS. Among others, the different orbit of the QZSS satellites requires a different choice of reference values for the semimajor axis, eccentricity, inclination, and nodal drift in the almanac and ephemeris parameters. Also, some flags and

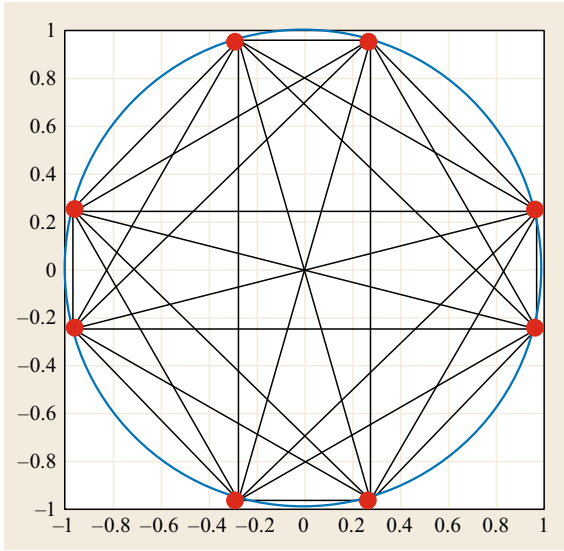

**Fig. 11.2** IQ diagram of the QZS-1 interplex signal comprising L1 C/A as well as the L1C data and pilot channels. Image credits: F. Antreich

signal-related parameters (e.g., group delay parameters) require a different content or interpretation than that in GPS. Finally, the QZSS exploits the flexibility of the civil navigation message (CNAV) and CNAV2 concept, by defining various new messages that are not required in a standalone navigation system. As an example, QZS-1 can provide retransmitted almanac, ionosphere, and time-offset parameters for the GPS satellites in addition to the native QZSS data [11.14].

Due to the specific characteristics of their orbit, the QZSS IGSO satellites are in permanent access of the master control station (MCS) and can be provided with updated navigation data on a rapid time scale. New clock and ephemeris data of QZS-1 are, for example, issued once every 15 min as compared to 2 h for GPS. Along with highly stable onboard clocks, this contributes to a very favorable signal-in-space range error of QZSS (Sect. 11.2.7).

The complete compatibility and interoperability between QZSS and GPS have been confirmed by GPS-QZSS Technical Working Group jointly established by the US and Japanese governments [11.29]. Here, compatibility refers to the fact that the two navigation systems will not interfere with each other in a harmful manner, while interoperability addresses the ability to jointly receive and use the signals of both systems in a single receiver.

### L1-SAIF Signal

Visibility restrictions in urban areas not only affect the tracking of GNSS satellites, but also likewise con-

strain the reception of ranging error corrections and integrity data from satellite-based augmentation systems (SBAS; Chap. 12). Traditionally, satellite-based augmentation system (SBAS) services are provided through geostationary satellites, which can host the SBAS transponder as a secondary payload and offer a continuous uplink capability from a fixed ground station. SBAS signals from geostationary satellites can well be received by aviation users with full-sky visibility, but are often unavailable for land mobile users due to their moderate elevation. A car running along an east–west street in an urban environment will commonly face severe signal interruptions, when buildings on the southern (or northern) side of the street obstruct the view to the SBAS satellite.

Due to its unique orbit, QZSS offers an ideal platform to relay differential GPS (DGPS) error-correction messages to mobile users in urban canyons. The continuous visibility of at least one high elevation satellite can overcome the aforementioned difficulties and users can obtain higher accuracy and reliability than normal standalone GPS navigation when using the augmentation signals.

The L1-SAIF (L1 submeter class augmentation with integrity function) signal design [11.14, 30] matches that of other SBAS signals and is based on a BPSK(1) modulation with a 1023-chip Gold-code ranging sequence of 1 ms duration. For the L1-SAIF signal, dedicated PRN numbers in the range of 183–192 have been reserved [11.25], which are different from the PRN used for the GPS-compatible ranging signals transmitted via the main L-band antenna. As an example, QZS-1 transmits standard navigation signals as PRN 193, but employs PRN 183 for the L1-SAIF signal.

The L1-SAIF signal is phase coherent with the L1 C/A and L1C signals but transmitted via a different antenna and amplifier to avoid an overly complex modulation scheme. The overall L1 spectrum and IQ constellation are presented in [11.31] based on signals analysis with a high-gain antenna.

In accord with the SBAS standard [11.32], the L1-SAIF employs a data message with a symbol rate of a 500 sps and a 1/2 forward error correction (FEC) yielding an effective data rate of 250 bps. Each message has a length of 250 bits including an 8 bit preamble, a 6 bit message identifier, 212 data bits, and a 24 bit cyclic redundancy check (CRC) field. For the provision of GPS range corrections as well as ionospheric delay and integrity information, the QZSS SAIF signal utilizes the same messages as traditional SBAS systems. This ensures good backward compatibility with existing SBAS and facilitates the build-up of L1-SAIF receivers from existing SBAS receivers.

On the other hand, QZSS-specific messages are required to provide QZSS orbit information in the SAIF data stream to support a self-contained ranging function independent of the GPS-type navigation signals. Due to the higher orbital inclination and eccentricity, the standard GEO ephemeris message (message type MT9) cannot be used with QZSS and is substituted by a new MT58 ephemeris message. Its concept is motivated by the GLONASS orbit model (Sect. 3.3.3) and the message provides a Cartesian state vector as well as perturbational accelerations. These data are then used to numerically integrate the QZSS trajectory from the given initial conditions. Aside from the QZSS ephemeris message, SAIF-specific messages are also defined for tropospheric corrections, intersignal biases, and selected other parameters. A comprehensive description of these messages is provided in the QZSS signal interface control document (ICD) [11.14].

Correction data transmitted in the L1-SAIF signal are generated in real-time based on observations of the Japanese GPS Earth Observation Network System (GEONET). This network of continuously operating reference stations (CORS) is operated by the Geospatial Information Authority of Japan (GSI) and comprises GNSS receivers in more than 1200 locations throughout Japan. For QZS-1, data from the GEONET monitoring stations are processed at the L1-SAIF Master Station (L1SMS) hosted by the Electronic Navigation Research Institute (ENRI) in Tokyo. The resulting SAIF messages are then forwarded to JAXA's MCS for uplink to the satellite [11.33, 34].

The SLAS offered by QZSS aims at providing DGPS correction messages to users throughout Japan. The SLAS correction data are designed for single-frequency GPS L1 C/A-code users and enable submeter positioning accuracy [11.35, 36], which represents a notable improvement over the GPS Standard Positioning Service (SPS) performance (typically 5 m three-dimensional (3-D) rms).

### LEX Signal

Besides the L1, L2, and L5 frequencies utilized by GPS, QZSS also transmits navigation signals in the Galileo E6-band centered at 1278.75 MHz. As indicated in Table 11.2, these signals serve the future Public Regulated Service (PRS) and the centimeter level augmentation service (CLAS). Both services will gradually be implemented along with the build-up of the QZSS IGSO and GEO constellation, but an *L-band EXperimental* (LEX) signal was already transmitted on QZS-1 to conduct preparatory experiments and technology demonstrations for the CLAS. The main characteristic of this signal is its high data transmission rate of 2 kbps,

which is realized through code shift keying (CSK) modulation.

The LEX (or E6b) baseband signal is generated with a chipping rate of 5.115 MChip/s. Its spectrum matches that of a BPSK(5) signal with a 5 Mcps PRN code, but is actually generated by interleaving two 2.5575 Mcps bit streams on a chip-by-chip basis [11.14, 37]. These comprise

- A 4 ms PRN short code with a length of 10 230 chips that is modulated by means of CSK with the Reed–Solomon (RS)-encoded navigation message, and
- A 410 ms PRN long code with a length of 1 048 575 chips that is modulated by square wave with a period of 820 ms beginning from 0 (010101...).

Similar to the GPS/QZSS L2C signal, a data channel and a pilot channel are thus combined in the LEX signal using time multiplexing. An overview of the signal generation is provided in Fig. 11.3.

The PRN codes for both channels are Kasami sequences [11.38], which are generated from the combination of a 20 bit and a 10 bit linear feedback shift register (LFSR) [11.14]. While the 10 bit register is common to both code generators, distinct 20 bit registers (albeit with identical feedback taps) are used for the two PRN codes. While the short code is truncated at 10 230 chips, the length of the long code corresponds to the maximum length sequence of a 20 bit LFSR. However, the long code is reset once at the start of a week, since the 820 ms repeat rate is not commensurable with the length of a day or week.

The LEX navigation message transmitted via the data channel has a total length of 2000 bits, and one complete message is transmitted each second. The LEX message is composed of a 49 bit header (including the 32 bit preamble as well as the PRN number (8 bits), the message number (8 bits), and a 1 bit alert flag), a 1695 bit data part and 256 parity bits. The latter are based on Reed–Solomon (RS) encoding of the data bits and the 17 header bits that follow the preamble [11.14]. With the given number of parity bits, errors in up to 16 8-bit data-plus-header symbols can be corrected before an unrecoverable frame error occurs. Following [11.39], a zero frame error rate was achieved above 10° elevation during LEX trials conducted in the Tokyo area. For a different receiver, using the L1 C/A-code signal as a reference for the CSK demodulation, a 90% probability of proper frame decoding is reported in [11.37, 40] for observations above 40° elevation based on LEX trials conducted in Melbourne, Australia.

The data rate (2 kbps) of the LEX navigation message is substantially higher than that of traditional direct-sequence spread spectrum (DSSS) signals used for GNSS navigation. At the 4 ms code duration, such signals could at best support a data rate of 250 bps. The exceptional data rate is achieved through the use of CSK modulation, which effectively treats the data component of the LEX signal as a communication channel [11.41].

The concept of CSK modulation is illustrated in Fig. 11.4. Considering a navigation message made up of a series of 8 bit symbols, the CSK modulation creates a shifted copy of the native PRN sequence, where the byte value $N_i$ of the $i$th data symbol specifies the number of chips, by which the PRN code sequence is shifted during the given data symbol. In the case of QZSS, the duration of a data symbol matches the 4 ms code period. The CSK modulation thus allows the transmission of 8 bits during one code period rather than a single bit in traditional DSSS signals.

While the CSK modulation is clearly favorable in terms of the data rate, it necessitates the availability of an independent pilot channel for synchronization, since

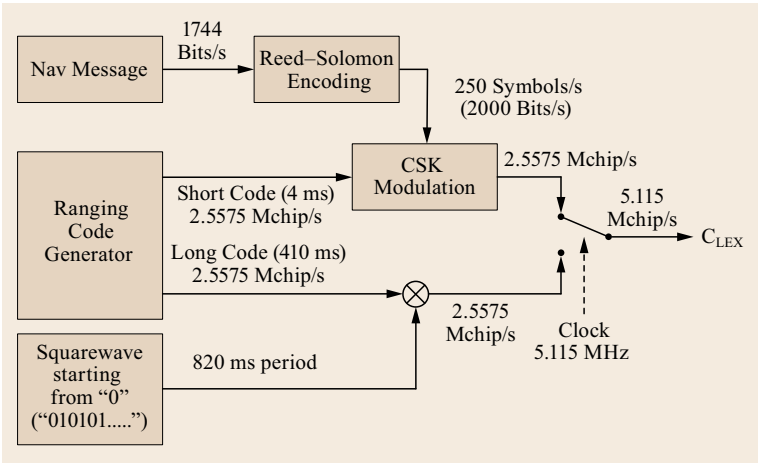

**Fig. 11.3** QZSS LEX signal generation [11.14]

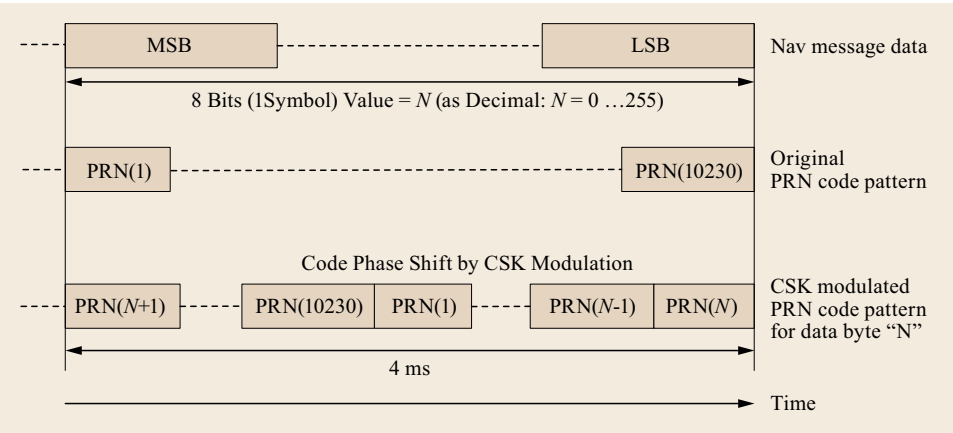

**Fig. 11.4** CSK modulation of the LEX data channel [11.14]

the cyclically shifted PRN code of the data channel would otherwise be very difficult to acquire [11.41]. Also, the CSK demodulation is more demanding in terms of receiver architecture than that of conventional DSSS signals and only a very limited number of receivers presently (2015) support a data extraction from the LEX signal.

The high data rate of the LEX signal provides the basis for the dissemination of real-time correction data for carrier-phase-based precise point positioning (PPP; Chap. 25). During the QZS-1 demonstration phase, different augmentation methods were tested by several Japanese organizations. Both GSI and the Satellite Positioning Research and Applications Center (SPAC) conducted experiments involving the transmission of carrier-phase correction data via the QZSS LEX signal. The GSI experiment aimed to facilitate surveying in urban areas with single-frequency network-based RTK [11.42], while SPAC targeted dual-frequency applications in surveying, precise firming, and construction machinery control [11.43].

For dual-frequency precise point positioning (PPP) applications, the LEX signals support the transmission of correction data in the State Space Representation (SSR) format defined by the Radio Technical Commission for Maritime Services (RTCM) [11.44]. RTCM-SSR messages comprise orbit and clock corrections for GNSS satellites relative to the respective broadcast ephemerides. Other than range corrections employed by wide-area augmentation systems, the SSR corrections are not restricted to regional users but can be applied on a global scale [11.45]. They have emerged as a new standard for real-time PPP users and can be provided through various communication channels. As an example, RTCM-SSR correction data for GPS and GLONASS are provided by the International GNSS Service (IGS) to its users [11.46] using real-time internet streaming. QZSS offers the unique possibility to transmit such corrections (with a suitably reduced volume) along with the navigation signal [11.47]. These facilitate real-time PPP in remote areas that are not well covered by other communication links. As part of the LEX experiments, JAXA also offers SSR corrections for multiconstellation PPP users [11.37, 48].

The experiments and technology demonstrations conducted with the QZS-1 LEX signal will provide the basis for CLAS of the fully operational QZSS. As described in [11.20], the new Block II QZSS satellites will provide two data channels using CSK modulation, thus offering a higher capacity for correction data.

### 11.2.4 Spacecraft

As of 2015, the QZSS is made up of a single demonstration satellite which transmits most of the planned navigation signals and helps to validate diverse augmentation concepts. Even though QZS-1 will ultimately become a full member of the final QZSS constellation, the follow-on satellites are independently developed and will differ in various aspects from the QZS-1 design. Nevertheless, the QZS-1 satellite is well suited to illustrate the basic elements of the spacecraft platform and relevant payload elements.

#### Platform

The first QZSS satellite (QZS-1, or *Michibiki*; Fig. 11.5) is designed based on JAXA's Engineering Test Satellite-VIII (ETS-8, [11.49]) and the derived DS2000 GEO bus system of Mitsubishi Electric Corporation (MELCO). By building on an established spacecraft design, the QZS-1 development cycle could be notably reduced and the use of a GEO spacecraft platform offered ample resources for the accommodation of the complex and power-intensive navigation payload.

QZS-1 was launched on September 11, 2010 with an HII-A rocket from Tanegashima Space Center and

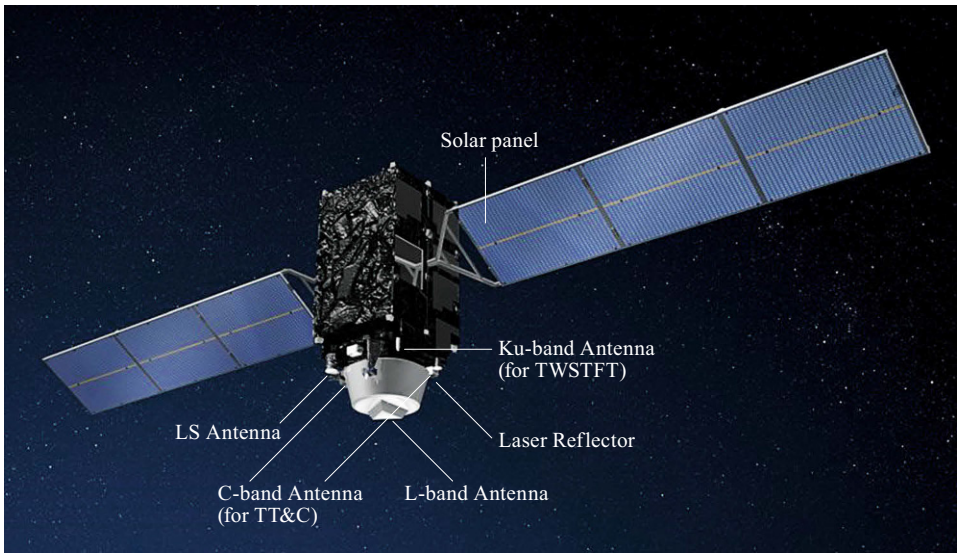

**Fig. 11.5** The first satellite of QZSS *Michibiki*. The artist's drawing illustrates the location of the main L-band navigation antenna (L-ANT) and the complementary SAIF antenna (LS-ANT) as well as the Ku-band antenna for bi-directional time comparison and the telemetry, tracking and commanding (TT&C) antenna (courtesy of JAXA)

injected into an elliptical transfer orbit. It was then raised into its final 33 000 km × 39 000 km orbit through multiple firings of its apogee boost motor.

Key characteristics of the spacecraft are summarized in Table 11.3. Compared to other GNSSs using MEOs, the QZS-1 satellite requires higher power and a large amount of propellant for injection into the geosynchronous orbit. Overall, QZS-1 carried about 2.3 t of fuel, which amounts to more than half the total mass at lift-off.

In order to ensure a sufficient life-time covering both the initial demonstration phase and the subsequent use as part of the fully operational QZSS constellation, QZS-1 has been designed with due redundancy. The spacecraft has dual independent electrical bus systems, high-capacity lithium ion batteries, and excess solar panel size. These features allow us to continue minimum operations with GPS interoperable signals in the case of a single electrical bus failure. Furthermore, QZS-1 offers a specific back-up configuration of the attitude control subsystem to continue operations in the case of attitude sensor failures [11.50].

The attitude and orbit control system (AOCS) of QZS-1 employs redundant star sensors, Sun sensors, and Earth horizon sensors for attitude determination. An orbit propagator fed with uploaded orbit information is used to translate between the inertial and orbital frames and to steer the rotation angle of the solar panels [11.50]. Four reaction wheels (complemented by thrusters for wheel unloading) serve as actuators for orientation changes [11.51].

Similar to other GNSS satellites, the QZSS satellite needs to point the navigation antenna toward the Earth throughout its orbit, while orienting the solar panels to the Sun. Depending on the Sun elevation above the orbital plane (the so-called $\beta$-angle), either the *yaw-steering* attitude control modes or the *orbit-normal* mode is employed by the QZS-1 satellite to achieve this goal (Fig. 11.6).

**Table 11.3** QZS-1 satellite system key parameters

| Parameter | Value |
|---|---|
| Dry mass | 1800 kg (total satellite system) |
| | 330 kg (nav. payload) |
| Wet mass | 4100 kg (at separation) |
| Dimensions | 2.9 m × 3.1 m × 6.2 m (Body) |
| | 25.3 m (Span) |
| Design life time | >10 years |
| Solar array power | 5300 W @ 10 years |
| Pointing Accuracy | 0.1° |
| TT&C | 5000–5010 MHz (uplink) |
| | 5010–5030 MHz (downlink) |
| Reliability | > 0.8 (Bus) |
| | > 0.7 (Payload) |

In yaw-steering mode, which is also most widely used by GNSS satellites in MEOs (such as GPS and GLONASS), a continuous rotation about the Earth-pointing (yaw) axis is performed to keep the solar panel rotation axis perpendicular to the Sun and Earth direction. In this way, the surface normal of the solar panels can always be aligned with the Sun direction, which maximizes the effective cross-section and thus the received energy. As a disadvantage, however, large and rapid yaw-slews near local noon and midnight are required during periods of low Sun elevation (Sect. 3.4 of this Handbook), which may exceed the capabilities of the reaction wheels. QZS-1, therefore, adopts the

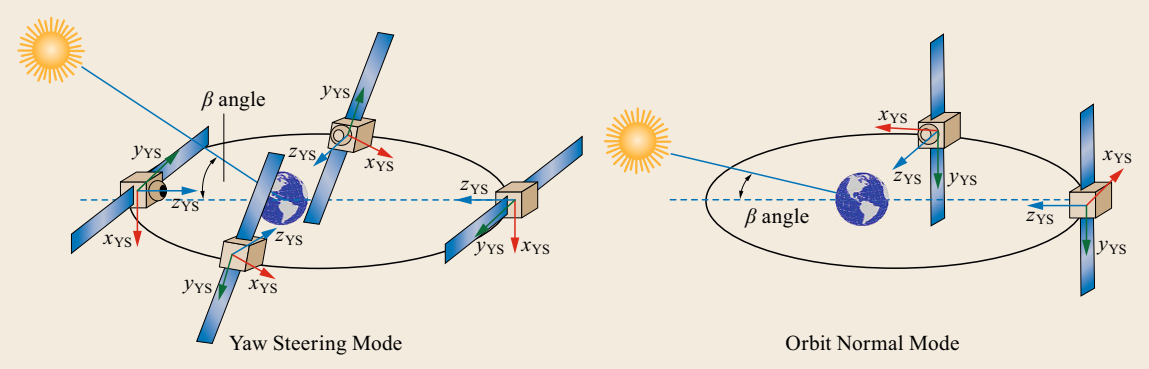

**Fig. 11.6** Attitude control modes of the QZS-1 spacecraft (adapted from [11.51])

orbit-normal mode for $|\beta| < 20°$. Here, the solar panel rotation axis is maintained perpendicular to the orbital plane. This avoids the need for yaw rotations, but yields a slightly reduced power output due to the suboptimal pointing of the solar panels.

Details of the QZS-1 attitude control system and the implementation of the two attitude modes are described in [11.51]. Mathematical models describing the nominal attitude of the QZS-1 spacecraft as a function of its orbital position and the Sun direction are given in [11.52]. As pointed out in [11.53], care must be taken, though, that the transition between yaw-steering and orbit-normal mode does not take place at $|\beta| = 20°$ exactly. Instead, the mode switch is conducted near this threshold at an orbital position that minimizes the required yaw-angle change during the mode transition.

### Payload

In accord with the overall QZSS mission goal, the navigation payload [11.54] constitutes the primary payload element of QZS-1. However, considering that QZS-1 is the first satellite in the IGSO, it also has been equipped with various environmental sensors as a secondary payload. The Technical Data Acquisition (TEDA) experiments serve to better characterize the IGSO environment and, if needed, to adapt the design of follow-on QZSS satellites [11.50]. More specifically, the TEDA package comprises a light particle telescope (including the alpha particle and proton sensor-B, APS-B, and the electron sensor-A, ELS-A) as well as magnetometers (MAM) and potential monitors (MAM). A detailed description of these sensors and the initial flight results is given in [11.55].

The navigation payload of QZS-1 comprises three individual subsystems:

- The *L-band signal transmission subsystem* (LTS) is the main part of the navigation payload, which generates the reference clock and baseband signal as well as the navigation message, and then modulates, amplifies, and transmits the navigation signals.
- The *Time transfer subsystem* (TTS) developed by the NICT enables two-way satellite time and frequency transfer (TWSTFT), comparison of the onboard atomic clock with a ground-based frequency standard, and a remote synchronization of an onboard crystal oscillator (RESSOX) from the ground [11.56, 57]. The measurements and control commands are exchanged through a dedicated bidirectional Ku-band communication link.
- The *laser reflector assembly* (LRA) is a fully passive device that enables high-accuracy distance measurements by satellite laser ranging (SLR).

Figure 11.7 provides a block diagram of the navigation payload on QZS-1. The onboard reference clock is generated by the time-keeping system, which comprises the Rubidium Atomic Frequency Standard (RAFS), a time-keeping unit, a synthesizer, and a navigation onboard computer.

The RAFS selected for QZS-1 has been manufactured by PerkinElmer and is identical to the rubidium clocks of the GPS IIF satellites [11.58] that are known for their superior stability. For redundancy purposes, QZS-1 is equipped with two independent RAFS units. Even though a space-capable hydrogen maser for use within the QZSS program has been developed by NICT [11.59], the use of rubidium clocks was ultimately preferred in view of their lower mass and power consumption [11.56].

The time-keeping unit also includes a voltage- and oven-controlled crystal oscillator (VCOCXO) with high short-term stability. This is steered by the navigation computer to follow the RAFS frequency on average. In this way, a clock signal with high stability over a wide range of time scales is achieved. As an alternative, the VCOCXO can also be controlled from the ground through the TTS. This has been demon-

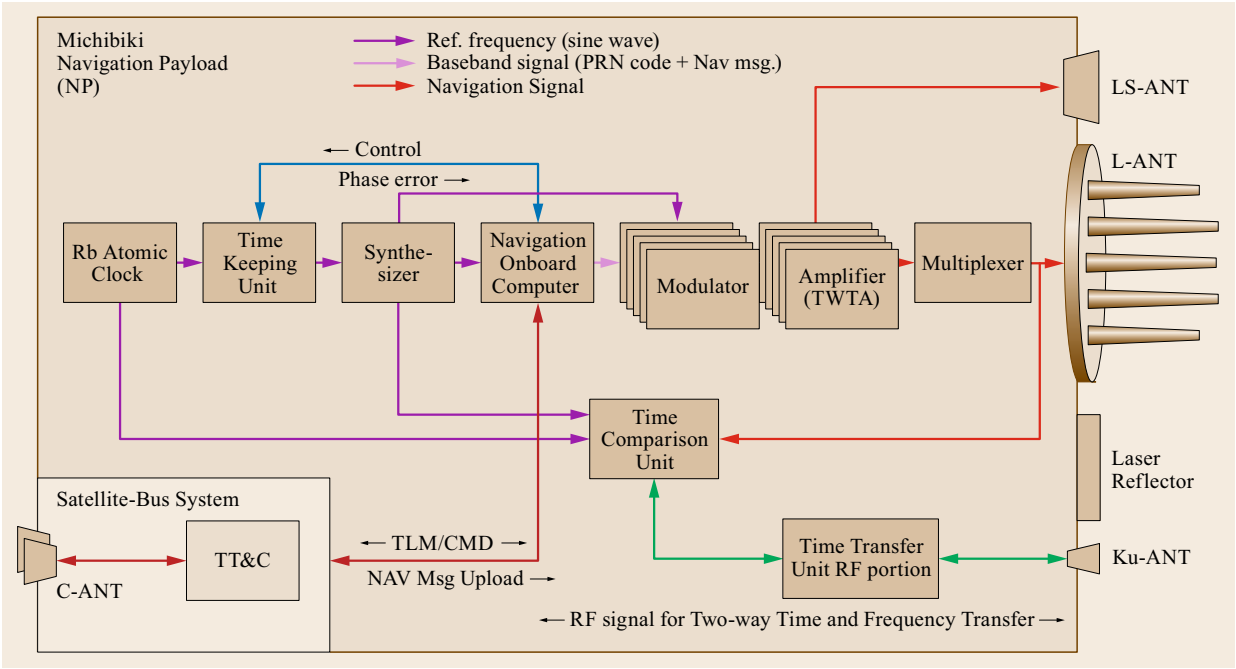

**Fig. 11.7** Block diagram of QZS-1 navigation payload

strated with the Remote Synchronization System of the Onboard Crystal Oscillator (RESSOX) described in [11.60]. Here, the QZS-1 reference oscillator is steered to follow a highly stable ground clock with sub-nanoseconds accuracy. While the resulting short-term stability achieved in the RESSOX experiments is lower than that of the standard onboard clock, an excellent long-term stability of $4.4 \cdot 10^{-14}$ was achieved at time scales of 100 000 s.

Based on the clock reference of the time-keeping unit, the synthesizer finally outputs the satellite clock and L-band carriers. The navigation onboard computer then generates the baseband signals with the navigation message, which are subsequently amplified, multiplexed, and transmitted.

Since the orbit of QZS-1 is higher than that of traditional MEO constellations, QZS-1 needs a higher transmission RF power. Values for the signals transmitted via the main L-band antenna are given in Table 11.4. The individual signals are amplified through an adjustable channel amplifier and a traveling-wave tube amplifier before being combined at the multiplexer (MUX). The peak power amounts to nearly 1 kW. In order to maintain enough margin with respect to high-power durability and thermal resistance, the L1-SAIF signal is transmitted through a different path and antenna than the other L1-band signals.

**Table 11.4** QZS-1 radio frequency output power

| Signals | Power (W) |
|---|---|
| L1 C/A & L1C | 91 |
| L2C | 20 |
| L5 | 70 |
| LEX | 63 |

The main L-band antenna shown in Fig. 11.8 is composed of 19 individual helix antennas arranged in an outer ring (12 elements), an inner ring (6) elements, and a central element. The individual elements are phase coherently combined to form a gain pattern, which provides uniform signal strength on the Earth's surface. Compared to the boresight direction, the antenna gain is about 0.2 dB higher at 5° boresight angle

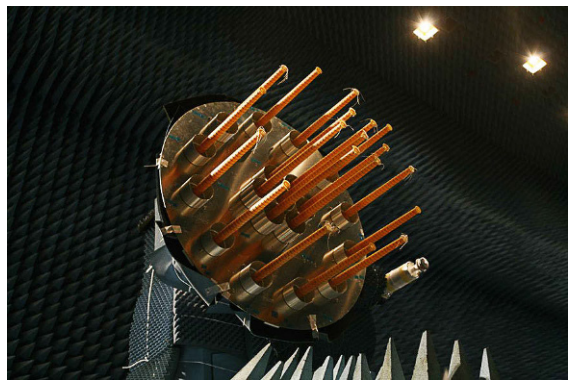

**Fig. 11.8** QZS-1 L-band antenna array during anechoic chamber testing (courtesy of JAXA)

and 0.5 dB lower at 8.5° (corresponding to the Earth rim) for L1 signals [11.59].

Figure 11.9 illustrates the location of the various antennas and the laser retroreflector array on the Earth-facing panel of the QZS-1 satellite. The main L-band antenna is placed such that the phase center is located on the $z$-axis of the spacecraft body coordinate system passing through the spacecraft center of mass. In this way, the phase-center location is unaffected by the spacecraft attitude and only a radial phase-center offset needs to be considered in the GNSS data analysis.

The laser retroreflector is accommodated opposite to the SAIF antenna. It consists of a planar array of $7 \times 8$ uncoated corner cube prisms of 4 cm diameter [11.61]. Laser ranging observations are routinely conducted by observatories in Japan (Tanegashima, Koganei, Tokyo, Japan) and Australia (Yarragadee, Mt. Stromlo) as well as various other stations of the International Laser Ranging Service (ILRS; [11.62]). Even though the SLR observations of QZS-1 are primarily used for the validation of GNSS-based precise orbit determination results [11.63], they can also serve as independent means for standalone orbit determination [11.64].

### 11.2.5 Control Segment

The control segment for the first QZSS satellite is composed of an MCS, the monitoring stations (MS) network, the tracking control station (TCS), and the tracking, telemetry, and command (TT&C) station. These are complemented by a time management station (TMS) for time measurement synchronization with external time scales.

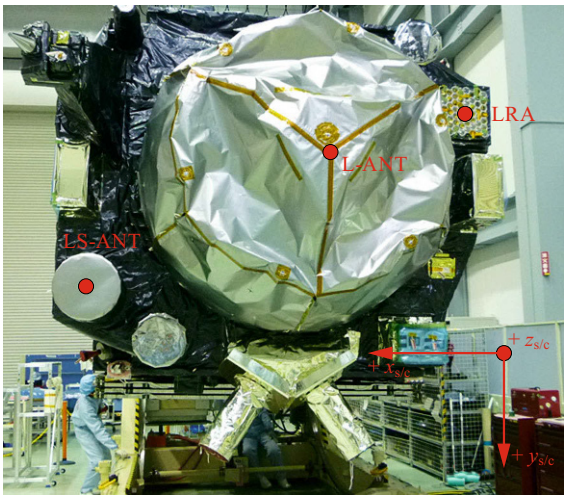

**Fig. 11.9** Earth panel configuration of QZS-1 showing the main L-band antenna (L-ANT), the L1-SAIF antenna (LS-ANT), and the laser retroreflectors assembly (LRA). The 19-elements helical array antenna is covered with a thermal insulator in order to maintain proper thermal conditions on the orbit. Arrows indicate the orientation of the spacecraft coordinate system adopted by JAXA (courtesy of JAXA)

This section provides descriptions of each subsystem of the control segment as well as the operation scenario and the current performance. Figure 11.10 shows the distribution of the control segment for the demonstration system.

#### Master Control Station

The MCS acts as the focal point of navigation-related QZS-1 operations. In particular, the MCS performs the following functions:

- Orbit and clock offset estimation and generation of navigation messages for upload to the satellite
- Monitoring and controlling of the navigation payload onboard the spacecraft
- Remote monitoring and controlling of the monitoring stations
- Monitoring of the navigation signal quality and user range error and generating health/alert flags in the case of malfunctions
- Handling of navigation messages and control commands generated by other research institutes as part of specific technology demonstrations and experiments.

The MCS is located at the Tsukuba Space Center (TKSC), approximately 60 km northeast of Tokyo downtown. Even though there is only a single MCS facility for the QZSS demonstration phase, it satisfies high-availability requirements through internal use of a hot-redundant system.

#### Monitoring Stations

Nine monitoring stations located in Japan as well as Asian and Oceania areas have been installed to receive the QZSS and GPS signals for precise orbit and clock estimation. A total of five monitoring stations outside Japan were established in collaboration with local organizations. These include National Aeronautics and Space Administration (NASA) (Kokee Park Geophysical Observatory, Kauai), National Ocean and Atmospheric Administration (NOAA) (Weather Forecast Office, Guam), Geoscience Australia (Mt. Stromlo), the Indian Space Research Organisation (ISRO) (ISRO Telemetry Tracking and Command Network, ISTRAC, Bangalore), and the Asian Institute of Technology (Geoinfomatics Center, Bangkok).

The monitoring stations receive L-band navigation signals from the QZSS and GPS constellation and transmit raw data to the MCS via ground or satellite communication link. A QZSS receiver and a GPS

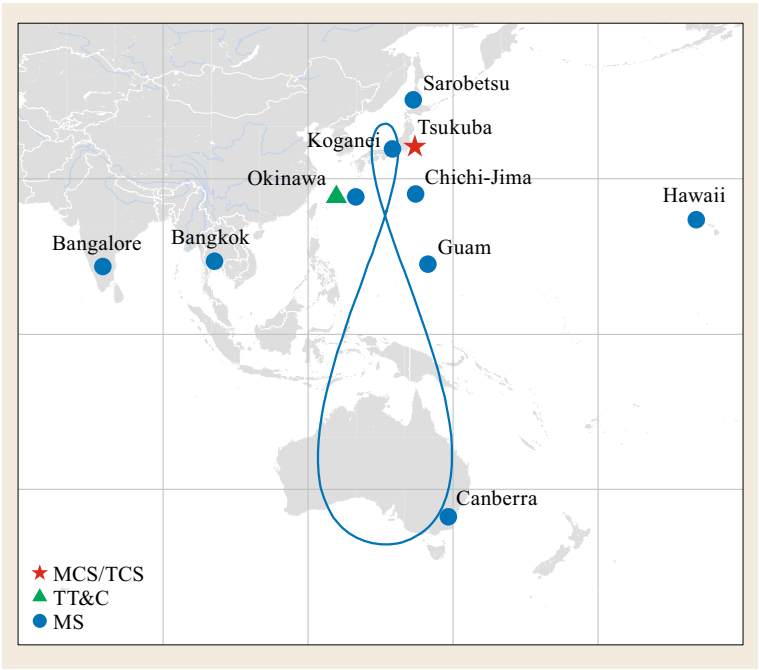

**Fig. 11.10** Control segment distribution for the QZSS demonstration. For reference, the ground track of QZS-1 is indicated by a solid line

receiver with cesium atomic frequency standard and a multiband antenna with radome as well as meteorological sensors, local computer, and communication equipment are installed in each MS. It is noted that the use of independent receivers for QZSS and GPS signals implies the need for estimating an inter-receiver (inter-system) bias for precise orbit determination of QZSS and GPS in the MCS.

### Tracking and Control Station

The TCS, which is collocated with the MCS at JAXA's TKSC, is in charge of the QZS-1 satellite bus operations. Among others, this covers the following functions:

- Performance of housekeeping operations, that is, monitoring of the spacecraft telemetry and issuing of commands for routine operation
- Remote monitoring and control of the TT&C station
- Planning and execution of orbit-keeping maneuvers and reaction wheel unloading
- Integration of all system operations as well as time and resource allocation between navigation payload and satellite bus system operation.

Due to the continuous visibility of the QZSS satellites, the GEO satellite operation system previously developed by JAXA could be applied to QZSS with minimum modifications.

From the early stage of the development phase, a model-based operation approach was adopted on the operations system and procedure design. Routine operations are fully automated so that less operators are required to control the satellite in an efficient manner [11.65, 66].

### Tracking, Telemetry, and Command Station

The main TT&C ground station for QZS-1 is located in the Okinawa main island, where QZSS is permanently visible and continuous operations can be ensured. Since the Okinawa district is regularly exposed to typhoons during the summer season, two redundant high-gain antennas with a diameter of 7.6 m and a protecting radome (Fig. 11.11) are installed at the TT&C station to ensure uninterrupted operation even in severe weather condi-

**Fig. 11.11** Tracking, Telemetry, and Command Station (TT&CS) in Okinawa island (courtesy of JAXA)

tions. The TT&C station is operated remotely from the TCS in Tsukuba.

#### Time Management Station

The TMS [11.57, 67] measures the difference between the QZS-1 onboard clock and a highly stable ground reference and conducts TWSTFT operations. Based on the TMS measurements, the coordinated universal time (UTC) offset parameters and the GPS-QZSS Time Offset (GQTO) for the QZS-1 navigation message are generated.

The TMS is operated by NICT, the Japanese authority, in charge of generating the national standard time. For redundancy purposes, the TMS comprises independent facilities at Koganei and Okinawa, each of which comprises a Ku-band antenna, an atomic clock, and a time-comparison equipment.

The TMS at Koganei is connected with UTC(NICT) and colocated with one of the QZSS monitoring stations. The receiver clock of the Koganei monitoring station is defined as QZSS reference time (QZSST) and the TMS measures the offset between this time scale and UTC(NICT). In addition, the Koganei TMS performs time and frequency comparisons with the United States Naval Observatory (USNO) in Washington via a TWSTFT link, which involves two GEO communication satellites and a relay station at Kogee Park, Kauai. The offset between UTC(NICT) and UTC(USNO) as measured by TWSTFT was used for the evaluation of the GQTO.

A secondary TMS is deployed at NICT's Subtropical Environment Remote-Sensing Center in Okinawa. While not directly connected to UTC(NICT), this TMS offers a larger antenna (3.7 m diameter as compared to 1.8 m in Koganei) and continuous 24 h visibility of QZS-1 [11.56]. Synchronization of both TMS facilities is achieved through TWSTFT.

### 11.2.6 Operations Concept

As a key function, the MCS performs a real-time estimation of the orbits and clock offsets for all active GPS and QZSS satellites. The process makes use of a square-root information filter and processes pseudorange and carrier-phase measurements of the (presently nine) monitoring stations at 30 s intervals [11.68]. Aside from the GNSS orbit and clock parameters, the filter state comprises the clock offset values of the monitoring stations as well as carrier-phase biases and station-specific tropospheric delays. Furthermore, empirical solar radiation pressure parameters are estimated in view of the limited accuracy of available a priori models. Overall, a total of about 500 parameters is adjusted in each measurement update.

Following [11.68], the orbit determination process is designed to recover the actual orbit with an accuracy of better than 0.7 m in the radial direction and twice this value in along-track and cross-track directions. Slightly larger values of 0.8 and 1.6 m apply for the associated orbit prediction, accuracy over a 2.5 h interval. For clock offset determination and 35 min prediction accuracy requirements of 2.5 and 4.4 ns have been specified. The targeted limit for the total signal in space range error amounts to 1.6 m, but is well outperformed in practice.

QZSS orbit information is referred to a realization of the Japan Geodetic System (JGS, [11.69]) maintained by JAXA based on GNSS observations of 40 reference stations (including the 9 QZS-1 monitoring stations as well as stations of the IGS and complementary SLR observations. The latest frame realization is known as JGS2010 and designed to be rigorously aligned with ITRF2008.

Clock offsets are initially determined relative to the QZSS system time scale (QZSST), which is defined by the receiver in the Koganei monitoring station connected with Japanese reference time standard, UTC(NICT). However, the time offset between QZSST and GPS time (GPST) is included into the clock offset parameters transmitted in the navigation message, so that user equipment can calculate positions without explicitly considering the time difference between both systems.

For the ionospheric error correction of single-frequency users, the same Klobuchar model as in GPS is used [11.14, 70]. However, the model coefficients for the QZSS NAV message are generated such as to best match the vertical total electron in the area surrounding Japan rather than aiming at a global fit. Observations from 300 nationwide CORS stations are used to adjust the Klobuchar parameters and the coefficients for the navigation message are frequently updated to better reflect the dynamic behavior of the ionosphere.

Nominally, the orbital ephemeris and clock parameters are updated every 15 min, while ionospheric correction parameters are updated once every hour. In contrast to this, the augmentation messages with state space or ranging error corrections, integrity, and other value-added information are generated and transmitted via QZSS in (near) real time. During the QZS-1 demonstration phase, several types of augmentation methods were tested and evaluated as described in Sect. 11.2.3.

As a regional navigation satellite system with a small number of satellites, care must be taken to minimize PNT service interruptions due to orbit maintenance maneuvers and thruster activity for reaction wheel unloading. The interval between two orbital maintenance maneuver is required to be more than 150

days, and wheel unloadings shall be separated by at least 40 days.

Orbit corrections for satellites in IGSO are required on a routine basis due to a secular increase of the semimajor axis induced by the Earth's triaxiality. For QZS-1, the perturbation amounts to roughly 85 m/d and results in a westward acceleration of the mean subsatellite longitude. To ensure that the center longitude remains in the specified range of 135°E ± 5°, periodic orbit maneuvers are conducted, in which the along track velocity and thus the semimajor axis are decreased. The orbit correction maneuver imposes an initial ground track drift in the Eastern direction, which is gradually stopped and reversed by the natural orbital perturbations within several months. The velocity decrement is calculated based on long-term orbital dynamics simulations so that the center longitude of satellite ground track would not go beyond the specified range at the next orbit maintenance maneuver. Overall, the orbit maintenance strategy for the QZSS IGSO satellites closely matches the east–west station keeping of geostationary satellites [11.71] but employs less frequent maneuver due to the much wider control window.

For QZS-1, orbit corrections are performed roughly once every six months. In order to correct both the semimajor axis and the eccentricity, each correction is split into three individual maneuvers with a total magnitude of 1–4 m/s which are performed within one orbital revolution. For semimajor axis control alone, a velocity change of about $\Delta v \approx 0.5$ m/s is required.

Concerning angular momentum build-up in the reaction wheels, the first four years of QZS-1 operations have shown a similar profile in each year. Based on the collected experience, the time interval between two momentum wheel unloading operations could be extended to up to 150 days. Various momentum wheel unloadings could thus be combined with orbit maintenance operations.

In the case of any maintenance operations, users are informed about the expected outages and the renewed service availability through *Notice Advisory to QZSS Users* (NAQU) messages. For QZS-1, these notifications are made available online through JAXA's *QZ-Vision* homepage [11.72]. Planned maneuver information is also incorporated into the real-time orbit and clock determination process in the MCS. The filter can thus converge to its nominal performance in less than 21 h after orbit-keeping maneuvers and 9 h after a standalone wheel unloading [11.68].

### 11.2.7 Current Performance

Michibiki was launched from Tanegashima Space Center at 11:17 UTC) on September 11, 2010. In the subsequent commissioning phase, the function and initial performance of each subsystem and the total system were checked out [11.73, 74], and the precise orbit determination (POD) software in the control segment was tuned. The L1 C/A and L2C signals were set healthy on June 22, 2011, followed by the L1C and L5 signals on July 14, 2011. All interface specifications and performances defined in the IS-QZSS were confirmed to be satisfied. In this section, the routine performance of the broadcast ephemeris and clock stability is described.

#### SIS-URE

The signal-in-space use range error (SIS-URE) describes the error in the modeled pseudorange caused by errors in the broadcast orbit and clock information. It is monitored in real time within the QZSS MCS. Each second, the instantaneous SIS-URE value is calculated from an average of the observation residuals at the nine QZS-1-monitoring stations using an elevation-dependent weighting.

Monthly performance reports are made available through JAXA's *QZ-vision* website [11.75]. By way of example, Fig. 11.12 shows the SIS-URE variation for July 2014. The root-mean-square (RMS) value in this period amounts to 0.34 m, which is well within the specified 95 percentile performance limit of ±2.6 m. Compared to GPS, the QZSS clearly benefits from the continuous observations, the permanent upload capability, and the short (15 min) update interval of the broadcast navigation messages.

An independent assessment of the QZSS L1 C/A legacy navigation message (LNAV) broadcast ephemerides has been performed in [11.76] based on comparison with post-processed orbit and clock products of JAXA. Here, monthly RMS SIS-URE values

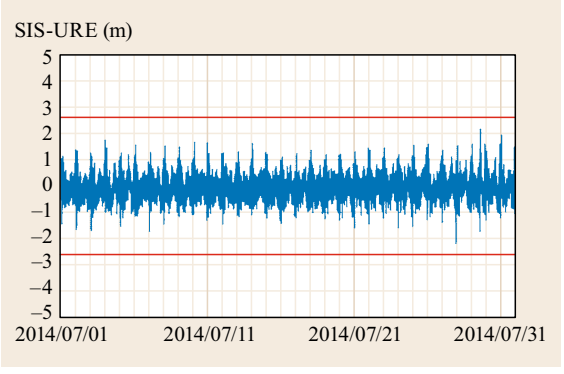

**Fig. 11.12** QZS-1 SIS-URE as derived from observations of the QZSS real-time monitoring station network for July 2014. The red line marks the 95 percentile threshold value of ±2.6 m specified for the QZS-1 routine operations (excluding orbit maintenance periods)

of $0.6 \pm 0.2$ m have been obtained for a one year analysis period starting March 2013. While theses results indicate a slightly inferior performance than the MCS monitoring, they represent average errors over the entire globe rather than errors in the vicinity of the monitoring QZS-1 network.

### Clock Stability

As discussed in Sect. 11.2.4, QSZ-1 is equipped with a TTS, which has been employed in various experiments of the NICT to assess and the stability of the QZS-1 onboard frequency standards [11.57, 67].

On the other hand, the performance of the RAFS is evaluated on routine basis using L-band observations of the QZSS MS-monitoring stations. For the clock stability assessment over short time scales (typically less than 1000 s) the one-way carrier-phase (OWCP) method [11.77] is applied. Here, the Allan deviation (ADEV) is derived from detrended carrier-phase measurements collected at a monitoring station that is connected to a highly stable reference clock. For QZS-1, observations from the Okinawa site have been used, which offers the most stable frequency standard within the QZSS-monitoring station network. The results shown in Fig. 11.13 demonstrate a stability of $3 \cdot 10^{-12}$ at 1 s averaging intervals and about $5 \cdot 10^{-14}$ at 1000 s. Compared to [11.78], superior results at very short time are achieved due to the reduced impact of receiver noise in single-frequency observations.

For longer averaging times, QZS-1 clock offset solutions obtained as part of the precise orbit and clock determination have been employed. These are routinely generated by the MCS within six days based on the observation of the QZS-1-monitoring station network. At a one day time scale, a stability of $1 \cdot 10^{-14}$ is achieved (Fig. 11.13) in good accord with the inflight performance of the GPS Block IIF RAFS. Despite the small bump in the ADEV near 400 s, which is attributed to the time-keeping system, the overall performance of the QZS-1 clock stability is well within the specification and all time scales.

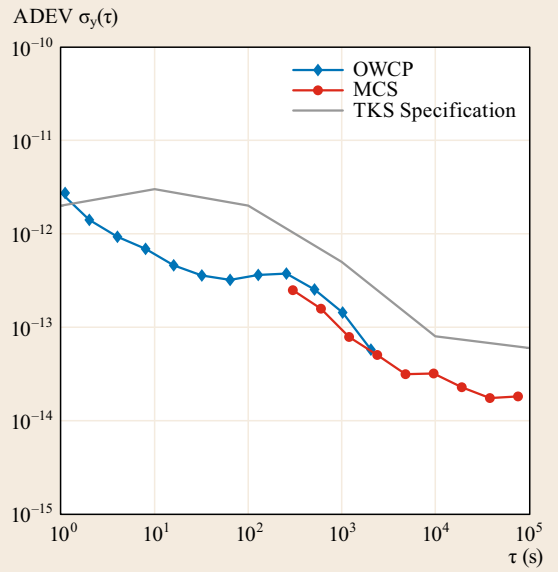

**Fig. 11.13** Clock stability (Allan deviation, ADEV) of QZS-1 as determined with the one-way carrier-phase (OWCP) method and the precise orbit and clock determination by the QZSS master control station (MCS) in Aug. 2014. For comparison, the gray line indicates the specified performance of the time keeping system.

## 11.3 Indian Regional Navigation Satellite System (IRNSS/NavIC)

The IRNSS is an initiative by the ISRO to establish and operate an independent satellite-based navigation system, which provides services to the users in the region covering India and an area extending up to 1500 km from its geo-political boundary [11.79]. IRNSS is also known by the operational name NavIC (an acronym for Navigation with Indian Constellation) which means sailor/navigator in Sanskrit. This section on IRNSS describes its architecture, the various segments, and the signal and data structures. It provides a comprehensive picture of IRNSS as one of the emerging systems in the world of satellite-based navigation.

The IRNSS marks India's entry into the realm of independent satellite-based navigation systems. The ISRO is the key agency for the realization, operation, and maintenance of the system. This involves building, launching, and operating the navigation satellites, as well as establishing the ground support systems.

The IRNSS is established with the objective of offering PNT services to the users in its service area. The system is designed to provide its users with a position accuracy of better than 20 m ($2\sigma$) in its primary service area.

The IRNSS classifies its service areas broadly into two regions, as shown in Fig. 11.14. The primary service area of IRNSS encompasses the Indian landmass and a region lying within a distance of 1500 km from its geo-political boundary. The secondary service area extends between latitudes 30°S to 50°N and longitudes 30°E to 130°E.

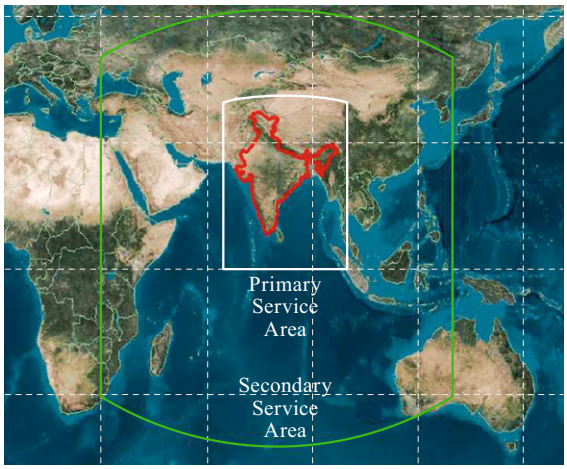

**Fig. 11.14** IRNSS primary and secondary service areas (courtesy of ISRO)

IRNSS provides two types of navigation services:

- The *Standard Positioning Service (SPS)* is an unencrypted service provided to all the users within the IRNSS service area.
- The *Restricted Service (RS)* is an encrypted service provided only to the authorized users in the service area.

Similar to the other global and regional systems, the IRNSS navigation infrastructure can be divided into three segments illustrated in Fig. 11.15:

- The *Space Segment* consisting of the seven space vehicles that broadcast the IRNSS navigation signals to its users
- The *Ground Segment* consisting of the ground infrastructure to support the operation of the IRNSS system, such as the precise timing system, the spacecraft ranging mechanisms, the navigation software, the communication networks, and the spacecraft telemetry, tracking, and command network
- The *User Segment* consisting of the civilian and authorized users of IRNSS employing various types of IRNSS receivers.

Key components of the space and ground segment are described in the following subsections.

### 11.3.1 Constellation

The IRNSS space segment is made up of seven satellites, including three satellites in the GEO and four satellites in the IGSO with orbital planes tilted by 29° with respect to the equator. This constellation was selected based on the following design considerations:

- Minimizing the dilution of precision (DOP)
- Visibility of the maximum number of satellites over the targeted area
- Minimum satellite constellation
- System sustenance even in the case of a one-satellite failure, and
- Availability of orbital locations.

Given the large number of satellites (about 18 or up) required to ensure a guaranteed visibility of at least four satellites in an MEO constellation, the seven-satellite GEO and IGSO constellation was found to be optimum in view of the regional service requirements. In addition, the permanent 24 h visibility of all satellites over the region of interest facilitates the ranging, tracking, and commanding.

A summary of all satellites in the constellation is given in Table 11.5. The three GEO satellites are roughly equally spaced on the equator, covering a longitude range of about 100° between central Africa and Indonesia. The IGSO satellites, in contrast, describe figure-of-eight ground tracks covering a latitude range of about ±30° and centered at 55.0° and 111.75° East longitude, respectively (Fig. 11.16). The phasing of the satellites in the inclined orbits is chosen such as to avoid singular DOP values that might occur, if all IGSO s/c were to cross the equator at the same time [11.9].

### 11.3.2 Signal and Data Structure

The IRNSS utilizes the L5- and S-band frequencies allocated for Radio Navigation Satellite Services (RNSS). The carrier frequencies and the bandwidths of transmission are shown in Table 11.6.

The traditional navigation services frequency bands, that is, the L1- and L2-bands, have been completely utilized by the existing GNSS service providers. Hence, it was difficult to accommodate IRNSS in the L1- and L2-

**Table 11.5** Satellites of the IRNSS constellation [11.80]

| Satellite | Long. | Inclin. | Launched |
|---|---|---|---|
| IRNSS-1A | 55.0° | 29° ± 2° | 1 July 2013 |
| IRNSS-1B | 55.0° | 29° ± 2° | 4 April 2014 |
| IRNSS-1C | 83.0° | < 5° | 15 October 2014 |
| IRNSS-1D | 111.75° | 29° ± 2° | 28 March 2015 |
| IRNSS-1E | 111.75° | 29° ± 2° | 20 January 2016 |
| IRNSS-1F | 32.5° | < 5° | 10 March 2016 |
| IRNSS-1G | 129.5° | < 5° | 28 April 2016 |

**Table 11.6** Carrier frequencies and bandwidths

| Signal | Carrier frequency (MHz) | Bandwidth (MHz) |
|---|---|---|
| L5 | 1176.450 | 24.0 (1164.45–1188.45) |
| S | 2492.028 | 16.5 (2483.50–2500.00) |

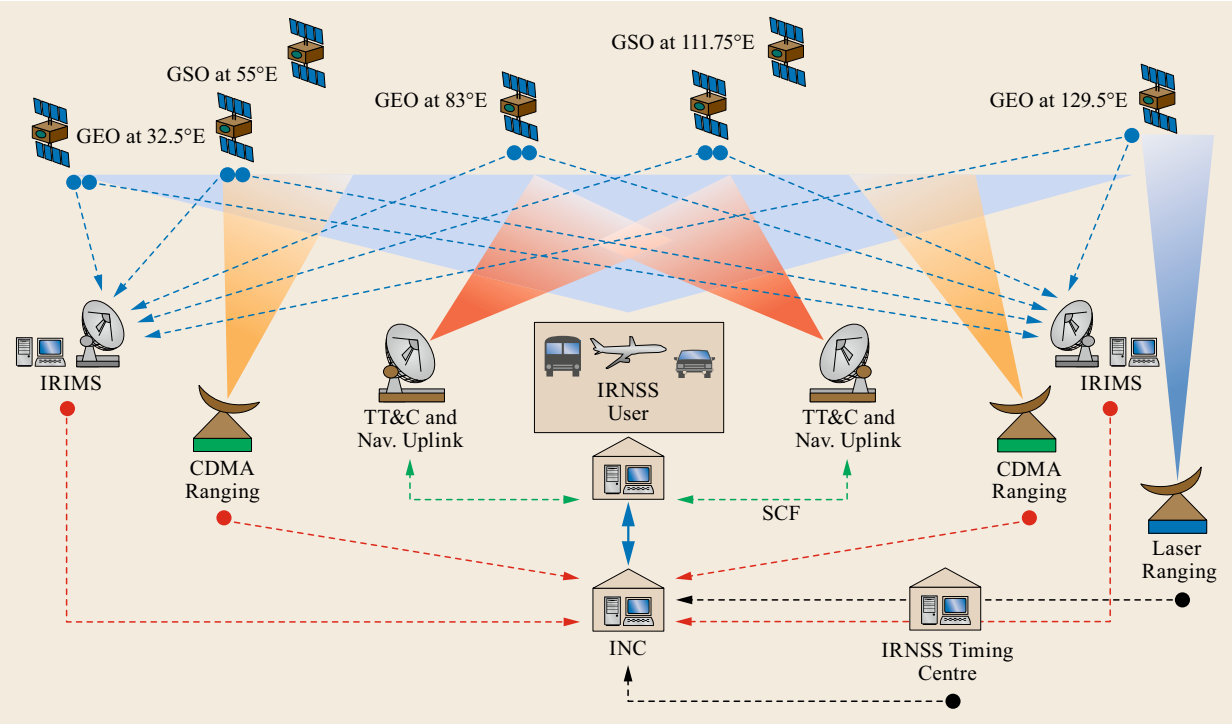

**Fig. 11.15** IRNSS/NavIC architecture

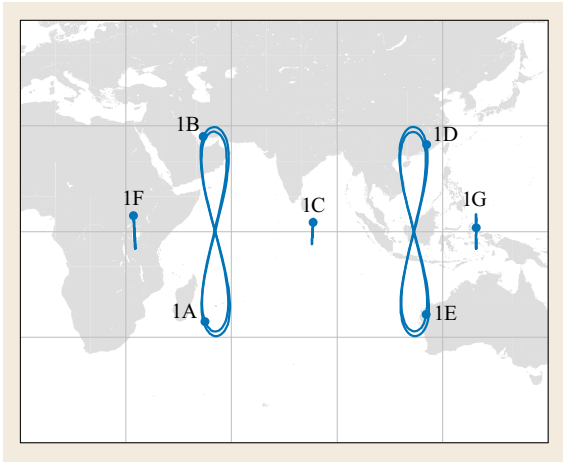

**Fig. 11.16** IRNSS/NavIC constellation. The figure shows the ground tracks of the seven IRNSS satellites over the Indian Ocean region on 2 Aug, 2016 with *circles* indicating the position at midnight.

bands. The L5-band was chosen as it was less populated and as it was possible for IRNSS signals to co-exist with other GNSS signal in this band. This choice shall also facilitate interoperability with other GNSS signals using a common RF front end in the user receiver.

A second frequency was required to achieve better positioning accuracy using dual-frequency user receivers. The S-band has been allocated globally for radio determination satellite services (RDSSs) in 2012. Since function-wise there is very little difference between RDSS and RNSS, the International Telecommunications Union (ITU) has allotted a maximum bandwidth of 16.5 MHz for RDSS/RNSS. Hence, the S-band was chosen as it is a newly introduced band for navigation services, which was not yet populated. Also, S-band signals are less affected by ionospheric perturbations than the L-band.

Power levels of the IRNSS signals received on ground are chosen suchas to co-exist with other GNSS signals operating in the respective frequency bands. They have been selected taking into account two primary considerations:

- The maximum power level of IRNSS shall not affect the reception of other GNSS signals and
- The minimum power level of the IRNSS signal shall provide sufficient signal strength to be detected even in the presence of other GNSS signals.

The resulting minimum and maximum power levels of IRNSS signals are given in Table 11.7.

### Modulation

Each of the two carriers is modulated by three signals [11.81, 82]:

- The SPS data channel using a BPSK(1) binary phase shift key modulation with a chipping rate of 1.023 MHz
- The RS data channel using a BOC(5,2) binary offset carrier modulation with a 2.046 MHz ranging code and a 5.115 MHz subcarrier, and
- The RS pilot channel, which likewise uses a BOC(5,2) modulation.

When passed through a power amplifier or traveling-wave tube amplifier (TWTA) operated at saturation, the combination of these signals would produce a nonconstant envelope. Hence, an interplex product (Chap. 4) is added as a fourth signal component to achieve a constant envelope at the TWTA output.

The mathematical description for the three baseband navigation signals (i. e., the SPS binary phase shift keying (BPSK) data signal $s_{\mathrm{sps}}$, the RS binary offset carrier (BOC) pilot signal $s_{\mathrm{rs_p}}$, and the RS BOC data signal $s_{\mathrm{rs_d}}$) is given by

$$
\begin{aligned}
s_{\mathrm{sps}} &= \sum_{i=-\infty}^{+\infty} c_{\mathrm{sps}}\left(|i|_{L_{\mathrm{sps}}}\right) d_{\mathrm{sps}}\left([i]_{D_{\mathrm{sps}}}\right) \\
&\quad \times \mathrm{rect}_{T_{\mathrm{c,sps}}}\left(t - iT_{\mathrm{c,sps}}\right) , \\
s_{\mathrm{rs_p}} &= \sum_{i=-\infty}^{+\infty} c_{\mathrm{rs_p}}\left(|i|_{L_{\mathrm{rs_p}}}\right) \\
&\quad \times \mathrm{rect}_{T_{\mathrm{c,rs_p}}}\left(t - iT_{\mathrm{c,rs_p}}\right) sc_{\mathrm{rs_p}}(t,0) , \\
s_{\mathrm{rs_d}} &= \sum_{i=-\infty}^{+\infty} c_{\mathrm{rs_d}}\left(|i|_{L_{\mathrm{rs_d}}}\right) d_{\mathrm{rs_d}}\left([i]_{D_{\mathrm{rs_d}}}\right) \\
&\quad \times \mathrm{rect}_{T_{\mathrm{c,rs_d}}}\left(t - iT_{\mathrm{c,rs_d}}\right) sc_{\mathrm{rs_d}}(t,0)
\end{aligned}
\tag{11.4}
$$

with time $t$ and the following definitions:

$c_{\mathrm{s}}(n)$ $n$th spreading code chip of signal s,
$d_{\mathrm{s}}(n)$ $n$th navigation message chip,
$sc_{\mathrm{s}}(t)$ binary subcarrier,
$D_{\mathrm{s}}$ number of chips per navigation data bit,
$L_{\mathrm{s}}$ spreading code length in chips,
$T_{c,\mathrm{s}}$ spreading code chip duration.

The operations $|i|_x$ ($i$ modulo $x$) and $[i]_x$ (integer part of $i/x$) provide the code chip index and the data bit index for a given signal, while $\mathrm{rect}_x(t)$ describes a rectangular pulse function of duration $x$. For the RS BOC signal, the subcarrier is defined as

$$
sc_x(t,\varphi) = \mathrm{sign}\left[\sin(2\pi f_{sc,x} t)\right] , \tag{11.5}
$$

where $f_{sc,x}$ denotes the subcarrier frequency. Individual signal parameters are summarized in Table 11.8. The choice of a BOC(5,2) modulation for the RS signal offers good spectral separation within the available bandwidth and is further discussed in [11.83].

A block diagram depicting the interplex signal generation is given in Fig. 11.17. Following [11.84] and [11.82], the composite signal at the carrier frequency $f$ can be described by

$$
\begin{aligned}
s(t) &= \frac{\sqrt{2}}{3}\left[s_{\mathrm{sps}}(t) + s_{\mathrm{rs_p}}(t)\right]\cos(2\pi f t) \\
&\quad + \frac{1}{3}\left[2s_{\mathrm{rs_d}}(t) - I(t)\right]\sin(2\pi f t) ,
\end{aligned}
\tag{11.6}
$$

where the interplex signal

$$
I(t) = s_{\mathrm{sps}}(t)\, s_{\mathrm{rs_p}}(t)\, s_{\mathrm{rs_d}} t \tag{11.7}
$$

is constructed in such a way as to realize the desired constant envelope.

**Table 11.7** Received power levels

| Signal component | Maximum received power (dBW) | Minimum received power (dBW) |
|---|---|---|
| L5 SPS | −154.0 | −159.0 |
| S SPS | −157.3 | −162.3 |

**Table 11.8** Parameter values for the IRNSS composite signal

| Parameter | Unit | Value | Description |
|---|---|---|---|
| $R_{\mathrm{d_sps}}$ | sps | 50 | SPS data rate |
| $R_{\mathrm{c_sps}}$ | Mcps | 1.023 | SPS code chip rate |
| $R_{\mathrm{d_rs}}$ | sps | 50 | RS data rate |
| $R_{\mathrm{c_rs}}$ | Mcps | 2.046 | RS code chip rate |
| $R_{\mathrm{sc}}$ | Mcps | 5.115 | Subcarrier frequency |

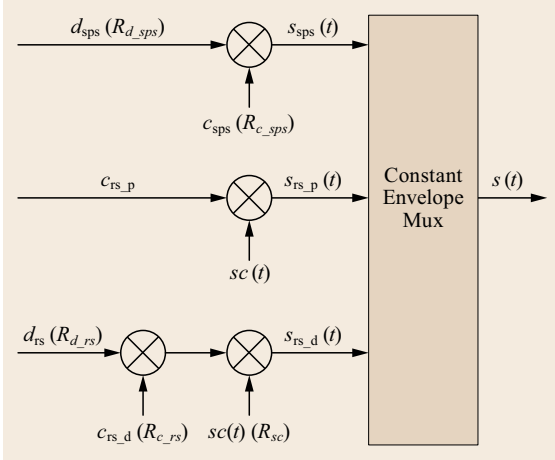

**Fig. 11.17** Composite signal generation (after [11.84])

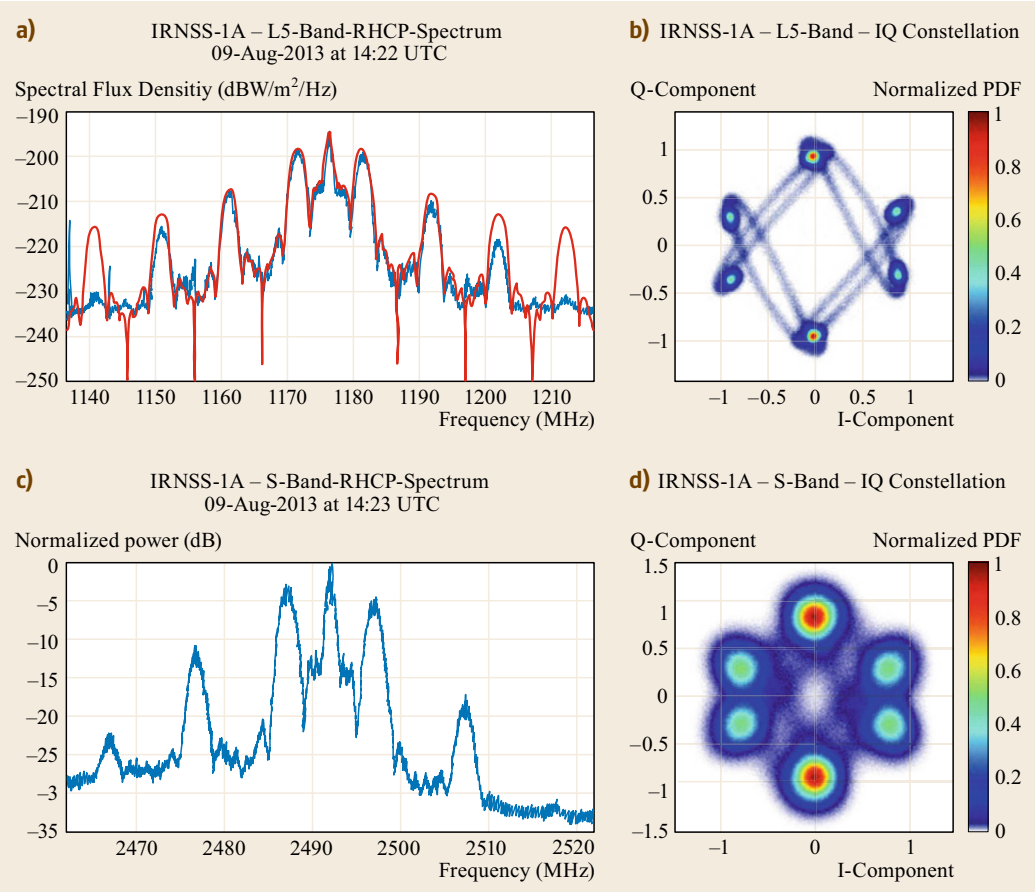

**Fig. 11.18** IRNSS spectra (a,c) and IQ signal constellation (b,d) as obtained from the observations of the IRNSS-1A satellite with a high-gain antenna at the signal monitoring facility of the German Aerospace Center (DLR) on August 9, 2013 (after [11.82])

For the purpose of illustration, the spectra and IQ constellation of the L5- and S-band signals of the first IRNSS satellite are shown in Fig. 11.18. While the narrow peak at the center frequency of the spectra relates to the SPS BPSK(1) signal, the BOC(5,2) modulation generates two distinct lobes of 2 MHz width, which are separated by ±5 MHz.

### PRN Codes

PRN codes selected for the SPS are similar to the GPS C/A Gold codes [11.85]. The length of each code is 1023 chips and the code is chipped at 1.023 Mcps. Each spacecraft is allocated a unique PRN code and distinct codes are employed for the L5- and S-band, respectively.

The individual PRN codes are derived from two 10 bit maximum-length linear feedback shift registers (MLFSR) G1 and G2, which generate individual maximum length sequences (Fig. 11.19). In accord with GPS [11.22], the G1 and G2 generator polynomials are defined as

$$\text{G1:}\quad x^{10}+x^3+1\,,$$

$$\text{G2:}\quad x^{10}+x^9+x^8+x^6+x^3+x^2+1\,.$$

Other than in GPS, however, which uses configurable taps to generate individual PRN code sequences, the IRNSS PRN codes are generated through different initial states of the G2 shift register to define the desired G2 chip delay. The resulting PRN sequence has a length of 1023 chips and is obtained from modulo-2 addition (xor-combination) of the G1 and G2 outputs. At the given chipping rate, the SPS code sequence repeats every 1 ms.

Initial values for the L5- and S-band PRN codes of the SPS and their association with the various IRNSS satellites are provided in Table 11.9.

For the regulated services, ranging codes with a length of 8192 chips and 4 ms duration are employed

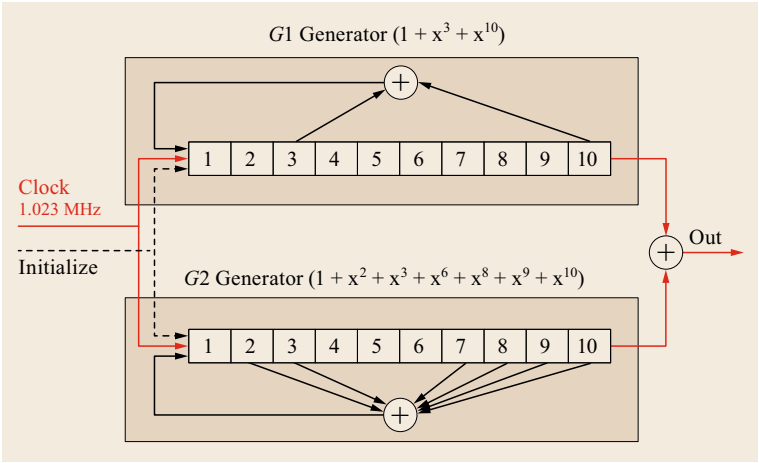

**Fig. 11.19** IRNSS SPS code generator

as discussed in [11.86] and [11.82]. The pilot signal, furthermore, employs a secondary code of 40 chips, yielding a repeat period of 160 ms.

### Navigation Data

The master frame of the IRNSS SPS navigation data comprise four subframes of 600 symbols length, which are transmitted at 50 sps [11.84, 86]. Each subframe has a 16 bit sync word followed by 584 symbols of forward error corrected and interleaved data. A 1/2 convolution encoding is applied for FEC of the navigation data, which results in a net amount of 292 bits per subframe (excluding the sync word). To protect against burst errors, the 584 symbols of the FEC-encoded navigation data are, furthermore, interleaved using a block interleaver with 73 columns and 8 rows. Data are first written in columns and read in rows. The start of each subframe is marked by a TLM word of 8 bits and each subframe ends with a 24 bit CRC to verify the data integrity of the received subframe bits as well as six additional tails bits.

The transmission time of each subframe is provided in the form of a time-of-week count (TOWC) following the telemetry (TLM) word. It is measured relative to the start-of-week and complemented by a week count transmitted in data of the first subframe. Both values refer to IRNSS System Time, which started at 23:59:47 UTC on August 21, 1999 and exhibits a constant nominal offset of 1024 weeks from GPS time.

The IRNSS navigation subframes employ a hybrid structure. Subframes 1 and 2 transmit a set of primary navigation parameters in a fixed structure. Subframes 3 and 4, in contrast, transmit secondary navigation parameters in the form of messages with varying structure and contents. As can be recognized from Table 11.10, the subframes 1 and 2 include a 232 bit data field, whereas subframes 3 and 4 employ a complementary 6 bit message identification number and a slightly shorter data field.

The primary navigation data in subframes 1 and 2 include information, which is essential for the computation of a position fix and, therefore, continuously transmitted with a 48 s repeat rate:

- Satellite orbital elements
- Satellite clock correction model parameters
- Satellite and signal health status
- User range accuracy
- Total group delay.

They are complemented by the secondary navigation parameters transmitted in alternating messages with varying update rates in subframes 3 and 4:

- Satellite almanac
- Atmospheric (ionospheric) correction model
- IRNSS time offsets w.r.t. UTC and GNSS
- Constellation status
- Ionospheric grid delays and confidence
- Text messages
- Differential corrections
- Earth orientation parameters
- AutoNav-related parameters.

The navigation data are generated in the IRNSS Navigation Centre (INC) based on one-way and two-way ranging measurements, timing information from the IRNSS Network Timing Center (IRNWT), telemetry parameters, meteorological data, and ionospheric information. The clock and ephemeris data are estimated and then propagated for subsequent days. The primary navigation parameters are predicted for the subsequent 24 h and uplinked. IRNSS uses the world geodetic system (WGS) 84 coordinate system for position computation. The AutoNav parameters are clock

and ephemeris data (similar to primary navigation parameters) predicted for seven days and uplinked to the spacecraft. In case the system is unable to uplink the primary parameters due to any reason, the AutoNav data are picked up from on-board memory and transmitted.

In the absence of data for a specific subframe, an idle pattern made up of alternating zeroes and ones is transmitted in the corresponding data field. In the case of missing primary navigation data in subframes 1 and 2, the transmission of the idle pattern is, furthermore, complemented by setting the alert flag in the subframe header [11.84].

Descriptions of the IRNSS navigation parameters and their application in the user receiver are provided in [11.87] as well as the IRNSS SPS ICD [11.84].

Based on various trade-off studies, a set of Keplerian elements as used in GPS and other MEO constellations has been adopted to describe the satellite orbits in the IRNSS broadcast ephemeris [11.87]. It may be noted that the same parameterization and orbit model are applied for both the IGSO and GEO satellites, whereas a special GEO model has, for example, been adopted for the regional BeiDou system to avoid potential singularities in the ephemeris generation at near-zero inclination [11.88].

The satellite clock offset from IRNSS System Time (also known as IRNWT) is described through a second-order polynomial and an eccentricity-dependent correction for periodic relativistic effects. The resulting clock offset applies for dual-frequency L5/S-band users, and a *total group delay* parameter ($T_{GD}$) provided in the primary navigation parameters needs to be taken into account by single-frequency L5 users. Complementary intersignal corrections accounting for group delays between SPS and RS signals are discussed in [11.81]. Finally, translation from IRNWT to UTC and UTC(NPLI) (the UTC realization of the National Physical Laboratory of India) as well as the GNSS time scales of GPS, GLONASS, and Galileo is accomplished through dedicated messages transmitted at 20 min intervals.

Ionospheric information for single-frequency users is provided in the form of eight coefficients ($\alpha_i$ and $\beta_i$, $i = 1, \ldots, 4$) for a Klobuchar-style single-layer model [11.89] as well as real-time correction values for a $5° \times 5°$ grid covering the Indian subcontinent. Both data sets are determined by the IRNSS Navigation Center from the monitoring stations distributed across the service area (Sect. 11.3.4).

### 11.3.3 Spacecraft

#### Platform

The IRNSS spacecraft is configured around the INSAT-1000 (I1K) platform, an indigenous 1 t class bus for three-axis stabilized spacecraft. The I1K bus has been selected because the weight of the payload and all the subsystems required for IRNSS can be accommodated in the structure. It offers a favorable ratio of structural weight to payload weight and volume, and meets the propulsion requirement of the satellites. The I1K bus also falls within the payload capacity of the PSLV (Polar Satellite Launch Vehicle), the workhorse of Indian space program. All the satellites for GEO and IGSO will be similar. The common design has been chosen in order to manufacture the satellite in a production mode to enable the deployment of constellation in a fast-track mode. Key parameters of the IRNSS spacecraft are summarized in Table 11.11. The stowed view of the IRNSS spacecraft is shown in Figs. 11.20 and 11.21.

The power system comprises the solar panels used to generate the required power, the batteries for storage and, eclipse support, and the electronics to manage, control, and distribute the power throughout the spacecraft. The solar cells generate a total power of around 1600 W to support a payload power requirement of 900 W.

The attitude and orbit control subsystem (AOCS) of IRNSS is configured as a three-axis stabilized zero momentum system with reaction wheels to provide a stable platform for the navigation application. The AOCS together with the propulsion subsystem facilitates the transfer orbit maneuvers, station-keeping maneuvers, and the fine adjustment of the spacecraft attitude. The star sensors provide the orientation data and the dynamically tuned gyroscope (DTG) delivers the body rates data to the AOCS, which computes the necessary control torque commands for the actuators. Other than common MEO GNSS satellites, the IRNSS spacecraft do not employ a nadir orientation, but continuously steer the yaw axis (and thus the antenna boresight) toward a point at 83° E longitude and 5° N latitude on the surface of the Earth. In this way, an optimum signal coverage is obtained for the envisaged service area. The solar panels are oriented to generate maximum power by maintaining the Sun direction normal to the panel surface.

**Fig. 11.20** IRNSS spacecraft in clean room (courtesy of ISRO)

**Table 11.11** IRNSS spacecraft characteristics [11.90]

| Parameter | Value |
|---|---|
| Dry mass | 614 kg |
| Lift off mass | 1425 kg |
| Physical dimension | 1.58 m × 1.5 m × 1.5 m |
| Power generation | Two solar panels generating 1660 W, one lithium ion battery with 90 Ah capacity |
| Propulsion | 440 N liquid apogee motor and 12 22 N thrusters |
| Control system | Zero momentum system;<br>Sensors: Sun sensors, star sensors, gyroscopes;<br>Actuators: reaction wheels, magnetic torquers, 22 N thrusters |
| Mission life | 10 years |

The thermal control system provides a benign thermal environment to the various subsystem elements of the spacecraft. A judicious combination of radiators and insulators is used to achieve the thermal balance. While conventional thermal control elements are used for the majority of the subsystems, special thermal control schemes have been designed and implemented for temperature-sensitive elements such as atomic clocks, clock-monitoring units, and the corner cube retro reflector.

The IRNSS satellites are equipped with a 440 N boost motor that is used to reach the desired mission orbit after separation from the launcher and deployment into the elliptical transfer orbit [11.80]. The required fuel contributes the dominant fraction of the wet spacecraft mass at lift-off. Further to the boost motor, a set of 12 22 N thruster is accommodated for fine orbit acquisition and maintenance maneuvers.

### Payload

The IRNSS satellites have two primary types of payloads, viz. the navigation payload and the ranging payload. The navigation payload of IRNSS covers the generation of navigation signals in the S- and L5-bands and their transmission to the users. The ranging payload, in contrast, supports two-way ranging of the IRNSS spacecraft from dedicated ground stations as part of the mission operations. As a third payload, the IRNSS satellites carry a retroreflector array for SLR.

*Navigation Payload.* The architecture of the IRNSS navigation payload is illustrated in Fig. 11.22. It comprises the following major subsystems:

- The RAFSs
- The atomic clock monitoring unit (ACMU)
- The clock distribution unit (CDU)
- The navigation signal generation unit (NSGU)
- The modulation and up-converter unit
- The high-power traveling-wave tube amplifier (TWTA)
- Output filters, and
- The dual-band array antenna.

A redundant set of three atomic clocks provides the basis for the onboard time and frequency generation. The RAFSs selected for the IRNSS satellites have been manufactured by Spectracom, Switzerland, which has earlier provided similar RAFS for the Galileo and

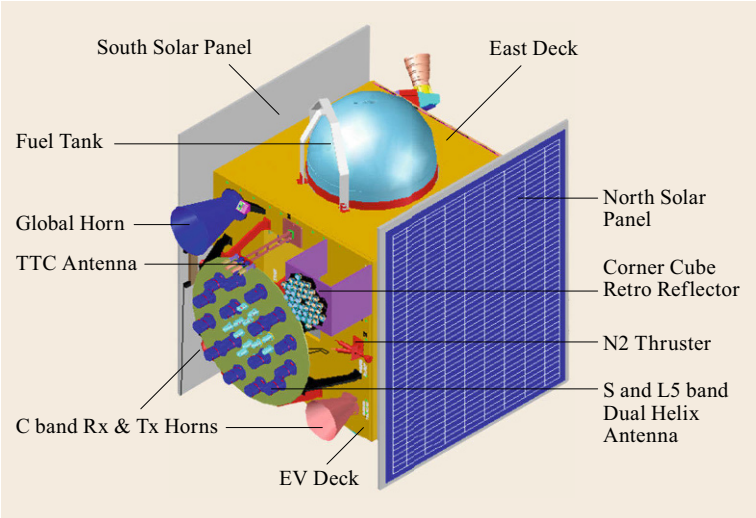

**Fig. 11.21** IRNSS satellite – stowed view (courtesy of ISRO)

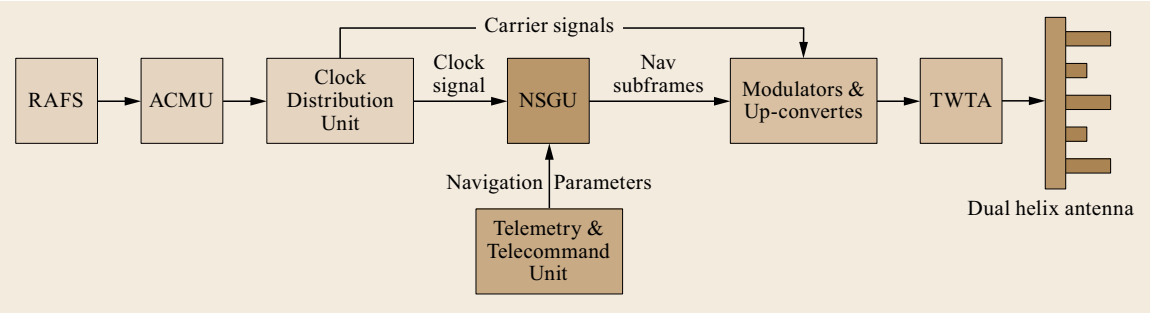

**Fig. 11.22** Navigation payload block diagram

BeiDou programs. They offer very high stability with an ADEV of better than $0.5 \cdot 10^{-12}(\tau/\mathrm{s})^{-1/2}$ over time scales from $\tau = 1$ to 10 000 s

Within the ACMU, the frequencies of individual frequency standards are compared and monitored. In addition, the fundamental frequency $f_0 = 10.23$ MHz is generated from the native 10 MHz output of the active RAFS. All carrier frequencies and chipping rates required for the navigation signal are rational multiples of 10.23 MHz (e.g., $f_{L5} = 115 f_0$ and $R_{c_sps} = 0.1 f_0$) and are coherently generated from the ACMU output through frequency multiplication or division.

The NSGU receives the navigation parameters computed on ground through the telemetry and telecommand unit and stores them in the NSGU memory. The stored data are time stamped, encoded, formatted, and combined into individual messages and subframes. The resulting broadcast navigation data are modulo-2 added to the satellite-specific PRN code and modulated on the carrier. Finally, the modulator output is up-converted, amplified to the required power level, and transmitted through the antenna.

To obtain a gain pattern with the desired shape and directivity, the IRNSS antenna is made up of an array of phase-coherently connected helix antenna elements. However, distinct elements are used for the L5-band (1176.45 MHz) and the S-band (2492.028 MHz), which differ by more than a factor of 2 in frequency and require different physical dimensions of the respective helix elements. As illustrated in Fig. 11.21, the antenna comprises 16 and 18 short axial helix elements for the L5- and S-band, respectively. The combined antenna has been designed such that the phase centers of both bands lie on the same axis, which also meets the overall antenna RF performance requirements. For thermal protection, the antenna array is covered with an insulation layer.

*Ranging Payload.* The IRNSS satellite has an independent C-band bent-pipe transponder for ranging. A code division multiple access (CDMA) modulation is employed for the ranging signal. This enables concurrent two-way ranging of the IRNSS satellites from up to four ground-based ranging stations [11.91].

The ranging payload comprises distinct C-band horn antennas for the uplink and downlink (Fig. 11.21), a pre-select filter, the receiver subsystem, the solid state power amplifier (SSPA), and the output band-pass filter. The narrow band transponder has a bandwidth of 25 MHz.

The CDMA ranging stations (IRCDR) located at different places in India perform the two-way ranging of the satellite and facilitate precise orbit determination of the IRNSS satellites. The two-way ranging also helps to validate the one-way range measurements performed by the reference stations (IRNSS Range and Integrity Monitoring Stations (IRIMS)).

*Corner Cube Retro Reflectors.* Corner cube retroreflectors (CCRRs) are placed on the IRNSS spacecraft to enable precise laser ranging. The retroreflector array has been developed in India is composed of 40 uncoated Suprasil-311 quartz prisms with a circular aperture of 38 mm diameter (Fig. 11.23).

The IRNSS satellites are routinely tracked by European, Australian, and Asian stations under the coordination of the ILRS [11.62]. The resulting observations offer a cm-level precision and are mainly used for the validation of the IRNSS precise orbit determination obtained from radiometric one- and two-way tracking. In addition, they can also be used for standalone orbit determination, even though the temporal coverage is substantially less dense than that of radiometric tracking data [11.92–94].

### Launch and Orbit Injection

The IRNSS satellites are launched from the Satish Dhawan Space Center (SDSC) in Shriharikota at the East Coast of India using the XL version of the well-proven PSLV (Fig. 11.24). With a total of four stages, the PSLV has an overall mass of 320 t and a height of 44 m. Solid propellant is employed for the first stage (which includes a core stage and six strap-on boosters) as well the third stage, whereas liquid fuel is used in stages 2 and 4 [11.95].

Following the burnout of the fourth stage near 20 min after lift-off, the IRNSS satellite is deployed into a transfer orbit of about 18° inclination, which reaches from a perigee height near 300 km to a peak altitude of 20 700 km at apogee. To achieve the desired geosynchronous orbit, the apogee is first raised to roughly 36 000 km using two burns of the satellites 440 N boost motor. Subsequently, the perigee is raised to the same altitude using a series of three consecutive apogee boot maneuvers. These are also used to adjust the orbital inclination to the desired target value. Details of the mission design and maneuver planning are provided in [11.80] for the example of the IRNSS-1A satellite.

## 11.3.4 Ground Segment

The IRNSS/NavIC ground segment comprises various infrastructure components supporting the spacecraft and mission operations [11.90]. It includes:

- The satellite control facility
- The navigation centre, and the
- The network timing facility, as well as
- Range and integrity monitoring stations
- CDMA ranging stations, and
- The data communication network.

These are complemented by SLR stations of external institutions providing supplementary tracking of the IRNSS satellites on a best effort basis. The location of the Indian ground segment sites is illustrated in Fig. 11.25.

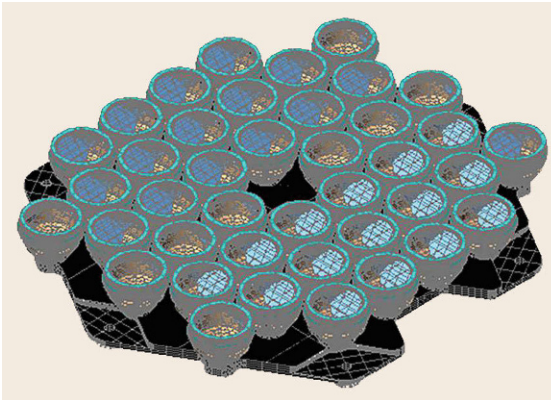

**Fig. 11.23** Laser retroreflector array of the IRNSS satellites (courtesy of ISRO/ISTRAC)

**Fig. 11.24** The PSLV used to carry the first IRNSS satellite into orbit (courtesy of ISRO)

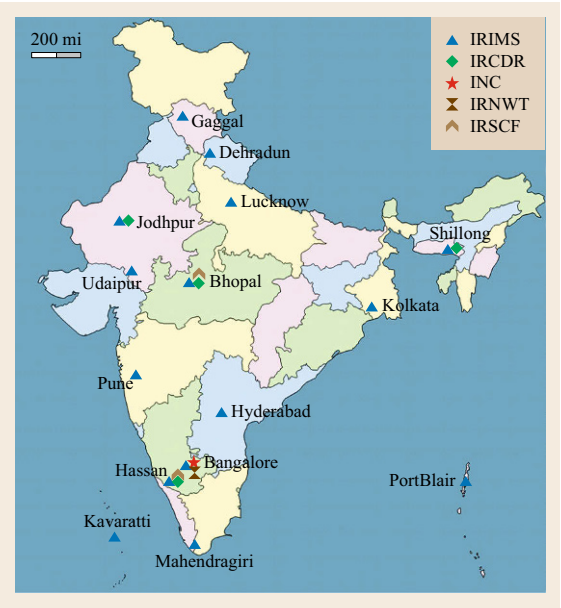

**Fig. 11.25** Map of the IRNSS ground segment

### IRNSS Satellite Control Facility

TT&C operations of the IRNSS satellites are carried out from the IRNSS Satellite Control Facility (IRSCF; Fig. 11.26). It comprises two Satellite Control Centres (SCC) and Spacecraft Control Earth Stations (SCES). For redundancy purposes, the main SSC at Hassan is complemented by a second SSC at Bhopal.

The Spacecraft Control Centre (SCC) consists of all the computers, servers, encoders, the monitoring and command software, etc., used to conduct the operations of the spacecraft platform. It monitors the telemetry signals, generates the telecommands, encodes them and forward them to SCES. These consist of several full coverage and full motion antennas, which are used to track the IRNSS spacecraft, to acquire their telemetry, and to uplink telecommands.

In addition to its regular (TT&C) operation, the IRSCF also receives the navigation parameters generated by the navigation software from the INC and uplinks them to the spacecraft.

As a GEO-IGSO combination of satellites has been chosen for the IRNSS space segment, regular station-keeping operations are required roughly once per month [11.94] to maintain the specified orbits and ground tracks. The station-keeping maneuvers cause a short outage of service for a given satellite. On completion of the station-keeping maneuver, the ranging and orbit determination of the satellite are again carried out and the new set of orbit and clock parameters are uplinked before the satellite is again declared operational. The processes are highly automated and the outage time is kept minimal.

**Fig. 11.26** IRNSS spacecraft control facility Hassan (courtesy of ISRO)

### IRNSS Navigation Centre

The INC at Byalalu near Bangalore is responsible for ensuring the navigation operations of IRNSS. It acquires and assimilates pseudorange and carrier-phase observations from the monitoring stations as well as two-way CDMA and satellite laser ranging measurements from the respective stations.

The navigation processing unit within the INC performs various functions such as range data processing, orbit determination, validation, and prediction satellite, station and system time computation, clock parameter estimation and prediction, as well as the ionospheric modeling. Based on these computations, the navigation software generates the primary and secondary navigation parameters, which are subsequently uplinked to the IRNSS satellites. The INC also performs remote monitoring and control of all distributed facilities from a centralized location.

The orbit determination and prediction of IRNSS use state-of-the art concepts for the trajectory and measurement modeling. Using different types of observations, a 3-D RMS consistency at the 10–20 m level has been demonstrated for individual solutions. A dedicated radiation pressure model with a priori box-cylinder-wing model and three adjustable parameters [11.96] is employed in the orbit computation to properly account for the specific spacecraft properties. The orbit determination system makes use of a batch least-squares estimator for routine operations but switches to an extended Kalman filter (EKF) for post-maneuver arcs or in the case of unexpected clock events to achieve the best performance and to minimize the associated outages [11.92, 93]. When utilizing the EKF mode, the ephemeris updated interval is reduced from a nominal value of 2 h down to 15 min. Users may distinguish the EKF mode from the *Issue of Data Ephemeris and Clock* (IODEC) parameter in the ephemeris message, which is

nominally in the range of 0–11, but assumes values of 160–254 after a maneuver [11.94].

Generally, the orbit and clock parameters are predicted in advance for 24 h and uplinked to the spacecraft. In order to cater for contingency situations resulting in a communication breakage from ground system to the spacecraft, AutoNav data are also uplinked to the spacecraft. The IRNSS satellites store 7 days of AutoNav data sets with ephemeris and clock parameters and support a subsequent broadcast of primary navigation parameters.

In order to mitigate the ionospheric errors for a single frequency user, IRNSS utilizes a specially devised grid-based ionospheric model in addition to the conventional Klobuchar-like model. The ionospheric grid parameters computed by the navigation software and uplinked to the spacecraft form the major part of the secondary navigation data. The time offsets w.r.t. other GNSS service providers are also computed and uplinked as a part of secondary navigation parameters. These time offset parameters facilitate time correlation between different systems in multi-GNSS receivers.

### IRNSS Network Timing Facility

The IRNSS Network Timing (IRNWT) Facility at Byalalu has been is established with the objective to generate and disseminate IRNSS system time as an independent IRNSS time scale with the required accuracy, stability and traceability to UTC. It covers the following functions [11.97]:

- Precise timekeeping to support the navigation mission
- Steering of IRNSS System Time (IRNSST) toward international atomic time (TAI) and provision of IRNSST-UTC time information to the users.

The IRNSS system time is realized by an ensemble of atomic clocks such as active hydrogen-maser (AHM) and cesium standards, with appropriate measurement equipments and timing algorithms [11.98]. The resulting time scale is steered to International Atomic Time (TAI). TWSTFT as well as GNSS common-view time transfer methods are adopted for time steering. IRNSST will be steered to TAI by linking with UTC(k) labs such that the difference between TAI and IRNSSTT is maintained within 50 ns ($2\sigma$) at any yearly time interval.

### IRNSS Range and Integrity Monitoring Stations

The IRIMS are located at well-surveyed locations covering the IRNSS service area. They perform the one-way range measurements, which form the primary set of observations for orbit determination and clock offset estimation of the IRNSS spacecraft. The IRIMS house the IRNSS reference receivers that continuously track the navigation signals from the IRNSS constellation and transmit the pseudorange and carrier-phase measurements to the NC for further processing. IRIMS also aid the integrity determination of the IRNSS constellation and are used for determining the ionospheric and tropospheric delays as well as other biases in the IRNSS signals.

The NovAtel GIII receivers (Fig. 11.27) used in the IRNSS monitoring stations are based on the design of the reference station receivers for the United States' Wide Area Augmentation System, but have been adapted to tracking of the IRNSS SPS signals in the L5- and S-band.

### IRNSS CDMA Ranging Stations

Two-way ranging [11.91] is used for orbit determination of IRNSS satellites, in addition to one-way range measurements from IRIMS. It is carried out through the IRNSS CDMA Ranging (IRCDR) stations placed at widely separated locations to meet the required orbit determination accuracies. Each station has a full motion antenna system, utilized in time-shared mode, to perform ranging measurements for all satellites in the constellation. The two-way ranging data are processed at INC to estimate the orbit by which the one-way range measurements are validated.

### Satellite Laser Ranging Stations

SLR provides precise distance measurements for the calibration of the IRIMS one-way ranging and CDMA two-way ranging of IRNSS, and for validating the orbit estimations obtained from these measurement systems. Laser ranging of the IRNSS satellites is accomplished by measuring the round-trip time of a laser pulse reflected from a retroreflector array mounted on the Earth

**Fig. 11.27** GIII reference receiver for the IRIMS (courtesy of NovAtel)

facing side of the satellite. IRNSS takes the support of the ILRS [11.62] to perform the laser ranging of its satellites in a campaign mode using stations located across the globe.

#### IRNSS Data Communication Network

The IRNSS Data Communication Network (IRDCN) is a high-availability communications network consisting of redundant terrestrial and satellite links. The IRDCN enables the digital communication between the IRIMS, IRCDR, IRNWT, IRSCF, and INC with the highest order of reliability and availability.

### 11.3.5 System Performance

Generally speaking, the user positioning accuracy can be described by the product of the user equivalent range error (UERE) and the Position Dilution of Precision (PDOP, [11.99]). Following [11.100], position dilution of precision (PDOP) values of about 3 can be achieved with the full constellation of seven IRNSS satellites over the Indian subcontinent.

The UERE is defined as the RMS of the pseudorange measurements and modeling errors experienced by a user receiver in the navigation process. These comprise the signal-in-space range error (SISRE) describing the impact of orbit and clock errors as well as user-specific errors such as receiver noise and multipath or unmodeled atmospheric path delays.

To assess the impact of the navigation message and to quantify the achieved SISRE, the difference between the smoothed pseudorange observations of the IRNSS monitoring stations and their modeled values for the given location is continuously monitored by the INC. As illustrated in Fig. 11.28 for the first three satellites of the IRNSS constellation, meter-level line-of-sight errors are obtained during normal operations, which yield an SISRE of 1–2 m in accord with the user range accuracy (URA) values reported in the navigation message during these phases. Increased line-of-sight errors of up to 5 m may, however, be encountered after orbit keeping maneuvers [11.92].

A very first standalone navigation fix was achieved in April 2015 shortly after the activation of the IRNSS-1D satellite. As discussed in [11.101], 3-D positioning accuracies of 10 m or better could be obtained with the four satellite constellation except during selected periods of highly unfavorable PDOP. With the launch of the seventh satellite IRNSS-1G, positioning accuracy better than 10 m is obtained at any time over the Indian Region. The initial experiments also confirmed the quality of the ionospheric corrections and demonstrated that single-frequency users with corrections will be able to achieve a similar performance as dual-frequency L5/S-band users.

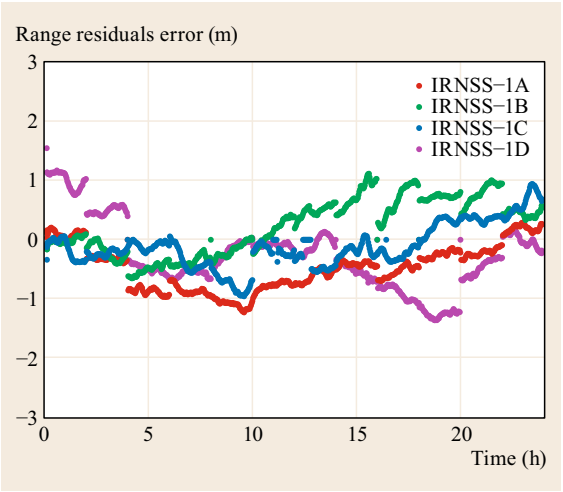

**Fig. 11.28** Difference of observed and modeled pseudoranges for IRNSS-1A, -1B, -1C, and -1D w.r.t. a monitoring station over a maneuver-free 24 h period (4 Sep. 2015)

The interoperability of the IRNSS L5 signal with other global and regional navigation satellite systems has been successfully demonstrated in [11.102]. Aside from evidencing a consistent measurement quality with that of GPS, Galileo and QZSS L5/E5a signals, the IRNSS observations were, for the first time, used in a combined multi-GNSS relative position solution together with the three other constellations. Compared to L1 signals, the longer L5 wavelength facilitates ambiguity resolution and the incorporation of IRNSS offers improved geometry and additional robustness for the obtained solutions.

# 12. Satellite Based Augmentation Systems

Todd Walter

Satellite-based augmentation systems (SBASs) are designed to enhance the performance of standard global navigation satellite system (GNSS) positioning. SBASs improve the positioning accuracy by providing corrections for the largest error sources. More importantly, SBASs provide assured confidence bounds on these corrections that allows users to place integrity limits on their position errors. Several systems have been implemented around the world and several more are in development. They have been put into place by civil aviation authorities for the express purpose of enhancing air navigation services. However, SBAS services have been widely adopted by other user communities, as the signals are free of charge and easily integrated into GNSS receivers.

This chapter describes the basic architecture, functions, and application of SBAS. Because the key motivation behind SBAS is integrity, it is essential first to understand the error sources that affect GNSS and how they may vary with time or location. It is then explained how the corrections and confidence intervals are determined and applied by the user. The different SBASs that have been developed around the world are described and how they are developed to the same international standards such that each is interoperable with the others. The performances and services of each system are described. Finally, the evolution of SBAS from its current single-frequency single-constellation form into systems that support multiple-frequencies and multiple-constellations is described.

The goal of this chapter is to explain the motivation for developing SBASs and provide the reader with a working knowledge of how they function and how they may be used to enhance GNSS positioning accuracy and integrity.

## 12.1 Aircraft Guidance

Satellite navigation is finding ever increasing use in aviation. The utility of satellite navigation is enabled by a variety of augmentation systems. These augmentation systems are independent of the individual satellite constellations and monitor their performance continuously. Most importantly, the augmentations detect faults in real time and warn the pilots within seconds. Such assistance is needed because the constellation ground control system may not detect and report faults for tens of minutes or longer. The fault detection alternatives include aircraft-based augmentation systems (ABASs), ground-based augmentation systems (GBASs), and satellite-based augmentation systems (SBASs). This chapter focuses on SBASs [12.1]. Particular emphasis will be placed on the wide area augmentation system (WAAS, [12.2]), which is the SBAS for North America and was also the first operational SBAS. SBASs have also been developed in Japan, Europe, and India and are being developed in Russia, China, and South Korea.

Currently, SBASs augment the global positioning system (GPS) with the following three services:

- Integrity monitoring to improve safety
- A ranging function to improve availability and continuity
- Differential GPS corrections to improve accuracy.

Thus augmented, GPS meets the performance requirements for most phases of flight, including vertical guidance during airport approach. The first SBAS, WAAS, was commissioned in July 2003. The accuracy of the system rapidly made it an industry standard in GPS receivers. It routinely achieves horizontal accuracies better than 85 cm and vertical accuracies better than 1.2 m 95% of the time [12.3]. SBAS has achieved widespread adoption in nonaviation fields due to its open standard, free provision, and high accuracy [12.4, 5].

### 12.1.1 Aviation Requirements

Navigation systems used for aviation are judged by four key measures [12.1]:

1. Accuracy: The reported aircraft position must be close to the true position. Accuracy generally characterizes nominal errors and is usually expressed as a 95% confidence number. That is, it is specified as a number $\geq$ 95% of the nominal position errors. Accuracy is the easiest requirement for SBAS to meet. Integrity, continuity, and availability are all much more difficult to achieve.
2. Integrity: An aviation navigation system must ensure that no position error larger than a maximum tolerable bound is presented to the pilot. All faults that could lead to larger position errors must be flagged within a specified time-to-alert (TTA), and the probability of failing to flag such a fault must be below some small probability per operation, typically between $10^{-5}$ and $10^{-9}$ depending on the operation.
3. Continuity: Once an aircraft begins a critical operation, the navigation system must continue to function until the operation is complete. The allowable probability of a navigation system outage during an aircraft approach operation varies from $10^{-5}$ to $10^{-9}$ per operation.
4. Availability: The navigation system must be functional and meet the above requirements a large fraction of the time in order to be useful to aircraft. Indeed, aviation requires availabilities better than 99–99.999% of the time. It is both unsafe and uneconomical to send an airplane to an airport only to discover once there that landing guidance is unavailable.

The numerical value for each requirement depends on the aircraft operation and they become more demanding as the aircraft is brought closer to other aircraft or to the ground, e.g., approaching an airport and preparing to land. So-called precision approach operations require vertical position accuracies of a few meters. Airport approach operations have particularly tough requirements for accuracy and integrity. Thus, most SBAS development and characterization effort focuses on this application. Generally, as long as the SBAS can meet the approach requirements, it will also meet the requirements for the other phases of flight.

Vertically guided approach is based on a smooth glide path with a constant rate of descent. This glide path, typically 3°, passes through a *decision height* where the pilot must decide whether or not to complete the landing. Pilots prefer vertically guided approach to the more challenging nonprecision approach. Nonprecision approach is also known as a step-down approach because pilots alternate a sequence of constant altitude segments with vertical step-downs as they approach the airport. This process requires the pilot to change the vertical descent rate of the aircraft at different points along the approach. This increased workload has contributed to a larger number of aircraft accidents. Before augmented GPS, an instrument landing system (ILS) or microwave landing system (MLS), sited at the airport, were the only systems able to provide precision

approach. SBAS enables precision approach without any airport-specific equipment. It allows the pilot to use a constant rate of descent down to a decision height of 200 ft above the ground, using a localizer precision with vertical guidance (LPV) procedure [12.6]. This is an important benefit as thousands of smaller airports are not equipped with ILS or MLS.

### 12.1.2 Traditional Navigational Aids

Traditionally, aviation has relied on radio-navigation signals from ground-based transmitters to determine aircraft position (Chap. 30). These systems are still largely in place and in wide use as the aviation community is very risk averse and slow to change. Typically, aircraft uses the same set of avionics originally installed in the aircraft, without update, for more than 20 years. It can be very difficult and costly to transition away from the existing set of equipment. The main set of navaids currently in use is:

- Distance measuring equipment (DME)
- Very high frequency (VHF) omni-range (VOR)
- The tactical air navigation system (TACAN)
- The ILS.

These are described in more detail below.

A DME consists of a fixed antenna and transmitter–receiver that responds to aircraft interrogations after a fixed delay. As the aircraft knows the amount of the fixed delay, it obtains a true range to the antenna by subtracting the delay from the time between interrogation and response and dividing by 2. Because it also knows the location of the antenna, the aircraft then knows that it is somewhere on a circle at a fixed distance from that location. By querying 2 DMEs or using other information, the aircraft can further refine its position. The typical ranging accuracy of a DME is on the order of hundreds of meters. Each DME can be received to $\approx 150$ nmi. The United States (US) Federal Aviation Administration (FAA) maintains $\approx 1100$ DMEs in the conterminous United States (CONUS) to ensure nearly complete coverage by multiple DMEs.

A very high frequency (VHF) omnidirectional range (VOR) sends out two signals: one is uniform in all directions and the other is highly directional. By measuring the time between receipt of these messages, the aircraft can obtain a directional angle from the VOR. The typical accuracy of a VOR is less than half a degree. Thus, a co-located VOR and DME can provide an absolute position good to several hundred meters although this uncertainty increases with distance from the navaids. As with DMEs, there are on the order of 1100 VORs within CONUS.

The TACAN system is a military version of a combined VOR/DME system. However, the DME portion of the TACAN signal is available for use to civilians and in the United States, most DMEs are actually TACANs. A VORTAC is a combined VOR and TACAN that meets both military and civilian needs

An ILS consists of two sets of antennas and transmitters, one to provide angular offsets from the runway centerline and the other to provide angular offsets from the desired vertical glide path. The first set, called the localizer, provides horizontal guidance and the second set, called the glideslope, provides vertical guidance. In order to provide guidance to a single runway end, both the localizer and glideslope equipment are required. To serve both ends of a single runway, separate glideslope and localizer installations are required. Depending on the level of calibration, an ILS can safely guide an aircraft to within 200 ft of the ground (Category I) or all the way down to a blind landing (Category III). There are $\approx 1300$ ILSs in the United States.

Each of these terrestrial navigational aids requires owned or leased land to occupy, reliable power and communication, maintenance, and constant calibration. Each piece of equipment is flight inspected for accuracy as often as every 2 months. The installation and ongoing support costs to maintain thousands of terrestrial navigational aids are significant. The FAA investigated satellite-based methods for providing guidance in order to reduce the existing navaid infrastructure and overall costs of maintenance.

### 12.1.3 Receiver Autonomous Integrity Monitoring (RAIM)

The first and most common use of GPS in aviation provides horizontal guidance by utilizing receiver autonomous integrity monitoring (RAIM [12.7]), which is a variety of ABAS, to detect faults. Such RAIM-capable receivers estimate aircraft position and then compute the measurement residual for each satellite. The residuals are the difference between the actual measurement and the expected value that corresponds to the estimated position without using that satellite. This check detects measurement faults, provided there are at least 5 satellites in view with good geometry. RAIM is further capable of isolating measurement faults provided there are at least six satellites in view with very good geometry (Chap. 24).

GPS-based RAIM is the most widely used form of satellite navigation by aviation to date. It only provides horizontal guidance, but does so without any expensive ground infrastructure. Its coverage is global and not subject to limited ground networks or loss of signal due to blockage by terrain. It is also generally far more ac-

curate than VOR/DME/TACAN, and does not require flight inspection to maintain calibration.

RAIM leverages the normally over-specified nature of the GPS position solution, but this method is very sensitive to the state of the GPS constellation. In poor geometries, RAIM quickly becomes unavailable. For this reason, RAIM receivers cannot be the primary navigation aid; they must supplement another navigation aid. In contrast, SBAS-enabled receivers may be the primary navigation system for nonprecision approach because the fault monitoring is done on the ground and communicated to the aircraft. SBAS can provide availability in much worse geometries than RAIM can support.

### 12.1.4 Satellite-Based Augmentation Systems (SBAS)

SBAS is capable of assuring better horizontal accuracy than RAIM as well as providing vertical guidance. Therefore, SBAS can safely bring the aircraft closer to the ground with fewer satellites in the sky and with worse observational geometry.

An SBAS utilizes a network of ground monitors to continuously observe the performance of the navigation satellites. As shown in Fig. 12.1, the reference stations send their measurements to master stations that determine differential corrections and corresponding confidence bounds. Each master station processes the measurements and transmits data to an uplink station. The uplink station relays this information to the end users via a geostationary Earth orbit (GEO) satellite. Each SBAS has multiple master stations, uplink stations, and GEOs so that it can reliably survive the failure of any one component. SBAS augments the core constellations with the following three services:

1. *Differential corrections*: SBAS broadcasts differential corrections for each satellite tracked by the ground network. The SBAS also transmits corrections for the effects of ionospheric delay over its region of interest. By applying these corrections to their pseudorange measurements, the user equipment improves its position accuracy.
2. *Integrity monitoring*: SBAS also broadcasts error bounds for each monitored satellite and each ionospheric correction parameter. These error bounds are used to determine the maximum possible airborne position error that may remain after the differential corrections are applied. Error bounds are appreciably more difficult to generate than differential corrections because the probability that the position error bound fails to overbound the true error must be smaller than $10^{-7}$ per approach. In addition, this information must be updated within 6 s of any unsafe condition.
3. *Ranging*: The SBAS GEO signals are similar to GPS L1 coarse/acquisition (C/A) signals in design and so an SBAS-enabled receiver uses essentially the same hardware as a normal GPS receiver. In addition, the SBAS signals are synchronized to GPS so they can be used for ranging. The additional ranging measurements are added to the suite of GPS ranging signals to improve the time availability and continuity of the position fix.

Each master station generates a grid of corrections for the ionosphere over its coverage region. This grid is 5° by 5° in latitude and longitude between 60° S and

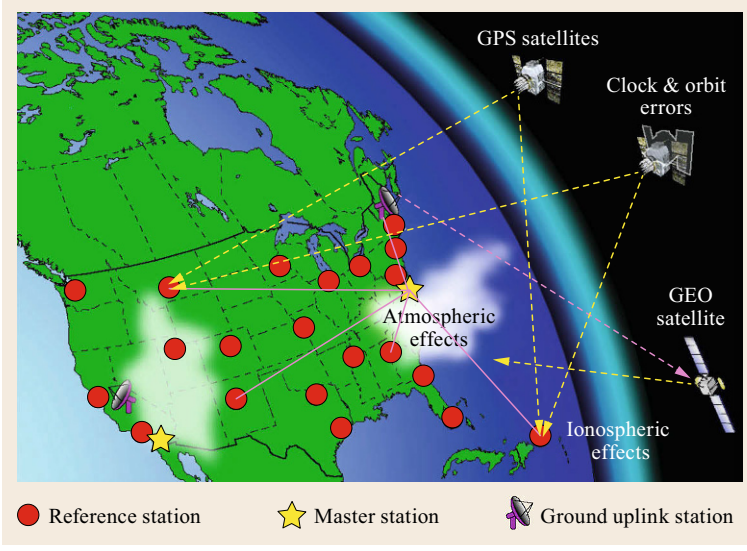

**Fig. 12.1** General concept of a satellite-based augmentation system (SBAS)

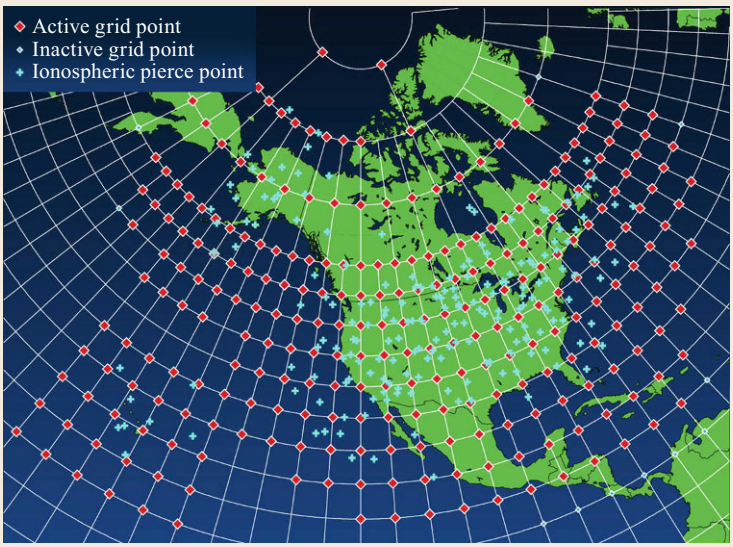

**Fig. 12.2** SBAS ionospheric grid over North America

60° N and is less dense over the polar regions [12.8]. As with the stand-alone GPS single frequency ionosphere model, the SBAS ionospheric corrections model the ionosphere as though it were a thin shell existing at 350 km above the surface of the Earth [12.9]. The line of sight between the receiver and the satellite penetrates this layer at a point labeled the ionospheric pierce point (IPP). The user applies the four surrounding grid values to interpolate the ionospheric delay specific to each location of their IPPs. Figure 12.2 shows the SBAS ionospheric grid over North America with the grid points used by wide area augmentation systems (WAASs) indicated by *red diamonds*. Also shown are the IPPs as measured by the reference stations at one particular time.

The master station also generates a vector correction for each GPS satellite in view of the reference network. One element corrects the satellite clock and the other three elements are corrections for the three dimensions of satellite position. These corrections are generated from the pseudorange measurements after the ionospheric contribution has been removed and errors due to the troposphere and multipath have been minimized.

While the processing to generate the ionospheric and satellite specific corrections is sophisticated, the more difficult task is to bound the position errors that will remain after the corrections are applied. The bounds for the residual errors in the ionospheric corrections are called grid ionospheric vertical errors (GIVEs). The GIVE bounds the ionospheric correction for a given point in the grid for a line of sight that passes vertically through that point. Lines-of-sight at other angles get multiplied by a geometric obliquity factor to adjust the delay and confidence values for the longer ray path. The master station also bounds the impact of the satellite-specific error after correction, and these bounds are called user differential range errors (UDREs). They bound the projection of the satellite clock and location errors when projected onto the line-of-sight to the worst-case location in the coverage area.

The master station packs the ionospheric corrections, satellite specific corrections, and associated bounds into the SBAS message stream. This message stream is uplinked to the GEOs. These satellites are essentially bent pipes – they simply shift the uplink signal frequency and broadcast the message to users everywhere in the geostationary footprint.

## 12.2 GPS Error Sources

GPS signals are affected by many potential sources of error. It is important to understand these error sources and the possible effect they may have on the signal. For integrity, we are primarily interested in the effect they have on ranging accuracy. The errors may cause unmodeled variations in the reception time of the signals and hence the apparent range to the satellite. An SBAS first attempts to correct these errors in order to improve

accuracy. Then, to the extent that it cannot fully correct the errors, it must describe to the user how much uncertainty remains on each of their corrected pseudorange measurements. It is therefore essential to understand and describe the physical source and effect of the different error sources. These sources are usually broken into three categories:

- Those originating on the satellite with the generation and broadcast of the signal.
- Those affecting the signal during its propagation from the satellite to the user.
- Those affecting the signal at the receiver and in its immediate vicinity.

The first category includes errors in the described satellite orbit position and clock offset, biases between the signals on different frequencies or between the code and carrier components, deformations of the signals, and look-angle-dependent biases from the satellite antenna. The propagation environment includes the effects of the ionosphere and the troposphere. The final category includes local multipath, receiver noise and tracking errors, and user antenna bias effects. For SBAS, both the errors affecting the reference stations and the users are important. The most significant error sources are described in greater detail below.

### 12.2.1 Satellite Clock and Ephemeris

Satellites suffer from nominal ephemeris and clock errors (Sect. 3.3.4) even when there are no faults present. These are typically very small for GPS, usually less than a meter in projected error. Occasionally, the broadcast GPS clock and ephemeris information may contain significant errors relative to the true state of the satellite position and clock. Such faults may appear as jumps, ramps, or higher order errors in the GPS clock, ephemeris, or both. These faults may be created by changes in state of the satellite orbit or clock, or simply due to the broadcasting of erroneous information. For example, a clock fault may lead to a sudden change in the timing of the broadcast signal while the position description remains accurate. Another example is an unannounced maneuver where the orbit suddenly changes, but the clock remains accurate. Alternatively, the satellite state may not change, but the navigation data that is broadcast to the user is changed to contain incorrect information. Another possibility is that everything about the satellite is correct, but either the user or the reference station incorrectly decodes the ephemeris information. For GPS, the nominal clock and position errors create projected pseudorange errors that typically have a standard deviation better than 1 m. Faults are rare on GPS, typically occurring no more than twice a year, but may lead to projected errors of several kilometers.

### 12.2.2 Ionosphere

The ionosphere (Chap. 6) is a complex three-dimensional (3-D) distribution of free electrons primarily distributed between 100 and 1000 km above the surface of Earth [12.9]. It is often modeled as a two-dimensional (2-D) structure occurring in a thin shell at a height of 350 km. The electron distribution varies over the course of the day with a maximum effect in the local afternoon when the Sun's radiation has created the largest number of free electrons, and a minimum effect at night when those same electrons have recombined with the positive ions. There are seasonal changes with the ionosphere as the Earth's magnetic field changes its orientation with respect to the Sun. The Sun also undergoes an $\approx 22$ year cycle where it reverses its magnetic field. This leads to an 11 year cycle in the ionosphere with significantly more ionospheric delay and disturbances near the maximum of the cycle than nearer to the minimum.

For nonequatorial regions (roughly $> 25^\circ$ of latitude), the thin shell model is usually a very good model. The ionosphere is easily estimated and bounded over large distances by assuming a linear variation in delay in the east–west and north–south directions. However, periods of disturbance occasionally occur where simple confidence bounds fall significantly short of bounding the true error [12.10, 11]. Additionally, in equatorial regions of the world, the ionosphere often contains significant 3-D structure. Disturbances can occur over very short baselines causing them to be difficult to describe in the limited SBAS message structure. Variations $>$ 20 m of vertical delay over a 50 km baseline have been observed, as have rates of change as large as four vertical meters of delay per minute.

### 12.2.3 Troposphere

Tropospheric errors (Chap. 6) are typically small compared to ionospheric errors or satellite faults. Historical observations were used to formulate a model and analyze deviations from the assumed model used by SBAS. The assumed model will not exactly match the local climatological conditions. There are unpredictable variations in barometric pressure, temperature, and moisture content. Each of these variations may produce up to a few decimeters of vertical delay error that can map to a few meters of error at very low elevation angles. Typically, the total vertical error is $< 10$ cm and therefore $< 1$ m at low elevation [12.12].

### 12.2.4 Multipath

Multipath (Chap. 15) depends upon the environment surrounding the antenna and on the satellite locations. In aircraft, a well-placed antenna may have a very clean environment and the motion of the aircraft usually causes multipath to vary quickly. Thanks to carrier smoothing, the overall aircraft multipath can be reduced to $< 25$ cm standard deviation for a narrow correlator receiver [12.13]. The reference stations however may be in much more cluttered environments and therefore can experience multipath errors of several meters. Because the reference station antennas are stationary, the period of the multipath can be 10 min or greater. For GPS, multipath also contains a periodic component that repeats over a sidereal day. Thus, severe multipath may be seen repeatedly for several days or longer. However, with two frequencies, the reference stations may use a very long time constant for carrier smoothing and also be able to achieve standard deviations $< 25$ cm after sufficient smoothing time.

### 12.2.5 Other Error Sources

The previous sections describe the four most significant error sources, but there are other error sources that usually are not a factor but that potentially could affect performance. One such example is signal distortions on the GPS codes [12.14, 15]. Because the signals are not strictly identical, there will be differences in their measured arrival time that depend upon the correlator spacing and bandwidth of the observing receivers. Such biases would be transparent to a network of identically configured receivers, but could be noticeably different to a user receiver with a different design. There are nominal deformation biases that are always present and may be several decimeters large. There is also concern over possible fault modes that could lead to errors $> 10$ m.

Another postulated threat is that a satellite may fail to maintain the coherency between the broadcast code and carrier. This fault mode is one that occurs on the satellite and is unrelated to incoherence caused by the ionosphere. This threat causes either a step or a rate of change between the code and carrier broadcast from the satellite. This threat has been observed on the L5 signals of the new Block IIF GPS satellites.

Look-angle-dependent biases in the code and on the carrier phase on both L1 and L2 are present on GPS antennas [12.16]. These biases may be several tens of centimeters. They may result from intrinsic antenna design as well as manufacturing variation. They are known to be present on the satellite antennas, on the reference station antennas, and on the users antennas. A closely related error source is survey error on the reference station antennas which could lead to errors in estimating the satellite corrections.

## 12.3 SBAS Architecture

As previously mentioned, an SBAS consists of three elements:

- The reference network
- The central processing facility
- The GEOs.

The reference network collects the basic GPS data in real-time and forward it for further analysis. The central processing facility evaluates the data and generates corrections and decisions about integrity. This information is then broadcast to the users via GEOs. These elements and their function are described in the following subsections.

### 12.3.1 Reference Stations

Each reference station contains independent threads of reference equipment. Each thread consists of an antenna, a dual-frequency GPS receiver, an atomic clock, and redundant communication links. Figure 12.3 shows racks containing three threads of equipment for a WAAS reference station. Redundant threads are included so that hardware faults may be readily detected. The reference receivers are dual frequency. Every sec-

**Fig. 12.3** A WAAS reference station (reproduced with permission of the FAA satellite navigation team)

ond they take pseudorange measurements and carrier-phase measurements at the GPS L1 and L2 frequencies. The L1 and L2 frequencies are 1575.42 and 1227.60 MHz, respectively. The atomic clock makes it easier to compare previous measurements to the current ones and to identify outliers. The raw measurements from the reference stations are sent to each master station along redundant communication lines to ensure that each measurement arrives with very high likelihood. Reference stations are spaced $\approx 200$ km or more apart. They are often placed at facilities that can provide security, reliable power (with backup), and reliable communications. No processing is performed at the reference station locations. Instead the raw measurements are all sent to the central locations for processing. The reference station network should have enough redundancy such that the loss of any individual station will not limit availability of the overall service.

### 12.3.2 Master Stations

An SBAS master station has four main tasks:

- Collect the data
- Formulate the corrections
- Determine the confidence bounds
- Pack the information into messages for broadcast.

The master station will seek to obtain all of the raw GPS data from every thread of every reference station. However, in order to meet the TTA it cannot wait too long for this data to come in. At a certain time it has to move forward and make its determinations with the information that it has for the epoch in question. This process is repeated every second as the master station continuously has to decide what the next message to send should be.

Upon getting the data from the receivers, the master station first performs consistency checks to identify and isolate erroneous data. The data from the parallel threads at each reference station must agree with each other and with previous information. If it does not, the master station must determine which information is incorrect. If it cannot do so, then it must immediately warn the user that the prior correction data may be unsafe. Much more commonly, it is able to identify and remove bad measurements before they are used downstream. Next the data is fed into various filters and estimators. There is a satellite clock and orbit estimator that also estimates reference station clock offsets. There is an estimator for the biases between the L1 and L2 signals that are induced by hardware on the satellites and at the reference stations. Finally, there is an estimator for the ionospheric delay at each of the grid points that the SBAS chooses to correct.

Most importantly, there are safety monitors that determine how much error may be present in the estimates. By correcting GPS with SBAS, one is initially doubling the risk of failure. There are now two very complex systems that can fail instead of just one. The first task for SBAS is self-monitoring to ensure that it does not introduce error. Each reference station contains parallel threads of equipment. Each thread operates independently of the others. As a first layer of screening for errors, the output of each thread is compared against the others. The expected geometry difference is first removed using the surveyed antenna coordinates and the broadcast satellite position. Additionally, the clock difference between each thread must be resolved from measurements. This is performed by combining information from all common satellites over time. If the corrected measurements disagree by too much then they are discarded. If too many measurements are discarded from a particular thread then it is flagged for maintenance. This cross comparison will identify any large receiver/clock failures as well as large multipath errors not common between the antennas. Smaller receiver errors or any common mode error can still escape detection. Later monitors compare the measurements from different reference stations for consistency as well as examine the temporal behavior to try to identify SBAS errors and prevent them from affecting performance. By screening measurements across multiple threads at the first stage, the vast majority of harmful errors are eliminated before they can affect downstream filters.

The monitors continue by characterizing the levels of code noise and multipath remaining on the measurements after error screening and carrier smoothing [12.13]. These screened measurements are used to monitor errors on the satellites and estimated delays due to ionosphere so it is very important to understand and bound the limits of observability. The confidence values associated with each measurement are then propagated through the subsequent monitors so that the monitors may accurately state how much certainty they have in their ability to screen for errors.

The postcorrection satellite clock and ephemeris errors are bounded by the UDREs. The master station looks at the projected clock and ephemeris error throughout the service volume and has to make sure that the UDRE is sufficiently large to protect all users. However, there are other errors that may be present on the satellite. The code and carrier signals may not be completely synchronized. Should this be the case, the measured range to the satellite will vary with the amount of smoothing that has been performed which can change for users depending on time of acquisition and most recent cycle slip. There is also the possibility of variations in the signals shape that can affect the

tracking of the signal. All of these possible error sources have to be covered by the UDRE.

Dual frequency measurements are required to generate the ionospheric corrections. The ionosphere is dispersive and so the ionospheric delay at L1 is different from the delay at L2. More specifically, the observed delay is inversely proportional to the frequency squared. The SBAS ground system leverages this relationship to estimate the ionospheric delay at the vertices in the grid. Unfortunately, the avionics directly cannot make use of the L2 signal because it lies in a nonaviation portion of the radio spectrum. The FAA cannot assure its availability. Hence, the ground system estimates the ionospheric delay for the avionics and sends the grid of ionospheric delay estimates to the airborne user. The density of the reference network is determined by the spatial decorrelation of the ionospheric delay [12.17]. Few reference stations are required if the ionosphere is always smooth. If the ionosphere has steep gradients, then a greater number is required. In the future, GNSS satellites will broadcast two signals for civil aviation (L1 and L5). At that time, new avionics will use both frequencies to compute the ionospheric delay in the aircraft because the L5 frequency does fall within a protected aviation band.

The ionospheric delay value at each grid point must be estimated from the individual ionospheric measurements from each reference station [12.18–21]. In addition, the ionospheric correction error at each grid point is bounded by the GIVE. Because the measurements do not coincide with the grid points they must be combined in a way to account for the potential spatial variation of the ionosphere.The GIVEs must account for the measurement errors and the uncertainty in the propagation model. The ionospheric grid points (IGPs) themselves are separated by roughly $\approx 500$ km. Therefore, it is not possible to resolve very fine scale structure of the ionosphere. Further the measurements from the reference stations are sparse. The SBAS method for correcting the ionosphere depends on the fact that the ionosphere is generally slowly varying over hundreds of kilometers. The IGP delay algorithm nominally assumes limited variation in latitude and longitude, but must be prepared to identify times when its assumptions are invalid. Sometimes the ionosphere may be in a more disturbed state where the basic SBAS model is not an accurate description. At these times, the algorithm must recognize the problem and increase the confidence bounds accordingly [12.22].

SBAS uses a standard tropospheric model to predict the amount of tropospheric delay that exists on both the reference station and user lines of sight [12.12]. This is a climatological model based on years of primarily North American observations but that has been verified after the fact with data from other parts of the world. It provides values for the barometric pressure, temperature, and other parameters given a latitude and time of year. From these parameters the amount of tropospheric delay can be estimated. This model also provides an upper bound on the error that may be remaining after applying it.

The satellite, ionospheric, and tropospheric corrections can be applied to each reference station measurement to evaluate the combined effect of the corrections for that specific line-of-sight. These errors should combine together in the expected manner. If the total error bound does not appear to properly bound all such measurements then the UDREs and GIVEs may need to be increased. This range domain check is another reasonability test to ensure all of the information is consistent.

As a final check, each reference station thread can evaluate its corrected position solution against the known surveyed location of its antenna. This helps to ensure that all of the corrections are working well together and are adequately bounded. The range domain and position domain tests ensure that all of the corrections combine together correctly. The integrity bounding methodology requires that the errors can be treated as though they are independent. A dependency that leads to a magnification of the errors in the position domain would become more obvious with these evaluations.

Finally, the message processor determines which 250 bit message should be sent for the current epoch and packages it appropriately [12.8, 23]. Usually the messages can follow an expected schedule. However, in the event of an integrity alert, the master station must send a message capable of alerting all affected users. If only a single satellite or IGP is affected, then the messages specific to those confidence bounds need to be sent. However, if many satellites are affected or the SBAS cannot autonomously isolate the faulty data, then more of the SBAS service may need to be alerted as potentially unsafe. Fortunately, such events are exceedingly rare. When alerts are broadcast, they are repeated four times in a row. This is due to the concern that a user receiver may miss an individual message (or even up to three messages). It is important to ensure that the user receives this data when prior information is no longer correct.

### 12.3.3 Ground Uplink Stations and Geostationary Satellites

Geostationary satellites are an excellent means for disseminating the SBAS messages. An SBAS can cover a large continental-scale region, as does the footprint of a GEO. The GEO signals are made very similar to

the GPS L1 C/A and L5 signals, respectively, on those frequencies. Thus, they provide extra ranging measurements for the user. These signals broadcast data at 250 bit/s, which is sufficient to transmit the SBAS corrections and confidences. The signals come from space and are therefore unlikely to be blocked by terrain in open sky environments where aircraft typically operate. The very name for SBAS, *satellite*-based augmentation system, comes from the pairing of the ground system with this satellite-based method of delivery. Figure 12.4 depicts the ANIK-F1R GEO used by WAAS.

The GEOs in use today are simple transponders. They listen for an analog signal at one frequency, translate it to the correct L-band frequency, and retransmit it toward Earth with minimum latency. The pseudo-random noise (PRN) code, messages, and timing are all generated on the ground. The signals are controlled through a closed-loop system that makes it appear as though they originated on the spacecraft [12.24]. The satellite effectively redirects the signal from the ground uplink station (GUS) back down toward the ground. The only change made by the satellite is from the uplink frequency to the correct downlink frequency. This approach is used because the transponder payloads are lighter and less expensive than the full navigation payloads on GPS satellites.

The GUS consists of a computer to receive messages from the multiple master stations, an atomic clock to provide a stable frequency reference, a signal generator to create the signal to uplink to the GEO, a receiver to monitor the GEO downlink signal, a GPS receiver to ensure the GEO is synchronized to GPS time, and a controller to steer the uplinked signal. Figure 12.5 shows the large antenna at the GUS in Napa valley, California, used by WAAS to uplink the signal to its GEO at 133° W. The ground uplink signal is most commonly > 3 GHz. The computer must decide which message to send the next epoch. This will be based upon which master stations it has received messages from and which ones it has sent in the past. Typically, it will continuously send messages from the same master station. However, if communication to that station is interrupted, or if it is commanded to switch to another master station, then it will switch. If it receives no valid messages then it can either send an empty message or initiate an alert sequence.

The generated signal is very similar to a GPS L1 C/A code signal. The main differences are that the center frequency is well above the L1 band and the data bits are switched at 500 sps (symbols per second). The message is encoded onto the signal and it is beamed up to the GEO. The GEO receives this signal and down-converts it to L1 and broadcasts it back down to Earth. The signal is received at the GUS and the center frequency and timing of the chips on the uplink signal are adjusted to make it appear as though the downlink signal was generated on the GEO in synchronization with the GPS satellites.

The GEO signals are generally less accurate than the GPS signals. The transponders for some GEOs have a narrower bandwidth. This difference creates a loss of precision and some signal distortion. By generating

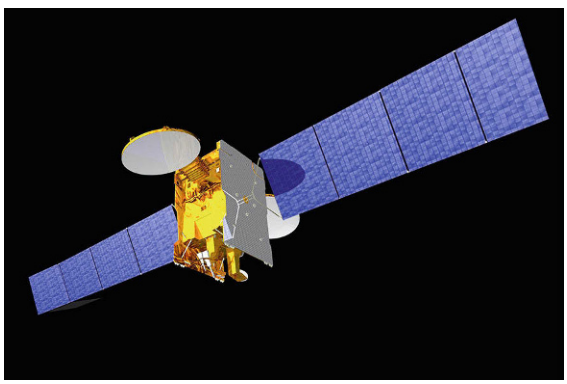

**Fig. 12.4** The ANIK-F1R GEO used by WAAS (reproduced with permission of the the FAA satellite navigation team)

**Fig. 12.5** A WAAS geostationary uplink station (reproduced with permission of the FAA satellite navigation team)

the signal on the ground some of the uplink path errors (e.g., ionosphere, troposphere) cannot be fully removed and therefore affect the downlink accuracy. Further, because the GEOs move very slowly in the sky, carrier smoothing does not reduce the multipath error on the ground at a static location, such as the reference receivers, very effectively. This increased error leads to less accurate orbit and clock estimation and larger uncertainty in bounding the error. Aircraft motion does cause enough variation for carrier smoothing to be effective in the aircraft.

### 12.3.4 Operational Control Centers

Figure 12.6 shows one of the two operational control centers for WAAS that has three master stations, one of which is located at this center. From this center, the operators can monitor the status and performance of WAAS. The operators schedule maintenance and upgrades of the various components at the reference, master, and uplink stations. This control center also monitors weather, air traffic, and the traditional navigational aids. The operators interact with other systems in the national airspace to ensure all

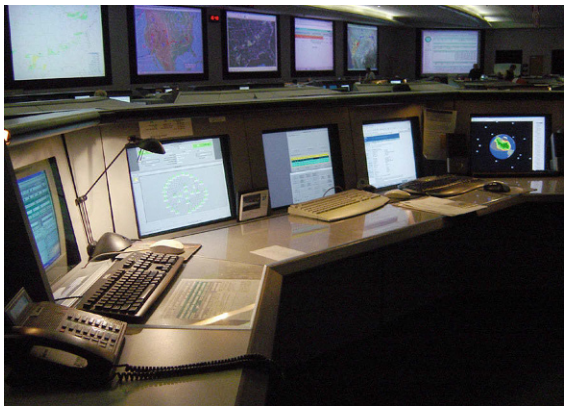

**Fig. 12.6** A WAAS operational control center (reproduced with permission of the FAA satellite navigation team)

are well integrated. The different systems are managed together to ensure that any routine maintenance can be optimally scheduled and unplanned disruptions are properly communicated. The control center also produces notices to inform users of changes to the system performance [12.25] and interact with operators of GPS.

## 12.4 SBAS Integrity

Augmentation systems for aviation are very different from conventional differential GPS services. They are supplementing and ultimately replacing existing navigational aids whose safety has been demonstrated over many years of operational experience. Consequently, the safety of an augmentation system must be proven before it is put into service.

The integrity requirement is that the positioning error must be no greater than the positioning confidence bound, known as the protection level. This requirement is specified with a TTA and with a probability. The TTA requirement means that if the position error exceeds the protection level, the user must be informed within a very short period (6 s for the most demanding SBAS operation). Once a fault has occurred, the position error must fall below the protection level or the pilot must be informed that the system is unsafe to use within 6 s. The probability requirement is that no more than one in ten million operations may suffer an unannounced position error exceeding the protection level for $> 6$ s. SBAS provides differential corrections and confidence bounds to the user. The correction confidence bounds are used, together with the geometry of satellites tracked by the user, to calculate the protection level. In order to use the calculated position for navigation, the protection level must be small enough to support the operation. The user only has real-time access to the protection level and does not know the true position error. Integrity is not maintained if the user has been told that the error in position is small enough to support the operation, but in fact, it is not. The majority of the effort in establishing an SBAS is in ensuring and demonstrating that these integrity requirements are met.

### 12.4.1 Integrity Certification

Certification is the process by which a provider ensures that the service it is providing meets the requirements. Certification involves analysis, testing, and documentation. Some of the important aspects of aviation integrity certification are [12.26]:

1. The aviation integrity requirement of $10^{-7}$ per approach applies to each and every operation. It is not an average over all conditions. The probability also applies to the worst allowed conditions.
2. Validated threat models are essential both to describe what the system protects against and to quantitatively assess how effectively it provides such protection.

3. The system design must be shown to be safe against all fault modes and external threats, including the potential for latent faults just beneath the system's ability to detect.
4. The small numbers associated with integrity analysis are not intuitive. Careful analysis must take priority over anecdotal evidence.

Because the requirement applies to all operations, threats and error conditions must be evaluated under worst allowable conditions. For example, if a user is allowed to operate under the maximum of the 11 year solar cycle, ionospheric errors must be modeled under this worst-case time. They cannot be an average of the high and low points of the solar cycle. Threat models are the means to capturing and describing the various errors that can occur and will be described in the next section. These models must describe both observed and anticipated threats and must treat them quantitatively.

### 12.4.2 Threat Models

Threat models describe the anticipated events against which the system must protect the user. The threat model must describe the specific nature of the threat, its magnitude, and its likelihood. Together, the various threat models must be comprehensive in describing all reasonable conditions under which the system might have difficulty protecting the user. Ultimately the threat models form a major part of the basis for determining if the system design meets its integrity requirement. Each individual threat must be fully mitigated to within its allocation. Only when it can be shown that each threat has been sufficiently addressed can the system be deemed safe. Quantitative assessment as opposed to a qualitative assessment is essential to establishing $10^{-7}$ integrity. SBAS works by analyzing specific failure modes and identifying which may be present and to what likelihood. Each potential failure mode must be ruled out within the limits of the system observability. If a failure mode is positively identified as being present in the system, or cannot be eliminated due to measurement noise, then the user must be notified within 6 s of it adversely affecting their position estimate.

SBAS is primarily thought of as addressing existing threats to GPS. However, it runs the risk of introducing threats in the absence of any GPS fault. By necessity, it is a complex system of hardware and software. Included in any threat model must be self-induced errors. Some of these errors are universal to any design while others are specific to the implementation. For example, the software design assurance of WAAS reference receivers is such that they cannot be trusted to be mistake free. Reference receiver software faults became a unique threat that had to be mitigated through downstream integrity monitoring.

### 12.4.3 Overbounding

Each individual error source has some probability distribution associated with it. This distribution describes the likelihood of encountering a certain error value. Ideally, smaller errors are more likely than larger errors. Generally, this is true for most error sources. The central region of most error sources can be well described by a Gaussian distribution. That is, most errors are clustered about a mean (usually near zero) and the likelihood of being farther away from the mean falls off according to the well-known Gaussian model. This is often a consequence of the central-limit theorem, which states that distributions tend to approach Gaussian as more independent random variables are combined.

Unfortunately, the tails of observed error distributions rarely look Gaussian. Two competing effects tend to modify their behavior. The first is clipping. Because there are many cross-comparisons and reasonability checks within SBAS, the larger errors tend to be removed. Thus, for a truly Gaussian process, outlier removal would lead to fewer large errors than would otherwise be expected. The second, and more dominant effect is mixing. The error sources are rarely stationary. Thus, some of the time the error might be Gaussian with a certain mean and sigma and at other times it will have a different distribution. Because we do not necessarily have the ability to identify which condition is present at which time, different conditions will be aggregated into a single distribution. Such mixing may result from a change in the nominal conditions or from the introduction of a fault mode. Mixing generally leads to broader tails or large errors being more likely than otherwise expected.

Mixing causes additional problems. If the error processes were stationary, it would be possible to collect as large a data set as practical and then conservatively extrapolate the tail behavior using a Gaussian or other model. However, because the distribution changes over time, it is more difficult to predict the future performance based on the past behavior. Furthermore, mixing leads to more complicated distributions whose tails are more difficult to extrapolate.

Overbounding is the concept that an actual distribution can be conservatively described by a simple, usually Gaussian, model [12.27]. The overbounding distribution predicts that large errors are at least as likely to occur as they are for the true distribution. Even though the true distribution may not be completely known, there needs to be a practical way to represent it for analysis. Usually this involves a fair

amount of conservatism. A true distribution that is made up of a mix of zero-mean Gaussian distributions, could be overbounded by its constituent with the largest standard deviation. Thus, a real distribution that has a sigma value ranging between 1 and 2 m will be represented as though it were always 2 m (or perhaps 2.5 m for added protection). Through various overbounding theorems, the overbound also describes how to combine the error with other terms that have been overbounded [12.27–29]. That is, SBAS will individually overbound the error for each satellite and each IGP. The GIVEs and UDREs broadcast by the SBASs describe overbounds of the actual error distributions affecting the corrections. The overbounding theorems allow users to combine these values to overbound the position errors by calculating the protection levels.

## 12.5 SBAS User Algorithms

The SBAS Minimum Operational Performance Standards (MOPS) are an internationally agreed upon document [12.8] that describes the method by which an SBAS transmits its differential GPS corrections and integrity information to users. The information is transmitted in 250 bit messages. These messages must be decoded and interpreted every second. The corrections are distributed across several individual messages. The corrections for individual satellites must be combined with receiver measurements and other local information to form the navigation solution and protection levels. The user must reconstruct and apply all of this information correctly. The MOPS ensures that all SBAS service providers encode their information in a compatible manner. The aviation receivers then know what to expect and will work with each of the different SBASs.

### 12.5.1 Message Structure

The broadcast message structure has 500 sps. These contain forward error correction to significantly reduce the risk of lost or misidentified bits [12.30]. The symbols go through a decoding process to produce 250 bit/s messages. There are two symbols for every message bit. The messages come once per second and contain 212 bit of correction data. Eight additional bits are used for acquisition and synchronization, 6 more bits to identify the message type and the remaining 24 bit designated for parity to protect against the use of corrupted data. Complementary message types must be stored and connected to the other individual components to form a single correction and confidence bound per satellite.

The SBAS messaging system contains the following elements:

- *Satellite corrections*: The SBAS broadcasts fast-corrections for satellite clock errors that may vary quickly in time. A fast-correction message corrects up to 13 satellite clock offsets and is sent every 6 s. Clock offset rates of change are obtained by differencing sequential fast correction offsets. The SBAS also sends corrections for slowly varying satellite location and clock errors. The corrections consist of $\Delta x$, $\Delta y$, and $\Delta z$ satellite locations (and possibly velocities) plus delta clock (and possibly delta clock rate). These long-term corrections are sent approximately every 2 min. Each long-term correction message corrects either two or four satellites depending on whether the rate of change information is also included.
- *Ionospheric corrections*: The SBAS broadcasts a grid of ionospheric corrections. Each ionospheric correction message updates the vertical delay estimate at up to 15 ionospheric grid points and is broadcast once every 5 min.
- *Confidence bounds*: In addition to the corrections, confidence bounds on the remaining errors are also broadcast. The UDREs must be sent every 6 s while the GIVEs are only updated every 5 min. These bounds are essential to maintain the integrity and TTA of the system. The UDREs are included in the fast-correction messages and the GIVEs are included with the ionospheric correction messages. In addition, there are messages that can provide the full $4 \times 4$ covariance matrix information for the clock/ephemeris error for each satellite. If broadcast, these matrices are sent every 2 min in messages that update two satellites. The covariance matrices are sent in a message labeled as message type 28 and are often referred to as message type 28 (MT28) parameters [12.31]. An alternate message can define regions where the UDRE values are to be increased. This regional information is sent in message type 27 and labeled as MT27 parameters. A system will either use MT28 or MT27 but never both as they both serve similar purposes but via different means.
- *Degradation parameters*: The potential error in the corrections increases over time. Parameters are broadcast to model these effects. The users apply

these degradations as their corrections age. They are particularly important in maintaining integrity and availability when a user misses the most recent correction.

- *Masks*: The PRN mask is used to designate which satellite belongs to which slot in the fast-correction messages. A mask is used to assign slots so that satellite identifications need not be sent with every fast correction. A similar ionospheric mask is used to associate each slot in the ionospheric correction message with a geographic grid point location. The use of masks reduces the required throughput because the masks are sent infrequently. They also inform the user as to which satellites and which IGPs are corrected by the specific SBAS.
- *Geostationary navigation message*: In contrast to the GPS satellites, the current SBAS satellites are geostationary. Consequently, their location (ephemeris) does not need to be updated as frequently. Nor do they require as large a dynamic range as the geostationary orbit is restricted to a limited region about the equator. These messages broadcast the absolute position ($x$, $y$, and $z$ in an Earth centered Earth fixed (ECEF) reference frame), as well as the velocity and acceleration values. The absolute clock and clock rate are also included in this message, as well as the reference time, and an issue of data. This message is broadcast every 2 min.
- *Preamble*: In order to allow the receiver to find the start of the 250 bit message an 8 bit preamble is included at the beginning of every message. There are three unique preambles that repeat in a fixed sequence. By searching for this specific bit pattern, a receiver can synchronize itself with the SBAS data signal.
- *Parity*: For data integrity, the SBAS must use a much stronger error detection algorithm than the six parity bits used in the GPS navigation message. Nonetheless, the overhead for error detection is reduced because the parity bits apply to longer messages than for GPS. The 24 bit cyclic redundancy check (CRC) ensures that the message the user applies is the one intended. Any bits corrupted in transmission are detected before they can create erroneous information.
- *Forward error correction*: Forward error correction is used so that the SBAS can send significantly more data than the 50 bit/s carried in the GPS navigation message. The chosen code for SBAS is a rate 1/2 convolutional code with a constraint length of 7.

The currently used SBAS messages are listed in Table 12.1.

### 12.5.2 Message Application

The user requires one long-term and two fast corrections for each satellite that it uses [12.23]. The two fast-corrections are differenced to determine the rate of change of the fast clock term. This rate is used with the most recent fast-correction to determine the fast clock value for the current time. The fast clock correction is added to the long-term clock correction to obtain the full clock correction. The orbit corrections are also taken from the long-term correction and added to the orbital location broadcast in the navigation message received directly from the GPS satellite. The UDRE is taken from the fast-correction and increased depending on how long ago the fast correction was received. If MT28 is used, the parameters are used to determine a scaled covariance matrix. This matrix, together with the normalized four-dimensional (4-D) line-of-sight vector, is used to determine a multiplier for the UDRE. Generally, when the user is close to the reference station locations, this scaling factor will be smaller. If the user is far from the reference stations, then this factor may significantly increase its product

**Table 12.1** SBAS message types

| Type | Contents |
|---|---|
| 0 | Do not use for safety applications (WAAS testing) |
| 1 | PRN mask assignments, set up to 51 of 212 bit |
| 2–5 | Fast pseudorange corrections and UDREs |
| 6 | Integrity information, UDREs (multiple satellite alert) |
| 7 | Fast correction degradation factor |
| 8 | Reserved for future messages |
| 9 | GEO navigation message (X, Y, Z, time, etc.) |
| 10 | Degradation parameters |
| 11 | Reserved for future messages |
| 12 | WAAS network time/Coordinated Universal Time (UTC) offset parameters |
| 13–16 | Reserved for future messages |
| 17 | GEO satellite almanacs |
| 18 | Ionospheric grid point masks |
| 19–23 | Reserved for future messages |
| 24 | Mixed fast/long-term satellite corrections |
| 25 | Long-term satellite corrections |
| 26 | Ionospheric delay estimates and GIVEs |
| 27 | WAAS service message |
| 28 | Clock-epemeris covariance matrix message |
| 29–61 | Reserved for future messages |
| 62 | Internal test message |
| 63 | Null message |

with the UDRE. If MT27 is used, then the UDRE will be multiplied by those parameters depending on the user's location. As with MT28, the UDRE is generally multiplied by a larger term if the user is farther from the reference stations. This product, which also will include degradation terms, is expressed as a one-sigma value and referred to as the fast and long-term correction bound or $s_{\mathrm{flt}}$,

Satellite corrections and confidences are all that are required for less precise lateral navigation. The user can apply the simple single-frequency ionosphere model broadcast by GPS and determine horizontal positions bounded to within a fraction 1 nmi. However, to obtain precise vertical guidance, the user must also apply the SBAS ionospheric corrections.

For each of their IPPs, the user must identify the surrounding IGPs and obtain ionospheric delays for each. It requires a minimum of three enclosing IGPs, but ideally the four defining a rectangle about the IPP are all available. The user then applies a bi-linear interpolation of the surrounding delay values to obtain the vertical delay estimate at the IPP. It applies the same interpolation to obtain the user ionospheric vertical error (UIVE) bound from the surrounding GIVEs. These are converted from vertical to slant by applying the obliquity factor. The resulting confidence term is now called the user ionospheric range error (UIRE). The delay value is subtracted from the pseudorange measurement to that satellite with the corresponding IPP. The user also subtracts the MOPS-specified tropospheric model delay estimate from each line-of-sight to fully correct the range error.

### 12.5.3 Protection Levels

The basic notion of the protection level equations is that the error sources are approximately Gaussian and that a Gaussian model is sufficiently accurate to be able to conservatively describe the positioning errors. Four error terms are used to describe satellite clock and ephemeris errors ($\sigma_{\mathrm{flt}}$), ionospheric delay errors ($\sigma_{\mathrm{UIRE}}$), tropospheric delay errors ($\sigma_{\mathrm{tropo}}$), and airborne receiver and multipath errors ($\sigma_{\mathrm{air}}$). The conservative variances of these terms are combined to form a conservative variance for the individual pseudorange error.

$$\sigma_i^2 = \sigma_{\mathrm{flt},i}^2 + \sigma_{\mathrm{UIRE},i}^2 + \sigma_{\mathrm{tropo},i}^2 + \sigma_{\mathrm{air},i}^2 \tag{12.1}$$

This pseudorange variance is inverted and placed on the diagonal elements of the weighting matrix, $\mathbf{W}$, and combined with the geometry matrix, $\mathbf{G}$, to form the covariance of the position estimate.

$$\left(\mathbf{G}^{\top}\mathbf{W}\mathbf{G}\right)^{-1} \tag{12.2}$$

Here the geometry matrix is expressed in a local east, north, up reference frame. The third diagonal element represents the conservative estimate of the error variance in the vertical direction. Since the vertical protection level (VPL) is intended to bound 99.99999% of errors it is set to the equivalent Gaussian tail value of 5.33. Thus, the final VPL for L1-only SBAS is given by

$$\mathrm{VPL} = 5.33\sqrt{\left[\left(\mathbf{G}^{\top}\mathbf{W}\mathbf{G}\right)^{-1}\right]_{3,3}}\,. \tag{12.3}$$

## 12.6 Operational and Planned SBAS Systems

Four SBASs have been implemented around the world and at least three more are under development. The operational systems are all compatible with the MOPS and with existing certified SBAS receivers, but they are not identical. They have been developed specifically for their own regions and sometimes faced unique challenges. However, despite any differences SBAS receivers will work equally well with any of these systems and should be able to seamlessly transition from one to any other.

### 12.6.1 Wide Area Augmentation System (WAAS)

The WAAS has been fully operational for safety-of-life services since July 2003 [12.2]. It consists of 20 WAAS reference stations (WRS) in the CONUS, in addition to seven in Alaska, one in Hawaii, one in Puerto Rico, four in Canada, and five in Mexico for a total of 38. There are 3 WAAS master stations (WMS) and 3 geostationary satellites (GEOs). The GEOs are the Intelsat Galaxy XV satellite at 133° W (PRN 135), the Telesat ANIK F1R satellite at 107° W (PRN 138), and the Inmarsat-4 F3 at 98° W (PRN 133). WAAS is also in the process of procuring replacement GEOs including the SATMEX-9 which will become active in 2017 and be located at 117° W (PRN 131). A full list of all SBAS GEOs can be found in Table 12.2.

Figure 12.7 shows the reference station networks for all of the current and some of the developing SBASs. As can be seen, there is good sampling around the northern hemisphere. WAAS provides excellent coverage for lateral navigation.

Figure 12.8 shows the lateral navigation coverage provided by WAAS, as well as the Japanese and European SBASs. It can be seen that all of North America

**Table 12.2** SBAS GEOs (after [12.32], courtesy of the US Air Force)

| PRN | SBAS | Satellite | Location |
|---|---|---|---|
| 120 | European Geostationary Navigation Overlay Service (EGNOS) | INMARSAT 3F2 | 15.5° W |

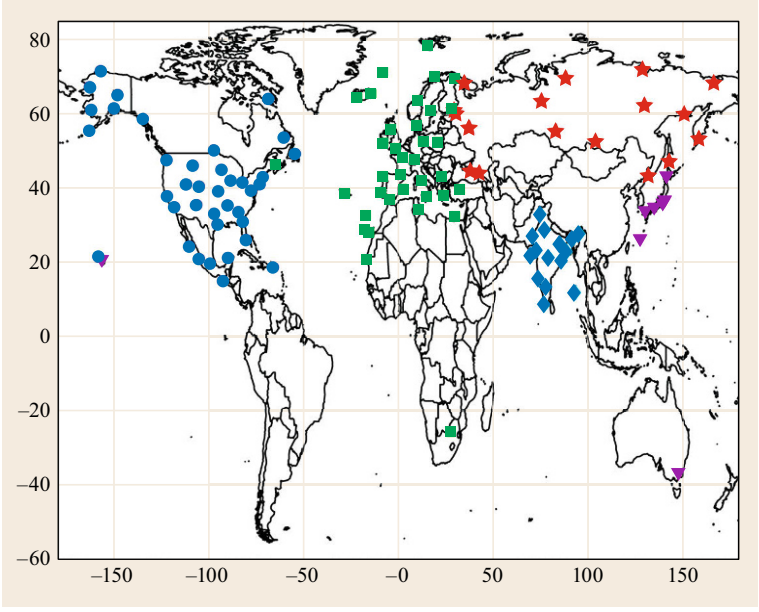

**Fig. 12.7** Reference station networks of WAAS (*dark blue circles*), EGNOS (*green squares*), SDCM (*red asterisks*), and GAGAN (*blue diamonds*)

and part of South America can rely on WAAS to navigate to and from any airport of choice. The edges of GEO footprints can be seen in the north of this figure as visibility to at least one of the GEOs is a requirement to get SBAS service. Vertical guidance requires the precise ionospheric corrections of the grid and therefore is restricted to a much tighter region around the reference stations.

Figure 12.9 shows the vertical guidance coverage area for the same three SBASs. It can be seen that WAAS covers CONUS, Alaska, and much of Canada and Mexico. Figure 12.10 shows the vertical coverage

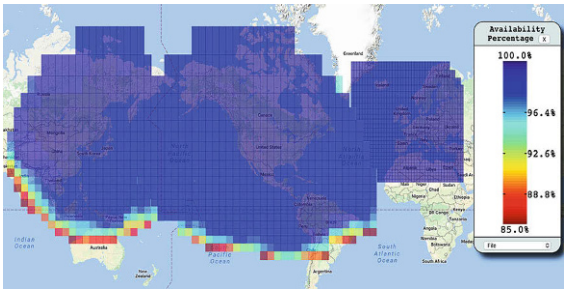

**Fig. 12.8** Lateral navigation coverage for WAAS, MSAS, and EGNOS (after [12.33], reproduced with permission of the William J. Hughes FAA Technical Center)

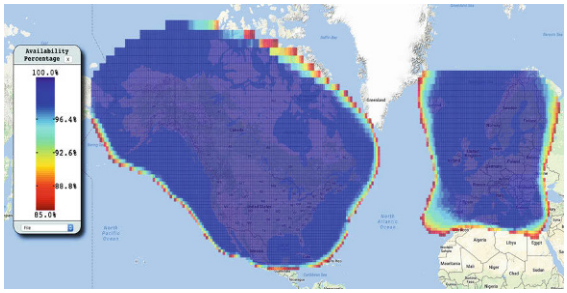

**Fig. 12.9** Vertical navigation coverage for WAAS and EGNOS (after [12.33], reproduced with permission of the William J. Hughes FAA Technical Center)

area in greater detail and also tabulates the percentage of each region that achieves a certain level of availability. On the day shown in Fig. 12.10, 100% of CONUS has 100% availability, while 95.04% of Alaska has 99.9% or better availability.

Accuracy is very good when using WAAS. Horizontal accuracy is $\approx 0.75$ m 95% in CONUS. This number can be compared to 3.2 m for uncorrected GPS under moderate ionospheric conditions. Under more severe ionospheric conditions the GPS positioning errors can be noticeably worse, but the WAAS corrected accuracy only worsens slightly. For example, in 2003 during a worse solar maximum period, uncorrected horizontal accuracy was 4.8 m 95% while WAAS corrected accuracy was 0.88 m. Horizontal accuracy in Alaska is also $\approx 0.75$ m 95% but it is slightly worse in Mexico ($\approx 0.90$ m) and Canada ($\approx 1.0$ m). Vertical accuracy for WAAS is $\approx 1.1$ m 95% in CONUS compared to 7.6 m for uncorrected GPS. In Alaska, vertical accuracy is $\approx 1.3$ m 95%. Again, somewhat worse 95% vertical performance is seen in Mexico ($\approx 2.0$ m) and Canada ($\approx 1.5$ m).

WAAS was fielded because its advantages relative to conventional navaids were enormous. It has made precision vertical guidance available throughout the majority of North America. No local airport infrastructure is required for this service. Already more than 80 000 WAAS-enabled aviation receivers have been sold. More than 3500 vertically guided approaches have been commissioned. This is nearly three times as many as provided by ILS. WAAS allows users to access more than 2000 airports that had no previous instrument

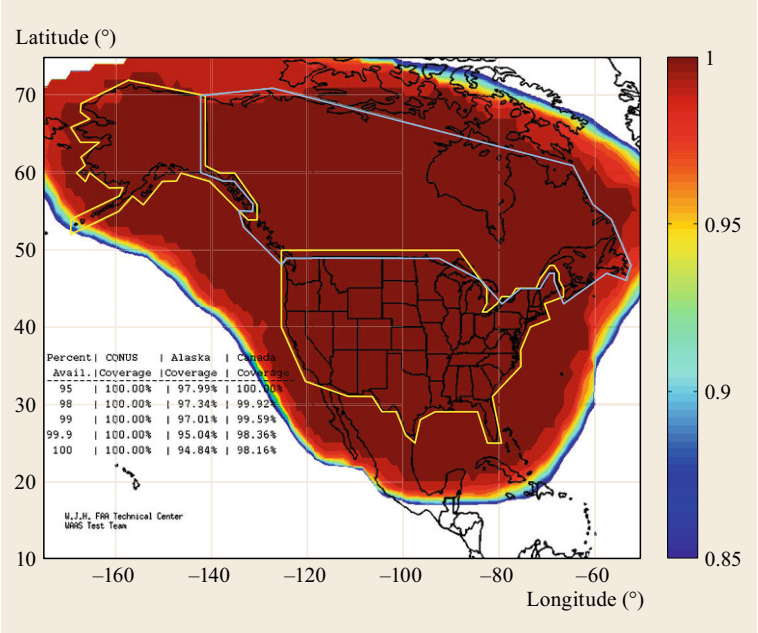

**Fig. 12.10** Detailed vertical navigation coverage for WAAS on 19 March 2015 (after [12.33], reproduced with permission of the William J. Hughes FAA Technical Center)

approach. It is also widely used in nonaviation applications [12.34].

Agriculture uses SBAS to more accurately position vehicles and reduce fertilizer and pesticide use. Maritime uses SBAS to guide ships more accurately in poor visibility conditions. SBAS is incorporated into nearly every cell phone as the GEOs are widely visible, the correction data is freely provided, and the system accuracy is greatly improved.

### 12.6.2 Multifunction Satellite Augmentation System (MSAS)

The multifunction satellite augmentation system (MSAS) consists of six ground monitoring stations (GMSs) on the Japanese islands, in addition to one in Australia, and one in Hawaii for a total of eight [12.35, 36]. The station locations are shown as magenta triangles in Fig. 12.7. There are two master control stations (MCSs) and two multifunction transport satellite (MTSAT) GEOs at 140° E and 145° E. MSAS was commissioned for safety-of-life service in September 2007.

Due to the limited network size, the GEO UDREs for MSAS are set to 50 m and therefore do not benefit vertical guidance. Further the limited ionospheric observations offer little availability of vertical service. As a result vertically guided operations have not yet been authorized based upon MSAS. The Japanese civil aviation bureau (JCAB) has studied performance improvements that could allow it to provide vertically guided operations. Until then, MSAS provides only lateral guidance. Like WAAS, lateral guidance is available for quite a large region around and away from the reference stations.

### 12.6.3 European Geostationary Navigation Overlay Service (EGNOS)

The European geostationary navigation overlay service (EGNOS) consists of 39 ranging and integrity monitoring stations (RIMSs) in Europe, Africa, and North America [12.37–39]. The station locations are shown as green squares in Fig. 12.7. EGNOS has four master control centers (MCCs) and six navigation land Earth stations (NLESs) that control their three GEOs. The two operational GEOs are the Imarsat-3 F2 satellite at 15.5° W (PRN 120) and the Inmarsat-4 F2 satellite at 25° E (PRN 126). There is an additional GEO, Astra 4B at 5° E (PRN 136), that is under test and will become operational in 2015. Astra 5B is being procured for operation at 31.5° E (PRN 123) beginning in 2016. EGNOS was declared operational in October 2009, and was certified for safety-of-life service in March 2011.

EGNOS also has very good accuracy. It achieves 1.2 m 95% horizontal and 1.8 m 95% vertical accuracy over Europe. For a variety of reasons EGNOS has chosen to implement its GEO satellites without a ranging capability. They are only providing differential corrections and integrity information. It is possible that future GEOs will include ranging.

EGNOS currently implements message type 27 (MT27) rather than message type 28 (MT28) as used by WAAS, MSAS, and the SBAS in India. MT27 restricts the use of small UDRE values to a box centered on the European region (from 20° N to 70° N and 40° W to 40° E). The edges of this MT27 box can be clearly seen in Figs. 12.8 and 12.9. MT27 limits lateral navigation service more so than does MT28, but there is still excellent horizontal coverage in and around Europe. Availability of vertical guidance is very high for most of Europe as shown in Fig. 12.9. Figure 12.11 provides a more detailed view of the availability of vertical guidance over Europe. Over 175 vertical approaches have already been implemented that serve over 100 airports and hundreds more are under development.

EGNOS was developed with a greater emphasis on multimodal support [12.40]. The other SBASs were implemented by their local civil aviation authorities (CAAs) and are therefore originally designed to support aviation needs. They do in fact support all modes of transportation, however, aviation is their only mandate. EGNOS has a mandate also to support other modes of transport such as maritime, rail, and automotive. EGNOS was also originally designed to incorporate the Russian global navigation satellite system (GLONASS). Although GLONASS is not used for its safety-of-life service, GLONASS is still monitored and its measurements are available for other purposes. EGNOS makes it data and corrections available through its EGNOS data access service (EDAS). EDAS provides near real-time access to the RIMS measurements and the broadcast messages. Thus, EGNOS is available to users who do not have visibility to any of its GEOs [12.5, 41].

### 12.6.4 GPS Aided GEO Augmented Navigation (GAGAN)

India is developing the GPS-aided GEO augmented navigation (GAGAN) system [12.42, 43]. Currently it has 15 Indian reference stations (INRES) all in India. The station locations are shown as blue diamonds in Fig. 12.7. There are two Indian master control cen-

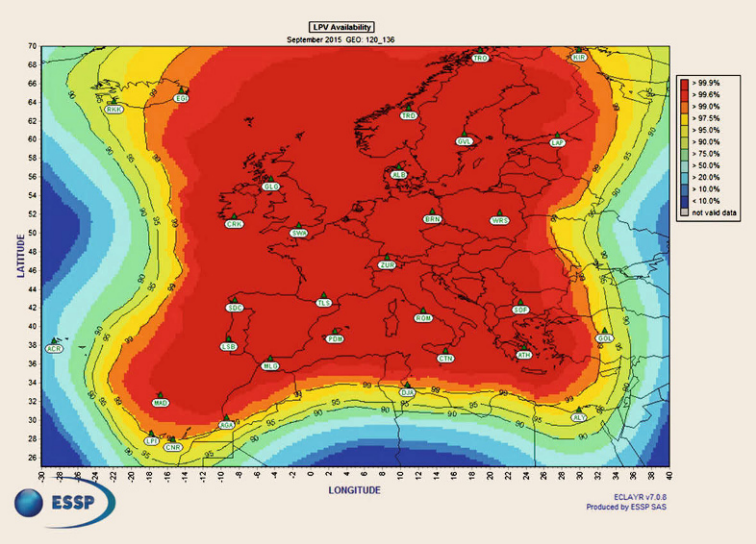

**Fig. 12.11** Detailed vertical navigation coverage for EGNOS in September 2015 (after [12.39], reproduced with permission by the European satellite services provider (ESSP))

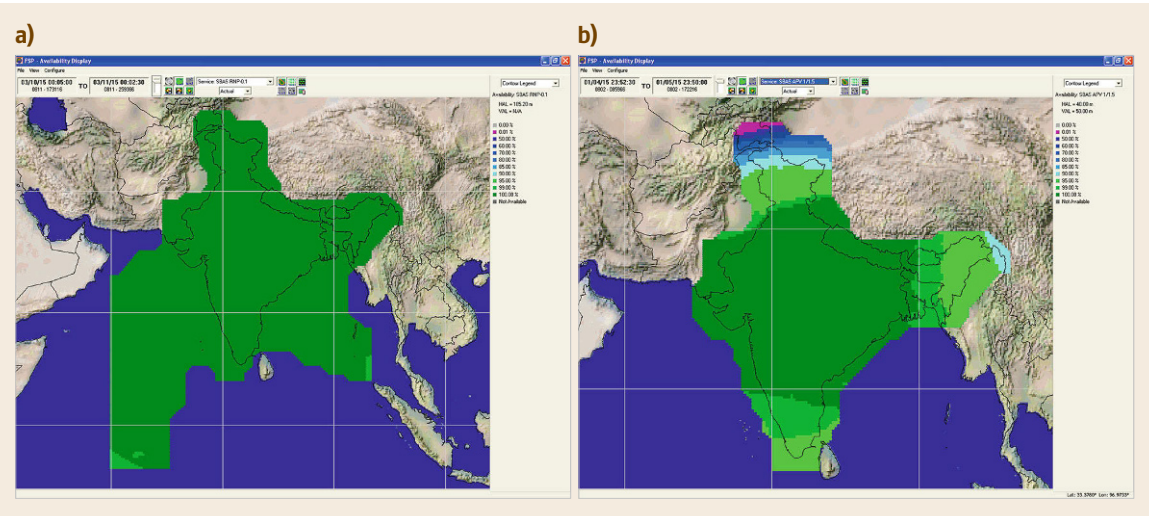

**Fig. 12.12** **(a)** Lateral navigation coverage for GAGAN, **(b)** vertical navigation coverage for GAGAN (after [12.42], reproduced with permission by the Airports Authority of India)

ters (INMCCs), and three Indian navigation land uplink stations (INLUSs) to control its GEOs. GAGAN uses GSAT-8 at 55° E (PRN 128) and GSAT-10 at 83° E (PRN 127) as its GEOs. GSAT-15 at 93.5° E (PRN 139) is currently being deployed and will be launched in 2015.

The geomagnetic equator passes through India and GAGAN therefore faces the full impact of the equatorial ionosphere. During peak ionospheric activity, vertical guidance is not always available. Within the equatorial region, post-sunset hours are frequently beset by large depletions and scintillation. The depletions create large gradients in the ionospheric delay that cannot be easily modeled by the SBAS thin-shell grid. Scintillations interrupt tracking to the satellite signals. Fortunately lateral navigation is less susceptible to these issues as service can be provided even with larger ionospheric delay uncertainty and fewer satellites in view. Figure 12.12a shows lateral availability within the Indian airspace.

Vertical guidance does require small ionospheric delay uncertainty and very good geometry. Thus, many evenings suffer a loss of service, especially during solar maximum periods. The current solar cycle reached its

maximum in 2014. Figure 12.12b shows vertical availability on a very good day. The advent of L5 will allow GAGAN to obtain high LPV-200 availability throughout all periods of the solar cycle. GAGAN was certified for lateral only service, which begun in February 2014. The vertical guidance service was certified in April of 2015.

The equatorial ionosphere also causes accuracy to be somewhat worse for GAGAN compared to the other SBASs located in mid-latitude. GAGAN achieves 2.3 m 95% horizontal and 3.7 m 95% vertical accuracy over India.

### 12.6.5 System of Differential Corrections and Monitoring (SDCM)

Russia is developing its system of differential corrections and monitoring (SDCM [12.44]). Currently SDCM has 19 prototype measuring points (MPs) in Russia and four prototype stations are available outside of Russia. The Russian station locations are shown as red stars in Fig. 12.7. There are also plans to use three GEOs: Luch-5A is at 16° W (PRN 125), Luch-5B at 95° E (PRN 140), and Luch-4 at 167° E (PRN 141). SDCM intends to add 27 additional MPs within Russia and three more outside of Russia. SDCM is still in its development phase with initial service expected in 2016 and fully certified service in 2019. SDCM further intends to augment both GPS and GLONASS. The SDCM prototype achieves 1 m 95% horizontal and 1.5 m 95% vertical accuracy over Russia.

### 12.6.6 BeiDou Satellite-Based Augmentation System (BDSBAS)

China's satellite navigation system is called Beidou. It includes SBAS-like terms in its navigation message, but these are not backward compatible with existing SBAS receivers. The level of safety associated with these terms is not yet known. A mask and 18 parameters labeled as UDREs are included in one of its subframe messages. An ionospheric grid is also defined over China and delay values and parameters labeled GIVEs are included in other subframes. China has recently announced that it intends to also provide an SBAS service that is compatible with the International Civil Aviation Organization (ICAO) standard to be called BeiDou satellite-based augmentation system (BDSBAS [12.45]). It currently has 20 prototype ground stations in China with plans to ultimately have 30 stations within China and 20 more stations in surrounding areas. GEOs are planned for 80° E, 110° E, and 140° E. The ICAO compatible service is expected to be available around 2020.

### 12.6.7 Korean Augmentation Satellite System (KASS)

The Republic of Korea has also announced its intention to develop its own SBAS [12.46]. This SBAS will consist of five or more reference stations, two central processing facilities, four GUSs and two GEOs. KASS is in the early development stage with a plan to have preliminary service by 2020.

## 12.7 Evolution of SBAS

Recently launched GPS satellites have two civil signals at protected aviation frequencies. When both signals are operational, they will allow users to measure the ionosphere directly instead of relying on the SBAS grid for corrections. The uncertainty of the users' direct ionospheric measurements will be much smaller than the broadcast SBAS confidence. Additionally, users can make these measurements anywhere, not just near reference stations. As a result, the service level will improve and the region of coverage will expand much farther from the SBAS networks. Further, additional constellations of navigation satellites are being fielded. The number of useful ranging sources for the user will soon dramatically increase. SBASs will be updated to take advantage of these improvements as they become available [12.47, 48]. The user will experience better availability for existing services and new, even more demanding, services will likely become available.

### 12.7.1 Multiple Frequencies

The GPS satellites now being launched contain a new civil aviation signal. L5 is centered at 1176.45 MHz and is in a protected aviation band. As such, it will be approved for navigation when it becomes fully operational. When the L5 signal is used in combination with L1, the ionospheric delay for each line-of-sight can be directly estimated and removed. Removing the ionospheric delay will dramatically lower the uncertainty of the pseudorange measurement. Thus, if the SBAS is upgraded to provide satellite clock corrections appropriate for an L1/L5 user and the user similarly upgrades their avionics, SBAS service can be

dramatically expanded beyond the current grid of corrections [12.49].

Another important advantage of the second civil frequency is its relative immunity to ionospheric disturbances that are not well modeled by the MOPS grid. Because the user is now directly eliminating the amount of delay they actually experience, they are no longer affected by shortcomings in the MOPS ionospheric model. Thus, a dual frequency user would also have good availability in equatorial areas, even during peak solar activity. The weaker effect of scintillation may have some impact, however, we do not expect to lose vertical guidance altogether, at least not over large areas and for many hours [12.50]. Furthermore, the availability of two civil frequencies offers some protection against unintentional interference. If either L1 or L5 is jammed, the user still has access to guidance on the remaining frequency.

At the moment, the MOPS for an L1/L5 user are at the very early stage of development, so any ground or user improvements are still speculative. When a user has access to two civil frequencies, they can remove the ionospheric effects by forming the ionosphere-free combination of the two pseudoranges

$$p_{\text{iono_free}} = \frac{f_1^2 p_1 - f_5^2 p_5}{f_1^2 - f_5^2} ,$$
$$\sigma^2_{\text{iono_free}} = \left(\frac{f_1^2}{f_1^2 - f_5^2}\right)^2 \sigma_1^2 + \left(\frac{f_5^2}{f_1^2 - f_5^2}\right)^2 \sigma_5^2 , \quad (12.4)$$

where $f_1$ and $f_5$ are the L1 and L5 frequencies (1575.42 and 1176.45 MHz), respectively. If $\sigma_1$ and $\sigma_5$ are comparable then the ionosphere-free combination has roughly three times as much noise as either single frequency term, but is still substantially smaller than $\sigma_{\text{UIRE}}$. Furthermore, satellites do not need a grid correction to be used, thus satellites farther from the network and the IGP mask can be incorporated into the position solution. The dual frequency confidence bound for a single satellite is then given by

$$\sigma^2_{\text{tot_if},i} + \sigma^2_{\text{flt},i} + \sigma^2_{\text{iono_free},i} + \sigma^2_{\text{trop},i} , \quad (12.5)$$

where $\sigma_{\text{air}}$ is used in place of $\sigma_1$ and $\sigma_5$ in (12.4). The VPL term otherwise takes the same form as is used in today's L1-only system. However, now (12.5) is used in place of (12.1) to compute the uncertainty for each line of sight.

Several of the SBAS providers are evaluating plans to offer an L1/L5 service that makes use of these modernized signals. This upgrade will also be accompanied by the inclusion of other constellations as described below.

### 12.7.2 Multiple Constellations

In addition to GPS L5 development, there are several independent navigation satellite systems being developed with comparable civil frequencies [12.51]. Galileo is being developed by the European Union and is envisioned as being compatible with GPS in which each satellite provides ranging using signals covering the L1 and L5 frequencies with similar modulations. Although the system is still being deployed, it is envisioned that Galileo satellites will provide a service that is fully interoperable with the GPS civil signals.

In parallel, China is developing the BeiDou system whose signals are also planned to be compatible with GPS. Initially BeiDou has a B1 signal near L1 at 1561.098 MHz and another open signal, B2, at 1207.14 MHz. Beidou plans to provide signals at the L1 and L5 frequencies sometime after 2020 [12.52]. However, there is some uncertainty about the timeframe and exact nature of these new signals. Unfortunately, this uncertainty makes it difficult to develop the standards needed to create certified avionics. Offering signals precisely at L1 and at L5 does allow for the most convenient integration of BeiDou. However, signals at nearby frequencies could also be accommodated provided they are in aviation frequency bands.

The Russian GLONASS system has been operational for many years. Its current openly available signals are broadcast using different frequencies rather than different codes to distinguish the satellites. These frequencies range from ≈ 1598–1605 MHz (near L1) and another open signal approximately between 1243 and 1249 MHz. There are modernization plans to broadcast signals at L1 and L5 that are more in alignment with the other constellations. It is not yet known when these new signals would be available.

EGNOS plans to correct both GPS and Galileo on both their L1 and L5 signals. SDCM is planning to augment both GPS and GLONASS. BDSBAS intends to augment both GPS and BeiDou. As these constellations mature and their signal offerings become better known, other SBASs may also choose to augment them. The additional signals essentially ensure that the user always has good geometry. With just GPS, one or more satellite outages can lead to a loss of vertical guidance service. However, with two or more constellations, service is tolerant to many satellite outages. Inclusion of multiple constellations into SBAS ensures continuity of service even if the constellations choose to maintain fewer satellites overall in the future. They also allow for the possibility of supporting even more demanding operations.

# 13. Receiver Architecture

Bernd Eissfeller, Jong-Hoon Won

This chapter discusses the basic architecture of global navigation satellite system (GNSS) receivers. It starts with a breakdown of the receiver function into individual building blocks along the processing chain (front-end, down conversion, mixers, numerically controlled oscillators, correlators, tracking loops, data demodulation, navigation, user interface), and describes the respective functions. A dedicated section describes selected hardware solutions (example chipsets for front-end and baseband processing, offering different levels of integration and capabilities). Finally, receiver designs performing the signal processing in pure software as well as receivers based on configurable hardware are discussed.

In this chapter, the facts on global navigation satellite system (GNSS) receiver technology are presented. It provides a systems, engineering overview addressing all the different architectural elements. With respect to the main architectural subsystems, the possible technology areas are described and the implementation alternatives are traded-off with each other. Although the global positioning system (GPS) receiver is in the center of discussion, a wider view is given in order to cover also future satellite navigation systems (Galileo, GLONASS, BeiDou) and new signals and frequencies. Starting off with historical reviews of civil and military receivers, early developments of receiver building-blocks are discussed with a sufficient level of detail: radio frequency (RF) front-end and antenna (including down conversion and filtering), analog-to-digital converter (ADC), crystal and other oscillators, RF and digital chip technologies, implementation issues, and multifrequency and multisystem receivers (including GLONASS, Galileo, military receivers). One goal of the chapter is also to identify the trends in receiver technology. Finally, the major types of receivers are basically described.

## 13.1 Background and History

GNSS receivers are now under development and production for over four decades. Already in 2013, around 1 billion civil GPS receivers (including 500–600 million GPS phones) were estimated to be in use on a global basis. The number of military or governmental receivers is about 300 000, in the North Atlantic Treaty Organization (NATO) and US-associated countries, which is much smaller. The long-term development cycle of receivers started off from 1975–1990 with analog boxes, and around 1990–1995, we saw the first integrated PC-type GPS original equipment manufacturer (OEM) cards. The next step was higher integration of these cards to *credit card* format till 2005. In contrast, mainly for the low-end market chipsets (RF chip + baseband chip), a single-chip hardware-based receiver was developed. In 2000, the software-defined radio (SDR) concept was applied to the GNSS autocorrelation receiver.

In general, the development line of GNSS receiver technology is strongly correlated with the history of the specific satellite navigation program and with progress in semiconductor technology. In the case of Navigation Satellite Time and Ranging (NAVSTAR) GPS, it started off in 1974 within the early hardware contracts for GPS Phase I [13.1]. In Phase I, three contracts for user equipment were established: Magnavox, Texas Instruments, and Rockwell International Collins Government Avionics Division for jamming resistant user equipment. These contracts included the development of monitoring receivers for the control segment, military receivers, and a civil type set as a utility for the military. Referencing again [13.1], the paradigm for the development of these receivers was: *Build a cheap set that navigates for less than 10000 US $.*

In the early GPS user equipment development in the United States, we can identify mainly two classical domains: in the first domain, we see military GPS user equipment which was developed in different phases for land, aviation, and maritime applications, and in the second domain, a development of civil GPS receivers took place by stepwise higher integration of components.

### 13.1.1 Analog Versus Digital Receivers

Phase I receivers were mainly analog receivers (Fig. 13.1), which made use of a single-analog hardware channel, and later on a second hardware (H/W) channel was added. As in our days, these receivers had an L-band antenna and a low-noise amplifier (LNA). The channel as such was built up by a down converter to an intermediate frequency (IF) and made use of an analog correlator, which was implemented in the IF filter amplification stages (linear IF correlation). The digitization by the ADC was performed at the very end of the channel chain. The post-correlated signals, pseudorange, carrier-phase and/or Doppler measurements, and demodulated navigation data were processed in the digital domain with a navigation processor. For the tracking process, a sequential technique was used; a satellite was acquired, tracked for some time interval, and, after this was over, a switchover to the next satellite was done. Thus, parallel all-in-view tracking was not possible within this architecture. For a fast moving platform, a dead-reckoning device was necessary to aid the sequential procedure and to guarantee a navigation solution. Over the years, the slow sequencing (30 s per satellite) was replaced by faster multiplexing (switching with 5 ms per satellite) throughout the visible constellation.

In the 1980s, a technology change in the receiver architecture took place: it was quite obvious that the

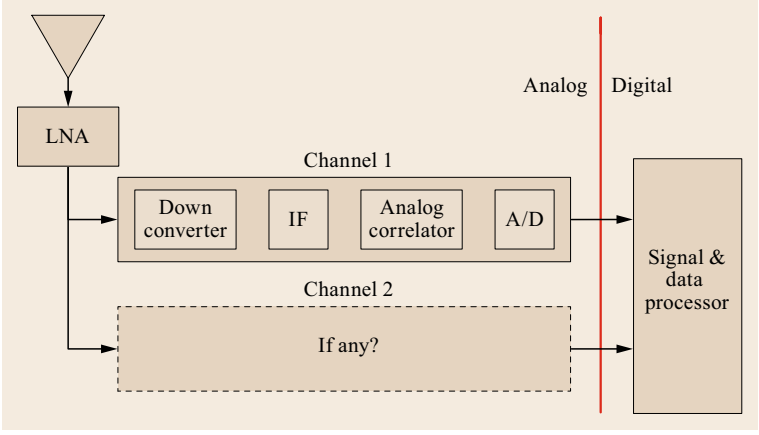

**Fig. 13.1** Analog receiver architecture with sequencing and/or multiplexing

better solution for the GPS positioning problem should, on the one hand, be based on a parallel multichannel structure. This architecture made it possible to track five satellites at the same time or to track, for example, four satellites and use the fifth channel for acquisition or re-acquisition as well as for searching next a satellite in view. On the other hand, pioneering developments took place from 1977 to 1981 for an all-digital GPS receiver [13.2]. Receivers that made use of digital correlation via an application specific integrated circuit (ASIC) were in the market around the 1990s. At this time, it was usually possible to implement six channels on an ASIC-type correlator chip. Typical devices of this kind were the Magnavox MX 4200 [13.3] and the Novatel GPS cards [13.4].

In the data flow of a modern digital parallel receiver, the antenna, LNA, and down converter are still based on analog technology. After the down-conversion step, the digitization via the ADC takes place. After the ADC, the further signal handling gets digital, that is, a bank of digital channels is built up (Fig. 13.2). The classical design of a digital all-in-view receiver is to implement this bank of channels on an ASIC by use of a semiconductor process (e.g., complementary metal oxide semiconductor (CMOS), 90 nm). The ASIC is interfaced to a microprocessor (MP) which has the function to steer and control the ASIC and to read out the measurements and data.

### 13.1.2 Early Military Developments

In the area of early military GPS receivers, we mainly observe two development lines. One development went in the direction of a personal navigation device for ground troops. It started in 1980 with the Rockwell Collins Man-Pack (AN/PSN-8) which was a single-channel, dual-frequency, coarse/acquisition (C/A)-and precise code (P-code) receiver in the form factor of a backpack. The Man-Pack had a mass of 7.8 kg. One decade later, the five-channel design was in production at Rockwell Collins and very large scale integration (VLSI) made significant progress. In the year 1993, the precision light weight GPS receiver (PLGR) was introduced in the NATO forces. The PLGR is a ruggedized handheld five-channel single-frequency L1, C/A-, and P(Y)-code receiver. The mass of the receiver is 1.2 kg, it has a jamming resistance of 24 dB, and antispoofing (A/S) is provided via the precise positioning service-security module (PPS-SM). The produced number of units is about 225 000. An upgrade with respect to an improved user interface and an improved power supply was provided with the PLGR+96. Since 2004, the PLGR was replaced by the DAGR (defense advanced governmental receiver) which is based on a GPS receiver application module-selective availability A/S module (GRAM-SAASM) form factor.

In the second development line, military aviation GPS receivers were designed. An early demonstrator of a five-channel military aviation receiver was the generalized development model (GDM) built by Rockwell Collins in contract with the Air Force Avionics Laboratory. The bulky system had a mass of 125 kg and was integrated on a flight-pad including the cooling system and the seats of the operators [13.5]. This activity was done in the concept demonstration Phase I of GPS. The first operational military aviation receiver was the Rockwell Collins 3A receiver [13.6]. This receiver was introduced in 1985 and was flown more or less on all Air Force, Navy, and US Coast Guard aircraft. Again it is a five-channel dual-frequency P-code receiver providing pseudoranges and delta ranges (integrated Doppler shift over 1 s) with a mass of 16.2 kg, a linear dimension of 42 cm and a power consumption of 116 W. The 3A was able to interface on the RF level with a controlled radiation pattern antenna (CRPA) and a fixed radiation pattern antenna (FRPA). Interestingly, besides other specific derivatives, a variant for Navy ship applications was derived which got the name 3S. Around 1990,

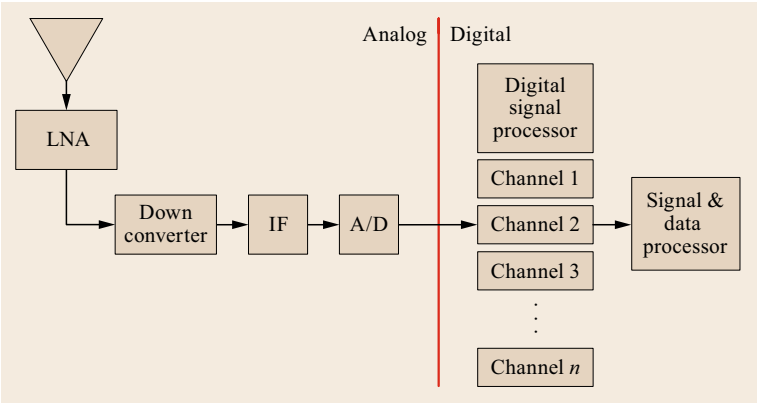

**Fig. 13.2** Digital all-in-view receiver architecture

Rockwell Collins released the miniaturized airborne GPS receiver (MAGR) as a five-channel dual-frequency P(Y)-code receiver making use of a PPS-SM. Its software design is identical with the 3A receiver [13.7]. With 5.6 kg the MAGR has a smaller mass and a reduced form factor of $30 \times 17\,\mathrm{cm}^2$ in the ground plane. Starting in 1998, a new contract for the production of the new MAGR 2000 was given to Raytheon in El Segundo. The MAGR 2000 is a form fit function compatible with the legacy MAGR. Since 2004, the MAGR 2000 is based on a standard electronic module, format E (SEM-E) form-factor GRAM-SAASM architecture.

### 13.1.3 Early Civil Developments

The first commercial GPS receiver was the Texas Instruments TI-4100. This receiver was a third-generation generation receiver and manufactured around 1981. It was based on large-scale integrated (LSI) components using the highest-speed bipolar digital technology which was available at this time. One version of the receiver was designed for commercial purposes, while the other was for a tri-agency version called GEOSTAR for use by the Defense Mapping Agency (DMA), National Oceanic and Atmospheric Administration (NOAA), and the US Geological Surveys (USGS).

The TI-4100 receiver (Fig. 13.3, [13.8]) is portable for field operations (it is about the size of a small suitcase) but can be mounted in a standard 19 in rack if desired. It has a small lightweight handheld control display unit, and contains a keyboard and a display window. The receiver is modular in design and allows for easy removal and replacement of circuit boards. The size of the TI-4100 is $37 \times 45 \times 21\,\mathrm{cm}^3$, the mass is 24 kg, and the power consumption is 93 W. The architecture of the receiver is based on a dual-frequency single hardware channel with a multiplexing tracking software package. It was able to track four satellites with a code and a carrier, that is, L1-C/A code, L1-P code, L1 carrier, L2-P code, and L2 carrier. If less than four satellites were visible, satellite data was acquired in a so-called degraded mode. In degraded mode, the receiver has the capability of adding an external atomic clock time standard input to provide clock-coasting.

**Fig. 13.3** Texas Instruments TI 4100 receiver (University of the Bundeswehr, 1985)

For the civil scientific community in the 1980s, the TI-4100 was the only possibility to track the complete GPS Block I satellite signals with pseudorange and carrier phase on all the three codes. Thus, it played a very important role in pioneering of GPS methods and solutions, for example, in developing early techniques in precise carrier-phase positioning and geodetic applications.

On the Magnavox side in the GPS Phase I, the GPS PAC receiver and later on the GPS Phase IIB receiver were developed. Obviously, based on these first military developments in the early 1990s, the Magnavox MX 4200 digital receiver was commercially available. It was a six-channel L1 C/A-code highly integrated receiver, which gave access to the entire raw data structure on the C/A-code. This receiver was used by industry and many research institutes for bread-boarding activities and the demonstration of early applications. Regarding the NovAtel OEM cards, a basic innovation came up [13.4, 9], which was the introduction of a wide-band ($< 20$ MHz) C/A-code receiver. This leads to the possibility of implementing a *narrow-correlator* technique in the signal processing. Previously, all C/A-code receivers [13.4] were mainly narrow-band (2 MHz) receivers, which employed a full single chip spacing in delay lock loop (DLL). The advantage of the narrow correlator was P-code-like thermal noise and better multipath rejection [13.9]. Besides these innovations, a new information policy on the receiver technology used in the GPS cards was established by NovAtel. This helped the civil user community to get a better insight into receiver design and signal processing and gave a push to university research in the field of receiver technology. The NovAtel GPS card of the mid-1990s was a 12-channel L1 C/A-code receiver. The 12 channels were implemented on two correlator ASICs (6 channels on each chip). Additionally, a transputer-based signal processor and an MP were used on the card.

At the beginning of 1990s, GEC-Plessey Semiconductors, a British-based International Electronics, Defense and Telecommunication Company, provided in the market a GPS L1 C/A-code receiver chipset solution, so-called GP2000 series, which was composed of three chips like GP2010/2015 for RF front-end, GP2021 for 12-channel digital correlator, and ARM 6/7 for the processor, together with all software source codes including detailed hardware design notes with a reasonable price [13.10]. Later, its digital parts (a digital correlator and a processor) were merged into an ASIC chip (GP4020) so that it became a two-chip solution. This GP series made it possible for many universities in the world to develop their own GPS L1 CA-code receiver solutions and/or to implement RF front-end devices being able to connect to general pur-

pose software-defined GPS receivers. The GPS chipset solution business part in GEC-Plessey Semiconductors was sold to other smaller companies in a series of merger and acquisitions, and became a technical baseline in many receiver developments.

In the next step of receiver development, the PC-type OEM board was miniaturized (higher integrated) on *credit-card* format from companies like, for example, Motorola, which had access to leading-edge semiconductor technology. A good example for this kind of receiver is the Motorola VP Oncore. There are many other examples for higher integration which happened in the early 2000s. This reduced form factor allowed the integration of small commercial handheld receivers and of small car navigation systems.

In general, it became obvious in the 1990s that low-end civil GPS receiver development at the low end would focus on L1 C/A-code only receivers, whereas for high-end users, availability of pseudorange and phase measurements on the second frequency was required. A dual frequency structure was necessary for compensation of the ionospheric path delay in differential and nondifferential GPS systems. Thus, a dramatic issue for the high-end community evolved, when it became clear that the US Department of Defence (DoD) intended to encrypt the public-domain precise code (P-code) to a classified Y-code. This was put into practice after the Gulf-War in 1991. Since 1994, all new Block II satellite made use of A/S encryption. Thus, no clear P-code would be available in the future, especially after the GPS full-operational capability (FOC) in April, 1995. Based on this perspective, all receiver companies, which developed for the high-end market such as Trimble Navigation, Ashtech, Leica, and NovAtel worked by reverse engineering on the problem to overcome the encryption of P(Y)-code L2. The techniques, still partly in use today, developed in this context were called codeless and/or semicodeless architectures. These techniques build on the fact that the P-code is encrypted by modulo-two addition of a W-code, which exhibits a notably lower chipping rate [13.11]. Thus, the basic idea [13.12] of advanced techniques is to narrow the RF bandwidth of 20 MHz down to the necessary smaller bandwidth [13.11] (500 kHz) by precorrelation of the received signal with a clear P-code. These methods are a generalization of the pure squaring, which goes back to the patent of *Charles Counselman III* [13.13]; this formed the basis for the Macrometer Model V-1000. With pure squaring the spreading code and the binary phase shift keying (BPSK)-modulated data is completely removed. A carrier-phase measurement resolving the half wavelength can be derived. Another approach made use by the fact that the Y-code is the same on L1 and L2. Thus, cross-correlating the signals on two frequencies with each other allowed determining the path delay between L1 and L2. The Ashtech concept [13.11] got later well known under the term Z-tracking. A comprehensive overview and analysis of many semicodeless methods is given in [13.14].

### 13.1.4 Early Receiver Developments for Other Satellite Navigation Systems

It can be seen from the history of GPS receivers that the step into GNSS receiver development is initiated if the satellite navigation system under development has obtained a certain state of maturity. Usually, the first types of receivers which are implemented are receivers for monitoring or sensor stations. Also, some early test user receivers are developed by the investment of research and development money. The investment in the GNSS receiver development by the existing or newly to-be-formed industry always happens with a delay of years. The reason is that, on the one hand, the stability of a satellite navigation program has to be shown by the service provider; on the other hand the compatibility with the claimed performance requirements has to be demonstrated.

#### Early GLONASS Receiver Developments

It is known that the Russian Global Navigation Satellite System (GLONASS) was developed in 1972 in parallel to GPS, but little is known about early GLONASS receiver development. The first GLONASS receivers like the ASN-16 or the Skipper became available in Europe around 1990 when Russian space industry opened to the Western world in order to establish joint-venture contracts with international space industry. German companies, that is, Kayser–Threde, Aerodata, and MAN Technology had several meetings with Russian colleagues. Mainly two Russian institutions were involved: the Institute of Space Device Engineering (ISDE) and Moscow and the Leningrad Scientific Research Radio Technical Institute (LSRRI), St. Petersburg. Contacts between the USA and Russia in this context are also reported. As the result of the German–Russian consultations, two types of receivers were available in Europe since 1992. The first one was the aviation receiver ASN-16 and the second one was a marine receiver called Skipper.

The ASN-16 (Fig. 13.4) was a single-channel GLONASS receiver which consisted of several subunits: a control and display unit, a navigation computer, an RF unit, an antenna, and a pre-amplifier. Via an ARINC-429 interface, raw data could be sent to a PC for display, storage, and further processing. The specified weight for the receiver was 25 kg and the power consumption was on a level of 180 W. In 1992, it was

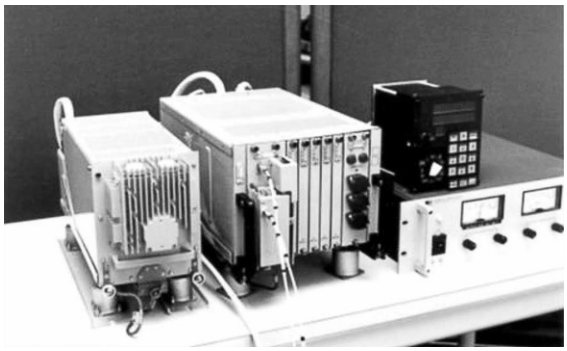

**Fig. 13.4** Russian GLONASS Receiver ASN-16 (courtesy of OHB)

announced by the ISDE to proceed with a higher integrated aviation receiver which was called the GNOM that was a 5 kg and 30 cm unit. In this weight class, the ISDE demonstrated a geodetic type of receiver named REPER, which was designed to provide precise carrier-phase measurements with 1–3 cm accuracy. Different GLONASS tests with the ASN-16 are reported in [13.15].

### Early Galileo Receiver Developments

In March 2002, the Galileo development phase was launched by a decision of the EC council. The official kick-off of the Galileo Phase C/D which marks the start of the industrial development goes back to December, 2004. In the time frame of the early 2000s, the first activities concerning the development of Galileo or combined Galileo/GPS receivers took place. These receiver development projects were funded mainly by European Space Agency (ESA). Later on, additional funding by European Commision, for example, in the framework program, FP6 (2003) and the FP7 (2007) context was provided for receiver activities.

For the Galileo ground mission segment (GMS) as well as verification and test activities of the payload, multifrequency receivers have been developed in Europe within ESA contracts.

The Galileo ground reference receiver (GRR) has been under development since 2002 [13.16]. It forms a part of the ground reception chain (GRC) which is a basic element of the Galileo GMS. Initially, Thales Alenia Space Italia (TAS-I), NovAtel, and Space Engineering were selected by the European Space Agency (ESA), its prime contractor European Satellite Navigation Industries (ESNIS), and Thales Alenia Space France (TAS-F), and work on the program began in June 2005. TAS-I has awarded NovAtel milestone contract for the continued development of the GRC reference receiver [13.17]. In the joint venture, 25 production units were to be delivered in order to support the in-orbit validation (IOV) phase of Galileo. NovAtel is delivering receiver components, which are integrated into the GRC.

The Munich-based company, IfEN, awarded a subcontract from Siemens Austria in the Galileo program to develop and produce a set of payload test receivers. The receiver is used to characterize the transmitted signal of a payload generator or constellation simulator before launch. The receiver is usually directly connected to the payload by use of an attenuation component. Mainly two versions of the payload test receiver were built. The first-generation IfEN Rx payload test receiver for IOV was built. It supports all services on Galileo IOV, for example, public regulated service (PRS) via an interface to a code encryption unit. The project was scheduled from 2006 to 2012. Additionally, a payload test receiver was developed and built in the time frame of 2010–2013 for the Galileo FOC testing. This receiver is a third-generation Rx of IfEN. It supports all services on Galileo FOC 2010–2013 including the PRS. It should be mentioned that the IfEN receiver development activities were initiated by the realization of the Galileo test range GATE, which was funded by German Space Management (DLR) (Bonn). For GATE, the first-generation E1, E6, E5a, E5b receiver was developed. This receiver was upgraded to a second-generation receiver called the NavX-NTR (Fig. 13.5).

In the field of test receivers for Galileo development phases, a Galileo experimental test receiver (GETR) was built by the Belgium-based company, Septentrio, in 2005: the GETR was used for the in-orbit validation of Galileo signals transmitted by GSTB-V2 satellites [13.19].

Other important developments of Galileo receivers or combined GNSS receivers in Europe are the test user receivers (TURs). A basic TUR was developed by Septentrio till 2010. The TUR is an all-in-view multifrequency Galileo/GPS receiver capable of tracking all Galileo signals together with GPS L1 and L5. The idea of the TUR project is to provide a user-like test receiver for the assessment of, for example, the user equivalent range error (UERE) of Galileo. A PRS-capable version (TUR-P) was developed in a joint venture between

**Fig. 13.5** Multifrequency Galileo test receiver NavX-NTR of IfEN GmbH (after [13.18], reprinted with permission)

Septentrio and the UK-based company, QuinetiQ, in 2010. In contrast to the Septentrio TUR development, a TUR-N and a TUR-P are under development at the Thales group.

A prototype Galieo PRS receiver called the Bavarian security receiver (BaSE) is developed under the lead of the Frauenhofer Institute for Integrated Circuits [13.20]. This is the first initiative in Germany to utilize the PRS of Galileo.

Besides these agencies-funded Galileo receiver projects (since the Galileo signal interface control document (ICD) was released in 2006), the open Galileo signals were integrated by many manufactures on a worldwide basis in the low-end and the high-end receiver domains. Thus, many chips are now on the market which provide a Galileo capability besides GPS.

### 13.1.5 Early BeiDou Receiver Developments

The GPS development program of US DoD and their announcement in 1984 to open it to civilian aircraft for free of charge served as the stimulus for China to begin to explore research on satellite-based positioning technology in 1985; the national-level satellite-based navigation system development program in China was named BeiDou (a Chinese name for *Big Dipper*). Later, this development program was extended to the regional satellite navigation system (BeiDou-1) to cover China and neighboring regions composed of two separate constellations operating since 2000. And, a full-scale global satellite navigation system (also known as COMPASS but recently named as BeiDou-2 due to frequency compatibility issue against Galileo) is currently under construction to have 35 satellites; it became operational in the Asia-Pacific region since 2011 with 10 active satellites, and its target year is 2020+.

Regarding BeiDou receivers, in 1995, the National University of Defense Technology in China began to investigate on baseband signal-processing algorithms. In 1998, the equipment is being tested in the ground station in Beijing. According to the data on the screen, the system was running well within the theoretical limits. It took three years in total from the theoretical design to the production of the receiver.

In November 2001, BeiDou became the third satellite-based navigation and positioning system together with existing GPS and GLONASS. However, problems occurred when the system was put into practice; the size of the receiver was too large (backpack-size). In 2004, the first BeiDou-1 portable navigation device (PND), which solved the portability problem of the receivers, in China was released. This means that it could be applied in many fields such as safety of life, defense, aviation, and so on. And it could also be used to communicate between different receivers to get the positions of each other by the short message functionality which is unique for the BeiDou system. In May 2008, a great earthquake took place in WenChuan, SiChuan Province, China. After 5 days of this disaster, the Beijing Satellite Navigation Center (BJSNC) received a message from the place where the disaster happened, indicating that the after-shock would keep happening in BeiChuan, and the water level of Haizi would keep raising. This message was delivered by the BeiDou-1 receiver owned by the rescue soldiers. This is the most famous application of the BeiDou-1 receiver in the public. In 2007, when one of the BeiDou satellites was running, a serious jamming was detected, causing the interruption in receiving the signals. After the analysis of the data by experts, it was discovered that the complex electromagnetic environment caused this interruption of the signal. And the research on antijamming began. In May 2008, antijamming equipment was successfully developed.

Currently in China, there are tens of companies researching the BeiDou chip-manufacturing process. However, only a dozen of companies have successfully developed the BeiDou chips; several of them own a complete chipset solution: the RF chip and baseband chip. For example, in the fleet management system for the government-owned vehicles of Guangzhou city, baseband chips from the Unicore Communications, Inc. and RF chips from the Guangzhou Ruixin Information Technology Co. are used. And, on the buses and trucks operated by the Ministry of Communications, more than 80 000 receivers were installed. Other famous company in this field includes the OLinkStar Co., the HuaXun Microelectronics Inc., the Beijing Hwa Create Corporation Ltd, the Hangzhou Zhongke Microelectronics Co., the Shanghai Fudan Microelectronics Group Co., and so on. The BeiDou baseband and RF chips in the market are independently designed. Chips from the worldwide major brands are integrated together; in this technique, it is claimed that there is a big gap (at least 15 years) between the domestic companies in China and major worldwide brands. Also, there is still a large gap in the manufacturing technique; the domestic companies can reach the 55 nm level while the major brands can reach a level below 40 nm. And until now, there has been no successful story of a Chinese companies to provide a single-chip combo solution, integrating the navigation chip and the communication chip in the largest market of navigation applications, for example, the mobile market. In the field of high-accuracy boards, the representative companies in China are Hi-Target Survey Instruments Company Ltd, the ComNav Technology Ltd, the South Survey/Mapping Instrument Ltd, the CHC Co., the Unistrong Co., and so on.

The followings are examples of BeiDou chips, receiver modules, and various application receiver systems compatible with GPS, GLONASS, or Galileo. UB240 is a BeiDou/GPS dual-system quad-frequency OEM board developed by Unicore/BDStar based on its multisystem, multifrequency, high-performance system-on-a-chip (SoC) technology with a self-owned intellectual property. UB240 uses low power consumption design and offers millimeter-level carrier-phase observations and centimeter-level real time kinematic (RTK) positioning precision, and is in support of multipath mitigation. Advanced technology for a long distant RTK is particularly appropriate for the application of high precision measuring and positioning [13.21]. CC50-BG was developed by OLinkStar based on their ProGee II GNSS engine. It provides the GPS, GLONASS, and BeiDou combined navigation solution. OLinkStar announced that this is the smallest satellite navigation module with BeiDou positioning functionality covering all over the world. The CC50-BG has been widely used in vehicle navigation and handheld devices on the Chinese market [13.22]. National University of Defense Technology recently developed a dual-band GNSS receiver with low-IF architecture for high-powered location-based service (LBS) in a 55 nm CMOS process. The receiver embodies two independent IF channels to support GPS-L1 and Compass-B1 signals, and can provide three operating modes (GPS-L1 and Compass-B1, GPS-L1, Compass-B1) with either passive or active antenna. The K508 GNSS receiver board is the first eight-frequency (BeiDou B1/B2/B3, GPS L1/L2/L5, GLONASS L1/L2) OEM board developed by the ComNav Technology Ltd that owns full independent intellectual property rights of this receiver board. It uses fast BeiDou high-dynamic and -accuracy computation algorithm engine to achieve a decimeter-level accuracy for the baseline of hundreds kilometers in a single epoch. The size, interface, and data command are compatible with OEM boards from major brands that support the same eight-frequency signals. It can be used in the areas of multisystem, multifrequency reference station, high accuracy surveying, aerospace applications, deformation detection, machine control, defense, etc. [13.23].

## 13.2 Receiver Building Blocks

A conventional GNSS hardware receiver is basically composed of the analog part, the digital part including the application processor, and the interfaces for input–output. The following building blocks [13.9] may be identified: single- or multifrequency L-band antenna plus cable, RF front-end including the LNA, the oscillator, down converter and mixers, and the bandpass filters, the ADC plus, optionally, an amplifier gain control (AGC). The digital part consists of a baseband integrated circuit containing the correlators, the MP, and the read only memory (ROM) and random access memory (RAM) memory units. Usually, correlator ASICs are in use plus a separate MP and memory elements. Sometimes these elements are integrated onto a single chip (systems-on-a-chip: SoC). Basically, the functions of the building blocks may be briefly described as follows:

- The antenna is to set the gain toward satellite ($\pm 3$ dBic) and is essential for out-of-band interference rejection.
- The preamplifier (LNA) is to set the noise figure $F$.
- The surface acoustic wave (SAW) filter is to band-limit the signal (bandwidth has impact on accuracy, for example, correlation loss).
- The ADC converts analog signal to digital (n-bit ADC).
- The AGC maintains the signal-plus-noise magnitude within the limits required by ADC level detectors.
- Major signal-processing functions are the following:
  - Reference signals (codes/carriers) are locally generated.
  - Autocorrelation is de-spreading the signal (high-frequency part removed).
  - Tracking loops (DLL and phase lock loop (PLL)) necessary to follow the time variations of the signals.
  - Carrier-aiding used to reduce noise in DLL, provides also dynamics.
- The reference oscillator generates fundamental frequency.
- The application processing computes the user's position, velocity, and time.

Before describing in more detail the different building blocks, some terms should be clarified which are used in the satellite navigation community to classify a type of receiver. In a classical hardware receiver, the baseband operations are hardwired on a baseband chip or an integrated circuit by making use of a state-of-the-art semiconductor integration process. The degree of flexibility in the case of upgrades is small. In an SDR,

hardware and software technologies are used in parallel to generate a reconfigurable solution. The goal is the ability to update the system by software changes. In any case, an analog front-end down to the ADC will be present: on the processor side, an field programmable gate array (FPGA), an MP or a general purpose computer or a mix of such a processor could be used. In GNSS software receivers, a general purpose processor is used: e.g., an Intel PC or an advanced risk machine (ARM) processor. All signal processing is programmed in a higher programming language like C/C++.

Figure 13.6 shows the building block diagram of a GPS C/A-code receiver. The specific typical technical parameters for L1 C/A-code receivers are added. In general all GNSS receivers are designed in such a way. For a more general GNSS receiver, the receiver parameters have to be adjusted to the specific signal structures.

### 13.2.1 Antenna

The role of the antenna (Chap. 17) is to receive an electromagnetic wave and convert it to an electronic signal. The modern goal in satellite navigation is to work with an all-in-view constellation. Thus, all satellites above the horizon should be received on the L-band carrier frequencies with an appropriate bandwidth. Therefore, a hemispherical radiation pattern is required for simultaneous L-band signal reception. In a real scenario, the maximum gain (+3 dBic) of the antenna is usually in the bore-sight direction (at 90° elevation). However, a significant gain should be present at lower elevation angles, because lower elevation signals suffer from higher attenuation (free space loss and atmospheric loss). The 0 dBic point is approximately located at 70°. However, below 5° of elevation, a sharp pattern role-off is necessary in order to attenuate multipath signals which are reflected from the ground or the platform mounting surface. In the lower hemisphere of the antenna pattern, high attenuation below −8 dBic or more is required (small back-lobes). Additionally, the antenna has to work with polarized signals: It should provide a good gain for right-handed circular polarized (RHCP) waves and a low gain for left-handed circular polarized (LHCP) waves. A sample gain pattern is illustrated in Fig. 13.7.

To understand polarization is essential for GNSS: in electromagnetics [13.25], the polarization state of a wave (and antenna) is described by its location (spherical coordinates) on the Poincare sphere (Fig. 13.8). Recall, that RHCP was introduced in GPS to get independent of the antenna pattern orientation at the satellite and the receiver. Circular polarization also plays a role in multipath rejection. In [13.25], a so-called wave-to-antenna coupling factor $\eta_d$ is introduced

$$C_d = \eta_d C$$
$$\eta_d = \left(\frac{1-d}{2}\right) + d\,\cos^2\left(\frac{\mathrm{MM_a}}{2}\right)$$
$$d = \frac{\text{polarized power}}{\text{total power}} \quad (0 \le d \le 1)\,. \tag{13.1}$$

In these equations, $C_d$ is the signal power at antenna output, $C$ is the signal power at antenna input, $\eta_d$ is

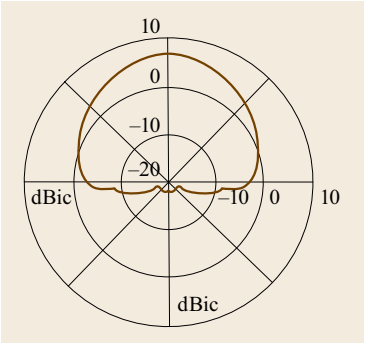

**Fig. 13.7** Typical RHCP antenna gain pattern for a GPS patch antenna (after [13.24])

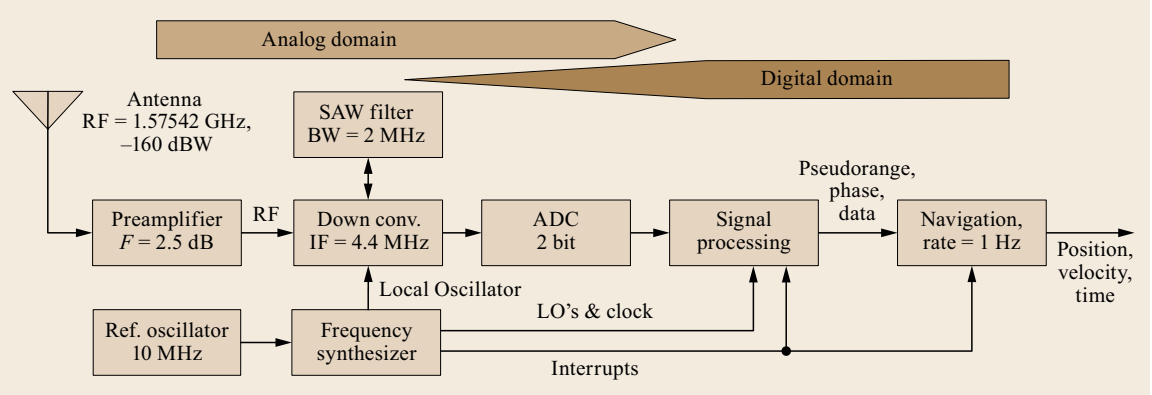

**Fig. 13.6** An example of building blocks for a GPS C/A-code L1 receiver

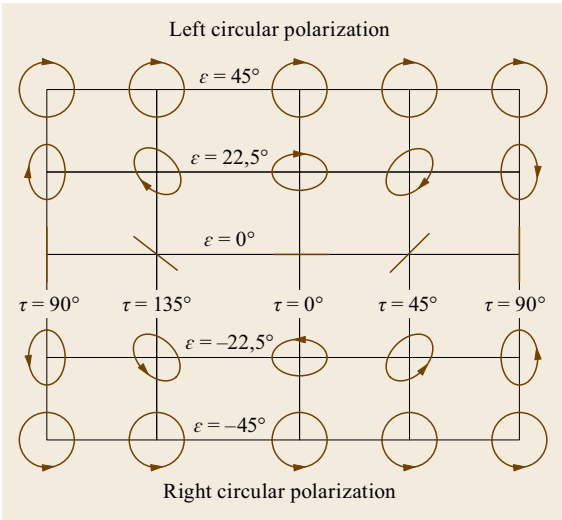

**Fig. 13.8** Polarization states on the Poincare sphere (after [13.25]) (latitude $= 2\varepsilon$, longitude $= 2\tau$)

the wave–antenna coupling factor, $d$ is the degree of polarization ($d \approx 1$ for GPS), and $MM_a$ is the spherical angle between the polarization states of the wave and of the antenna on the Poincare sphere. For example, the angle $MM_a$ is 180° for an RHCP antenna and an LHCP wave, while it is 90° for an RHCP antenna, and a horizontal or vertical linear polarized wave. Right-handed and left-handed elliptical polarizations have intermediate locations on the Poincare sphere.

For a GNSS antenna five primary design parameters may be identified:

1. Center frequency
2. Bandwidth
3. Radiation pattern and gain
4. Axial ratio (AR)
5. Phase response.

An antenna behaves like a bandpass filter around the center frequency. Thus, the bandwidth should be large enough to pass the modern GNSS wide-band signals. The axial ratio ($AR \geq 1$) is another parameter to describe the polarization state. It determines the latitude ($2\varepsilon$) on the Poincare sphere by the relation $2\epsilon = \cot^{-1}(\pm AR)$. The phase response is important for precise carrier-phase tracking because it is related to the stability of the phase center in spatial directions.

In general, four physical design forms of antennas are in use [13.26, 27]. It should be outlined that the antenna design chosen is related to the target application: civil, military, hand-held, mobile phone, aviation, space, and geodesy.

### Active and Passive Antennas

A technical difference has to be made between active and passive GNSS antennas. In an active antenna, the LNA is integrated into the antenna. The advantage is that the cable loss can be overcome by applying an appropriate gain at the LNA output. The active antenna needs a remote power feed from the receiver via the antenna cable. In a passive GNSS antenna, the LNA is built-in into the RF unit of the receiver. Usually, this approach is only used if the distance between the antenna element and the receiver is short (some cm). The market is dominated by active antennas.

### Helix Antennas

If properly designed, helical antennas can be the best antennas for GNSS reception. Helix antennas appear in GNSS in two forms: spiral helix and/or quadrafilar helix (volute). Helical antennas provide wider bandwidths than the planar antennas at the expense of higher back-lobes. The bandwidth of a broadband helix antenna can be sufficient for receiving wide-band signals up to 30–50 MHz. Phase-center stability is an issue. Using multiple-turn techniques [13.26], the bandwidth of the helical antenna can be increased. This can be helpful in order to cover the dual frequencies L1 and L2 of the GPS by a single antenna. The radiation pattern characteristics and the symmetry of the pattern symmetry are improved. The same holds for the axial ratio. The remaining problem of poor pattern roll-off in the horizon and high back-lobes has to be overcome by means of the ground plane, choke-ring, or the use of a stealth ground plane (with absorbing material). In early geodetic receivers like the TI-4100, a helical antenna was used. As described in [13.27], it is possible to build small ($18 \times 10\,mm^2$) helical antennas by dielectric loading.

### Planar Antennas

The main technology used for low-end GNSS applications which require small antenna profiles [13.26] is the planar antenna technology. Planar antennas may be produced with medium to low cost. Planar technology is usually implemented as a classical microstrip patch antenna or a small microstrip version. We will also cover ceramic chip antennas in this context. Microstrip antennas [13.27] have a thickness of some mm and can be integrated on dielectric substrates. A patch antenna yields sufficient AR, gain pattern, and stable phase-center location and adequately low back-lobes. The a priori limiting factor of a microstrip antenna is the relatively narrow bandwidth of around 3–5 MHz. So-called wide-banding concepts have to be used in order to enhance their bandwidth.

For many low-end applications like mobile phones or personal navigation devices, the size of the GNSS

antenna is the critical factor. For a quadratic patch, the engineering rule for the size $D$ is given by

$$D = \frac{\lambda}{2}\frac{1}{\sqrt{\varepsilon_r}}, \tag{13.2}$$

where $\lambda$ is the free-space wavelength in L-band, that is, about 200 mm and $\varepsilon_r$ is the dielectric constant of the used substrate. This leads immediately to the fact that a microstrip antenna element with $\varepsilon_r = 2.0$ has a size of $50 \times 50\,\text{mm}^2$. Using alternative substrate materials like $Al_2O_3$, the dielectric constant could be increased to $\varepsilon_r = 10$ or even higher for $SrTiO_3$ with $\varepsilon_r = 270$. The latter material would theoretically allow designing a ceramic L-band chip antenna with a size of only $3 \times 3\,\text{mm}^2$. A small ground plane and circuitry have to be added.

Microstrip antenna elements are also the standard choice for building antenna arrays.

### Array Antennas

Controlled radiation pattern antennas (CRPAs) are in use for decades in military applications. An analog version was the GPS Antenna System 1 (GAS-1) which basically consisted of a seven-element array on the associated ground plane. The physical space between a pair of antenna elements is $\lambda/2 = 10\,\text{cm}$. The design resulted in a large aviation antenna with a diameter of 35.6 cm, a height of 2 cm, and a mass of 1.8 kg.

Multiantenna arrays can be used on the one hand for the purpose of beam forming in the directions of GNSS satellites. Here, the purpose is to increase the gain and to enhance the carrier-to-noise ratio ($C/N_0$) of specific satellites. On the other hand, the more classical application is the spatial nulling of jammers in the horizon. With $n$ array elements, $n-1$ pattern nulls may be generated, that is, $n-1$ jammer or interference sources can be eliminated. A simple four-antenna array is illustrated in Fig. 13.9.

Depending on the required performance, synthetic or adaptive techniques can be used to perform the beam forming and/or nulling. It can be carried out by means of analog techniques (in RF or IF frequency domain) or digital techniques.

The use of an antenna array compared to an omnidirectional antenna imposes additional challenges to be addressed, if the user is changing the attitude of the antenna array and the variations in the received signal have to be monitored, and, in the case of a phased array, the beams have to be controlled in their direction to the satellites. Depending on the size of the array, significant complexity is added to the receiver architecture and signal processing because a complete receiver chain is necessary behind each array element. For high-precision carrier-phase application, the determination of the antenna phase centre is critical because of the time-dependent variation of the antenna gain pattern.

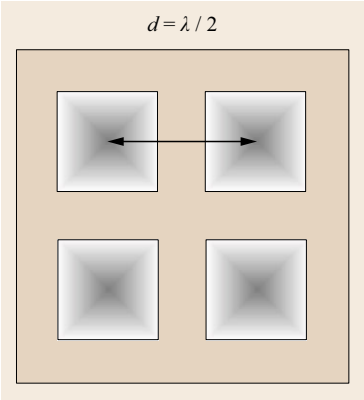

**Fig. 13.9** Principle of array antenna with four planar elements

CRPAs play a role in jamming resistant GNSS user equipment. Because a CRPA has a huger form factor and profile, it is only usable on larger platforms (large military–civil transport aircraft, ships, static reference stations on ground). Because of higher complexity, it adds also significant cost to the GNSS receiver. The future challenge will be in the design of small-sized arrays [13.28] by making use of ultra-small patches with dielectric loading. For the more complex RF circuitry, single-chip solutions with multiple RF chains are already available.

### Additional Elements for Multipath Suppression

In high-precision carrier-phase applications, for example, for surveying and geodesy, additional requirements exist for the antenna: ground reflections and the propagation of surface waves have to be suppressed, whereas on the other hand, the antenna phase center has to be determined with submillimeter precision. Fortunately, the technical solution for the first problem area supports also a stable phase-center. Ground reflections enter into the antenna element as multiple reflections. These can be treated by the fact that a single reflection changes the polarization state of the reflected wave to LHCP and is thus mitigated by an RHCP GNSS antenna. In any case, a change of the polarization state of the GPS wave will happen only with perfect conductors and perfect specular reflectors.

In order to generate a sharp gain pattern role-off at low elevation angles, three solutions exit which are commercially available by high-end receiver manufacturers.

The first solution that is known since the 1980s is the use of co-centric choke rings around the antenna element. The choke rings have a depth of $\lambda/4$. The concept is to generate an area of high impedance which then prevents propagation of surface waves [13.29].

A second solution introduced by Trimble [13.15] is to use a Stealth ground plane. A material is used which offers a high radially increasing sheet resistivity from the antenna element to the edge of the ground plane. Similar technology is used in the Stealth military aircraft systems. The performance of the antenna is said to be independent of the carrier frequency. Thus, the technology could be a good choice for multifrequency, multisystem, high-end antennas.

A third solution is the *pin-wheel* technology invented by NovAtel. In this technology, printed rings are used instead of massive physical choke rings.

#### Phase Response and Phase Center Variation

The phase response of a GNSS antenna varies with frequency, elevation angle (and azimuth), and temperature. In a good antenna design, the phase-response uncertainty has to be minimized. The idealized intersection point of the electromagnetic wave from different satellites is the antenna phase center. Depending on the antenna design, the phase center may exhibit offsets of up to 10 cm in height and mm to cm level horizontally relative to the mount point. The phase-center variation, which describes the deviation of the waveform from a sphere, adds additional direction-dependent biases of several mm to cm to the carrier-phase measurement and must be taken into account in the high-precision modeling of GNSS observations (Chap. 19). Calibration techniques for determining the phase-center offset and variation of receiver antennas are, furthermore, described in Sect. 17.6.2 of this Handbook.

### 13.2.2 RF Front End

In a modern GNSS receiver, the RF unit is the most critical subsystem, because it determines cost, size, and power consumption of the receiver. Especially for highly integrated single-chip receivers, the front-end design is of primary importance. The overall bandwidth of the pre-correlation filter chain determines the post-correlation pseudorange accuracy, because a trade off decision between wide- and narrow-band design is done. The key components of the RF front end are the LNA, the RF, and IF filters, and also the local oscillator (LO) used for down conversion. This RF oscillator is usually coupled to a crystal oscillator by means of a phase-lock loop (PLL). The down-conversion scheme of a GNSS receiver poses requirements on the crystal oscillator (stability, phase noise, and frequency).

#### Concepts of RF Processing

The block diagram for a typical GNSS receiver front end is shown in Fig. 13.10. The first necessary subsystem in the chain for such a front end is the antenna, which was already described in the previous chapter. After the antenna, usually an RF filter is used to eliminate unwanted emissions that could otherwise enter the LNA. The necessary selectivity of this filter determines the technology and also (together with the LNA noise figure) the loss introduced into the pass band.

As stated in the previous chapter, most antennas are built as active antennas, that is, they include the LNA and the RF pre-filter. After the LNA, a second RF filter, which could provide the necessary image rejection, is used. The RF signal is converted down into a first IF in the range of typically hundred MHz. An IF filter, which could be much narrower than the RF filter, is used to eliminate unwanted spectral parts. A second down conversion delivers the received signal in a frequency range of several MHz. In a real receiver scenario, the center frequencies of the front-end depend on the implemented frequency plan. The subsequent IF filter eliminates unwanted spectral components. It ensures that the ADC fulfills the sampling theorem.

#### Mathematical Description of Front-End Operations

Descriptions of the front-end functions are found in several textbooks, for example, [13.9, 11]. In this section, we perform a description in the frequency domain based on Fourier transform (FT), making use of the Dirac delta function and the frequency-shift theorem of

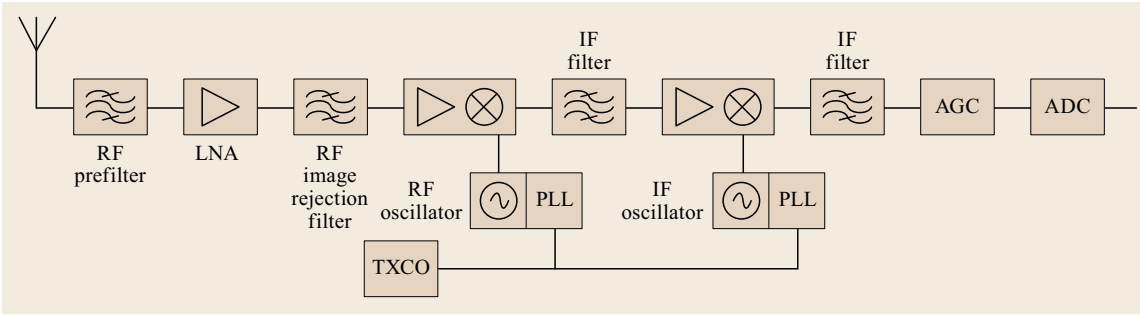

**Fig. 13.10** Typical heterodyne RF front end of GNSS receivers (after [13.30])

Fourier transform. Because the carrier frequency is substantially larger than the chipping rate of spreading code (e.g., by a factor of 154 for L1 P-code), we consider the code chip $c(t)$ constant and discuss only an unmodulated, that is, constant amplitude carrier

$$s(t) = a\,\cos(\omega_1 t + \phi) + n(t)\,, \tag{13.3}$$

where $s(t)$ is the signal, $a$ is the amplitude, $\omega_1 = \omega_0 + \Delta\omega_D$ is the Doppler-shifted nominal carrier frequency with $\omega_0$ denoting the nominal carrier frequency, $\Delta\omega_D$ is the Doppler shift, $\phi$ is the phase of the carrier, and $n(t)$ is the thermal noise. We define the Dirac delta function as usual

$$\delta(\alpha) = \begin{cases} \infty & \text{for } \alpha = 0\,, \\ 0 & \text{for } \alpha \neq 0\,. \end{cases} \tag{13.4}$$

The Fourier transform of the harmonic signal $s(t)$ may then be written as

$$\begin{aligned} F[s(t)] &= S(\omega) \\ &= a\pi[\delta(\omega+\omega_1) + \delta(\omega-\omega_1)] + N(\omega) \end{aligned} \tag{13.5}$$

with a spectral representation of signal $S(\omega)$ and noise $N(\omega)$. For the mixing operations, we multiply the signal (13.3) with the mixing signal

$$\cos(\omega_{LO})t = \frac{1}{2}(e^{+j\omega_{LO}t} + e^{-j\omega_{LO}t}) \tag{13.6}$$

in the time domain. The frequency $\omega_{LO}$ is the reference frequency of the LO generated by the PLL of the mixing stage. Applying the frequency-shift theorem,

$$F[g(t)]e^{j\omega_0 t} = G(\omega - \omega_0) \tag{13.7}$$

yields

$$\begin{aligned} S_{mix}(\omega) &= F\left[s(t) \times \tfrac{1}{2}\left(e^{+j\omega_{LO}t} + e^{-j\omega_{LO}t}\right)\right] \\ &= \frac{1}{2}S(\omega-\omega_{LO}) + \frac{1}{2}S(\omega+\omega_{LO}) \end{aligned} \tag{13.8}$$

and by computation,

$$\begin{aligned} S_{mix}(\omega) = \frac{a}{2}\pi[&\delta(\omega+\omega_1-\omega_{LO}) + \delta(\omega-\omega_1-\omega_{LO}) \\ &+ \delta(\omega+\omega_1+\omega_{LO}) + \delta(\omega-\omega_1+\omega_{LO})] \\ &+ \frac{1}{2}[N(\omega-\omega_{LO}) + N(\omega+\omega_{LO})]\,. \end{aligned} \tag{13.9}$$

We see that by the mixing operation, spectral lines will occur at $\pm(\omega_1+\omega_{LO})$ and $\pm(\omega_1-\omega_{LO})$. Also, the spectral representation of noise $N(\omega)$ is shifted with respect to $\pm\omega_{LO}$. We now put the difference to the target intermediate frequency (IF) as

$$\begin{aligned} \omega_1 - \omega_{LO} &= \omega_{IF} \quad \text{and} \\ \omega_1 + \omega_{LO} &= 2\omega_1 - \omega_{IF}\,. \end{aligned} \tag{13.10}$$

This yields the final expression

$$\begin{aligned} S_{mix}(\omega) = \frac{a}{2}\pi[&\delta(\omega+\omega_{IF}) + \delta(\omega-2\omega_1+\omega_{IF}) \\ &+ \delta(\omega+2\omega_1-\omega_{IF}) + \delta(\omega-\omega_{IF})] \\ &+ \frac{1}{2}[N(\omega-\omega_1+\omega_{IF}) + N(\omega+\omega_1-\omega_{IF})]\,. \end{aligned} \tag{13.11}$$

Following the terminology in RF technology [13.16], the frequencies in (13.11) which are not identical to the carrier frequency $\omega_1$ are called the image frequencies, that is, the frequencies $\pm(2\omega_1-\omega_{IF})$ and $\pm\omega_{IF}$. The final step is a dual bandpass operation applied on the IF center frequencies $\pm\omega_{IF}$.

For simplification, an ideal IF filter, sometimes called a *brick-wall* filter, with a rectangular transfer-function $H_{IF}(\omega-\omega_{IF}) = H_{IF}(\omega_{IF}-\omega)$ can be applied. This will remove the high-frequency term containing $2\omega_1-\omega_{IF}$, where $B_{IF}$ is the single-sided bandwidth of the bandpass filter

$$H_{IF}(|\omega-\omega_{IF}|) = \begin{cases} 1 & \text{if } |\omega_{IF}-2\pi B_{IF}| \le |\omega| \\ & \text{and } |\omega| \le |\omega_{IF}+2\pi B_{IF}|\,, \\ 0 & \text{otherwise}\,. \end{cases} \tag{13.12}$$

The idealized result of the bandpass filter operation for the signal on the IF is

$$\begin{aligned} S_{IF}(\omega) &\approx H_{IF}(\omega-\omega_{IF})\,S_{mix}(\omega) \\ &= \frac{a}{2}\pi[\delta(\omega+\omega_{IF}) + \delta(\omega-\omega_{IF})] \\ &\quad + \frac{1}{2}H_{IF}(\omega-\omega_{IF}) \\ &\quad \times [N(\omega-\omega_1+\omega_{IF}) + N(\omega+\omega_1-\omega_{IF}]\,. \end{aligned} \tag{13.13}$$

We see in (13.13) the two remaining spectral lines of the cosine function at $\pm\omega_{IF}$. Additionally, the white-noise signals in the pass-band will remain in the IF signal, like it is to be expected. The real situation of the front end is much more complex: as described in [13.9], the LNA and mixer have nonlinear transfer characteristics. Thus, they could potentially generate additional harmonics especially in the case of interference. Let's assume for

a moment that we have spectral lines not only at RF frequency $\pm\omega_1$, that is, assume $\omega_1 = \omega_{IF}$ but also on the IF frequency $\pm\omega_{IF}$ for some reason: we see from (13.11) that in this case, the term $2\omega_1 - \omega_{IF}$ equals $\omega_{IF}$. This means that these components would map to the IF filter pass-band. The same holds for so-called image noise and the oscillator feed-through [13.9]. Band-stop pre-filtering and careful design of the frequency plan are necessary to avoid additional spectral components in the IF pass-band.

### Down-Conversion Schemes

In general, two basic approaches exist for frequency handling in the front end: homodyne and heterodyne down conversions. The homodyne approach is also known as the direct-conversion receiver (DCR) or the zero IF receiver. In the superheterodyne approach, the initial carrier frequency is converted to an intermediate frequency before digitization.

*Homodyne Down Conversion.* In the direct digitization ADC, amplification, sampling, and processing are done at RF. This concept leads to the most simple front end. No mixers and IF filters are necessary. Because the number of analog components is minimized, problems with respect to temperature variations and aging are less. The draw-back is the high power consumption of the ADC and a high computational load on the digital signal processor (DSP). Although this solution is technically feasible for GNSS receivers, leading-edge digital components are necessary, which implicate a high-cost and high-power consuming receiver. However, it is an opportunity for future software-defined GNSS receivers which need multifrequency and multiband. RF ADCs, for example, from Texas Instruments are able to sample RF frequencies up to 2.5 GHz with 12 Bit resolution [13.31] and a power consumption of 2.2 W per channel.

*Superheterodyne Down Conversion.* In the superheterodyne down conversion, the amplification and filtering are done at the IF level. It can be done in a single step, which results in a less number of analog parts in the front end. Usually, the digitization is done at an IF of about 4–200 MHz. It provides the advantages of a complete digital solution but relaxes the requirements for the ADC and the follow-on digital processing units by reduced sampling speed. It is a typical solution for single-chip integration at the low end.

At the high end, superheterodyne concepts work with a dual- or triple-step down-conversion scheme, reducing step-by-step the filter bandwidth and thus obtaining very good spectral selectivity. It provides good interference rejection, that is, out-of-band rejection. The price to pay is in more analog parts and higher power consumption. Associated problems in multiple frequency devices with aging and temperature-dependent group delay have to be considered.

Additional schemes are called baseband or near-zero down conversion. In this concept, the down conversion goes down to 0–100 kHz in a single step. Amplification and filtering are done at RF frequency which results in higher power consumption. In this case, the advantage is that filters and amplifiers are eliminated at IF. However, a price has to be paid in lower interference rejection. This approach could be a solution for single-chip integration where power consumption is not a driver.

### Filters

For bandpass filters in the front end, different technologies are possible. In the RF stage, classical inductor-capacitor (LC; from their electrical component representation in circuit theory) circuits and ceramic filters have been used. SAW filters are used in both the RF and IF stages. Filters are determined by the parameters such as center frequency, pass-band frequency, 3 dB bandwidth, insertion loss, attenuation at maximum and minimum frequency, operating temperature range, impedance, and packaging type.

In LC filters, parallel and serial switching circuits with coils and capacitors in a certain complexity level are employed. The complexity of the analog circuits is designed in such a way that the required transfer function of the filter is obtained.

A ceramic filter is a combination of a ceramic resonator (using a mold of ceramic powder under high temperature) with a capacitive coupling network. The center frequency of the resonator depends on the length and the dielectric constant. Ceramic filters are of small size, low-cost, and have a low insertion loss. One drawback of them is that their minimum frequency is 400 MHz (up to 6 GHz). Another drawback could be temperature stability. Ceramic filters have a Chebyshev-type transfer function.

A SAW filter is, in principle, a mechanical filter concept. It makes use of a piezoelectric substrate as a physical basis. The SAW filter has an input transducer and an output transducer. Between these two transducers, the acoustic surface wave travels and couples with the piezoelectric substrate. Usually, the application frequency goes up to 3 GHz with a bandwidth of several MHz. SAW filters can be implemented on quartz ($SiO_2$). They exhibit a nearly rectangular transfer function and are well described by a Butterworth filter transfer function of higher order.

The transfer function of these filters determines the correlation loss and the shape of the autocorrelation function in post-correlation signal processing.

### Computation of System Noise Temperature

For the sake of completeness, the analytical model for the computation of the system noise temperature $T_{sys}$ and the associated noise power density

$$N_0 = kT_{sys} \quad \text{with} \quad k = 1.38 \cdot 10^{-23}\,\text{J/K} \tag{13.14}$$

in 1 Hz bandwidth is reviewed. More details may be found in [13.9] which references [13.32].

Based on the *Friis* formula [13.32] for noise temperature in a cascaded system of stages, where each stage has its own gain factor $G_i$ and noise figure $F_i$, we obtain the well-known expression

$$T_{sys} = T_A + \left(\frac{1}{G_1} - 1\right) 290\,\text{K} + \frac{(F_2 - 1)\,290\,\text{K}}{G_1} + \frac{(F_3 - 1)\,290\,\text{K}}{G_1 G_2} + \cdots \tag{13.15}$$

for the system temperature $T_{sys}$ at a given antenna temperature $T_A$. By way of example, a system temperature of

$$T_{sys} = 130\,\text{K} + (1 - 1)\,290\,\text{K} + \frac{(1.83 - 1)\,290\,\text{K}}{1.0} + \frac{(1 - 1)\,290\,\text{K}}{30} + \cdots = 370.7\,\text{K} \tag{13.16}$$

is obtained for the system illustrated as in Fig. 13.11.

We see again that the noise figure of the LNA, in this case $F_2 = 1.83$, contributes significantly to the overall system temperature in addition to the antenna noise temperature.

### Group Delay Distortion in Multifrequency Receivers

In multifrequency receivers, additional delay problems arise in the front end on different carrier frequencies. Front-end group delay biases (GDBs) are mainly due to the group delay characteristics of filter devices in the front-end chain. Filter technologies used in the front-end on the RF- and/or IF level exhibit a wide range of group delay variation in the frequency band of interest from 0.5 ns to some tens of ns. Thus, an adequate filter choice is essential to control the overall group delay characteristics of the receiver.

A code division multiple access (CDMA) system with a single carrier is affected by group delay distortion, but in a constant way for all satellites. This problem is mitigated by solving for the clock error term in the navigation algorithm. Because of only small Doppler shifts (±5 kHz) relative to carrier frequency and signal bandwidth, only small inter satellite GDBs will result on the same carrier.

A frequency division multiple access (FDMA) system with multiple carriers, for example, like the Russian GLONASS [13.33] is tremendously affected by group delay, because the GDBs for different carrier frequencies and/or signal bandwidths could be completely different.

A constant (frequency independent) group delay is common to all signals/frequencies and is removed together with the receiver clock bias in the navigation algorithm. In the general case, the group delay varies (nonconstantly) for different carrier frequencies and over the signal bandwidth, which passes, for example, a wideband receiver, and introduces GDB errors.

A significant improvement of receiver group delay distortion can potentially be achieved by means of moving the filtering functions from the analog filters to highly stable digital filters. Through the current advances in ADC technology, it is potentially possible to perform the analog–digital (A/D) conversion at high IF and, hence, to decrease the number of analog filtering components in the receiver chain. It is also recommended to use identical components in different channel paths to decrease the impact of hardware variation on the interchannel group delay characteristic of the receiver.

In [13.34], group delay effects were investigated for a NovAtel GPS/GLONASS MiLLenium-G receiver card over the GLONASS L1 frequency band from 1602–1616 MHz. The interfrequency GDB relative to GLONASS frequency channel no. 1 was measured and analyzed (Fig. 13.12). The frequency spacing between the GLONASS satellites is known to be 0.5625 MHz. In the test of this high-end receiver, differential pseu-

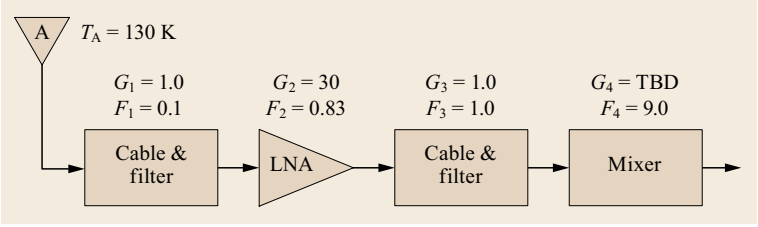

**Fig. 13.11** Typical front end of a GNSS receiver adapted for the application of the Friis formula

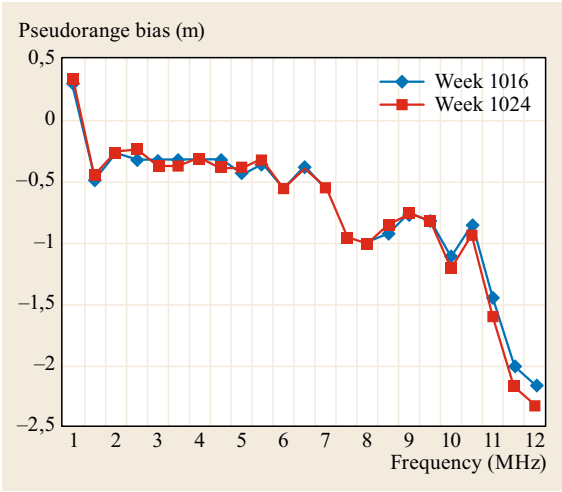

**Fig. 13.12** GLONASS pseudorange biases with respect to frequency no.1 over 8 weeks (after [13.34])

dorange biases at the level of ±1–3 m and differential carrier-phase biases of ±0.02–0.03 cycles were found. Aging effects are present with 15 cm per 8 weeks and temperature-dependent effects in the GDB are of the order of ±0.5 m per 10 K change in the operating temperature of the front end.

Group delay distortion is not only a frequency-dependent path delay effect. It also changes slightly the shape (and the inherent timing information) of the chips on the signal. This will finally result in an asymmetrical shape [13.33] of the autocorrelation function after signal processing. From this, it becomes clear that a wide correlator (e.g., with E-L spacing of 1 chip) will be more affected by group delay distortion than a narrow correlator because of different asymmetry levels between 0.1-chip spaced and 1-chip spaced E-L correlation points.

### 13.2.3 Analog-to-Digital Conversion

In a modern GNSS receiver, the digitization is done immediately after the down conversion, filtering, and amplification. The ADC is a piece-wise linear discontinuous system element in the receiver signal flow. It comprises two basic functions: conversion of continuous time to discrete time (sampling) and conversion of continuous amplitude to discrete amplitude (quantization). Two associated problem areas are related to digitization: quantization noise and/or quantization loss and all related problems to the sampling issue, like aliasing.

The basic elements of the ADC (Fig. 13.13) are a local oscillator to set the sampling frequency, the sample and hold circuit to define the digital time increment of the receiver, a threshold comparator to compare the analog amplitude (on input axis) with a number of $n$ predefined thresholds (Fig. 13.14), and an encoder to convert the result of the comparison (between the amplitude levels) to a certain number of bits (on the output axis).

The number $n$ of thresholds on the input axis could be even or odd. The standard case is that an odd number of thresholds are used. In this case, no level at zero is present and the encoding can be done to 1 bit, 2 bit, ..., $k$-bit words. If $n$ is even, a level at zero (dead-zone) exists. A further decision state becomes necessary (e.g., in the case of two thresholds, that is, $-\Delta$ and $+\Delta$, three levels exist: $-L$, 0, $+L$). For encoding this logical situation, 1 bit is not sufficient and full 2 bit is not necessary, because we need only three logical states. Because of this hybrid situation [13.12], these quantizers are called 1.5 bit, 2.5 bit, etc.

Based on the classical link-budget for a GNSS channel, it is known that the signal amplitude is at least about 20 dB below the thermal noise level. Therefore, the thresholds of the ADC are dithered by Gaussian noise if no interference is present. The signal itself is deeply buried into noise.

In a digital GNSS receiver, the ADC is a very important subsystem. The implementation used will determine the size of the pre-correlation bandwidth contributions to the implementation loss and will determine the digital data stream, which has to be processed in the signal processing unit (SPU).

In a linear ADC, the transfer function is a straight line with steps around it. It is possible to construct

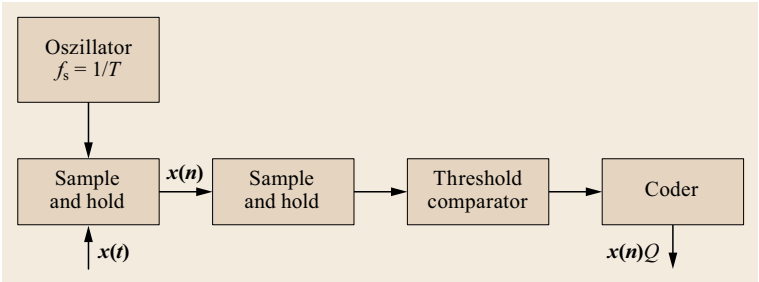

**Fig. 13.13** Schematic view of an analog-to-digital converter

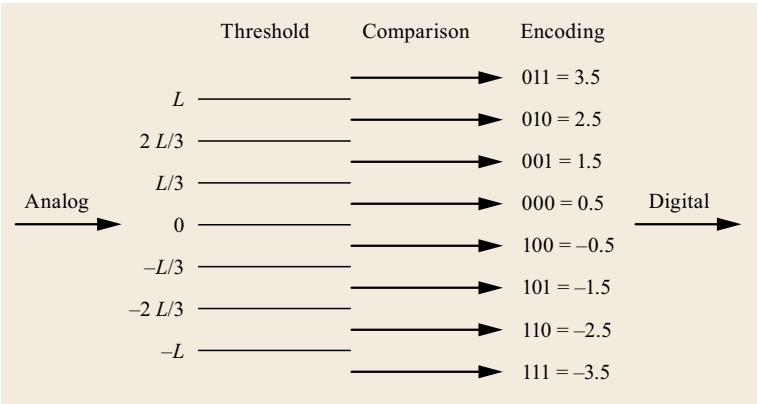

**Fig. 13.14** Concept of quantization in the ADC (after [13.9])

nonlinear ADC versions where the location of the thresholds could be changed in an adaptive way and the output level comparison is weighted by applying a weight $w$.

### Sampling Rates

The discussion of sampling rates in a digital GNSS receiver is a more complex issue than it looks at a first glance. Following the sampling theorem, we have to consider in general three cases:

1. Oversampling
2. Nyquist sampling
3. Sub-Nyquist sampling (or under-sampling).

We assume that the front-end filtered signal has a single-sided bandwidth of $B$ in the frequency domain and that the sampling rate is $f_s$. In digital GNSS receivers, the different types of sampling may be distinguished as follows:

- *Oversampling*: For $f_s > 2B$ in baseband sampling or $f_s > 4B$ in IF sampling, a larger band relative to the GNSS signal band is sampled. This leads to the situation that mainly noise bandwidth and potential interference outside the useful band are sampled. Original white noise is converted to colored noise (correlated noise) which could cause additional issues. If the front end is designed properly, no additional information is gained by oversampling. In this context, a wide-band receiver is not treated as an oversampled receiver.
- *Nyquist sampling*: For $f_s = 2B$ in baseband sampling or $f_s = 4B$ in IF sampling, we sample exactly the useful bandwidth of the GNSS signal. A historical discussion in receiver technology concerns the question whether only the main lobe of a signal should be sampled (which leads to a narrow-band receiver with a standard correlator) or if the entire signal including the side-lobes should be sampled in the transmitted bandwidth (20 MHz for GPS C/A-code). The latter case leads to a wide-band receiver where narrow correlation is possible. In an IF-sampling receiver [13.9], the $I$ and $Q$ baseband components are obtained directly in the sampling process without mixing with sine and cosine references. As described in [13.9], signals (the $I$'s and $Q$'s) are sampled at successive 90° phase shifts. This requires an additional factor of 2 in the Nyquist rate in comparison to sample a single sine or cosine component.
- *Under sampling*: This case is encountered for $f_s < 2B$ in baseband sampling or $f_s < 4B$ in IF sampling. It is clear from the sampling theorem that if a signal has to be reconstructed, Nyquist sampling is necessary. Otherwise, aliasing issues will result. However, it was discovered during the implementation of early software receivers (where processing of very fast digital data stream posed a problem) that in fact no stringent requirement exists to reconstruct the GNSS signal [13.35, 36]. The main requirement on the sampled signal is that it is useable for the computation of an autocorrelation function in the time domain or for a convolution operation in the frequency domain. This means that (against common thinking) under-sampling will work in an autocorrelation receiver. Of course, a price has to be paid which is the aliasing of noise and the reduction of the effective $(C/N_0)$ factor.

We conclude this section with a comparison of baseband sampling and IF sampling. By the Nyquist theorem, a bandlimited signal can be perfectly sampled from a countable sequence of samples if the bandlimited signal is sampled with a sampling rate greater than twice the bandwidth. This fact can also be interpreted that a modulated signal with a null-to-null bandwidth of $2B$ centered at an IF $f_{IF}$ can be perfectly sampled by any sampling rates which necessarily satisfy the Nyquist

theorem (i. e., $f_s \geq 4B$, not $f_s \geq 2(f_{IF}+B)$) without any loss of information, thereby the resulting final IF $\bar{f}_{IF}$ of the aliasing spectrum becoming lower than the original IF (this is a type of down conversion by intentional aliasing). In other words, because the bandpass signal is repeated at integer multiples of the sampling frequency, we can obtain down-converted sampled signal by selecting the appropriate sampling rate. For example, a GPS C/A-code signal ($2B = 2$ MHz) modulated at $f_{IF} = 95$ MHz can be effectively sampled with $f_s = 4$ MHz which is extremely undersampling of the harmonic function at IF, and the final IF becomes $\bar{f}_{IF} = 1$ MHz. This is known as the bandpass sampling technique (also known as the direct conversion or effective intentional aliasing technique) [13.37–39]. In addition to the constraint of the sampling rate by the Nyquist theorem, to avoid unintended aliasing effect, we have to select both the sampling rate and the resulting final IF, not to overlap the information spectrum with the aliasing spectrum [13.40].

### Quantization Loss

In the quantizer, the amplitude of the analog signal is converted to a binary representation of the signal (analog-in and binary-out). Depending on the quantization step, $q$, a certain loss in the signal-to-noise ratio will happen, because the continuous curve is finally represented by a straight line plus a number of rectangular steps. The mathematical description of quantization loss may be found in different sources including [13.9, 41–44]. More or less all of these publications employ a statistical model making use of the probability distribution function (pdf) of a binary signal ($\pm 1$) plus Gaussian white noise. We follow the description of [13.41]. The ratio $\delta$ between output and input $(C/N_0)$ (which refers to the ADC transfer function) may be defined as follows

$$\delta = \frac{(C/N_0)_{out}}{(C/N_0)_{in}} = \frac{\sigma^2}{c^2}\,\frac{\left(\bar{N}_S - \bar{N}_{noise}\right)^2}{E\left(N_{noise}^2\right)} \,. \tag{13.17}$$

The quantizer loss $L$ may be defined [13.41] as

$$L = -10\log_{10}\delta \,, \tag{13.18}$$

where $\sigma^2$ is the variance of the additive zero-mean white Gaussian noise (AWGN) process. In this context, only a Gaussian pdf, $N(0,\sigma^2)$, is considered. The quantity $c$ describes the signal content $(+c,-c)$, $\bar{N}_S$ is a measure for the square-root of the signal power after quantization, correlation, and accumulation, $\bar{N}_{noise}$ is a measure for the square-root of the noise power after quantization, correlation, and accumulation, and $E()$ is the statistical expectation operator. In order to simplify the discussion, it is assumed that the signal is on zero IF frequency.

The input signal is sampled in amplitude [13.41] by the ADC through segmenting the input into a series of linearly spaced levels defined as $t_i$ $(i \in -n, \ldots, +n)$ as illustrated in Fig. 13.15. In this context, $t$ is not the time. The output levels are shown as monotonically increasing. In general, nonlinear assignments of the input range to output state can also be supported. There is an extended region around the zero input levels which yields a zero output level. The weights, $w_i$, of the output levels are assumed to be 1, 2, 3, etc. as set by most ADCs (linear weighting). But this is not necessarily required as the output levels can be assigned any arbitrary output weight $w_i$ for $t_i < x \leq t_{i+1}$.

In the presence of a signal element $c$, the conditional probability that the ADC input $(x)$ in the range $t_i < x \leq t_{i+1}$ is occupied is given by

$$P(t_i \leq x < t_{i+1}|c) = \int_{t_i}^{t_{i+1}} P(x|c)\,\mathrm{d}x \,, \tag{13.19}$$

where $t_{m+1} = \infty$ and $t_{-(m+1)} = -\infty$.

Then, for the binary signal $s$, which can attain the values $s = +c$ or $s = -c$, the average number in the accumulator after $n$-independent experiments is

$$E(N_S) = \bar{N}_S = n\sum_i \begin{Bmatrix} w_i\,P_i(s=+c)\,p_+ \\ -w_i\,P_i(s=-c)\,p_- \end{Bmatrix} . \tag{13.20}$$

The terms, $p_+$ and $p_-$, are the a priori probabilities that the signal is either +1 or −1 (equal to 1/2 for ideal random sequences). The minus sign associated with the term $P_i(s=-c)$ reflects multiplication by the code replica (de-spreading). The measure of signal power is $\bar{N}_S^2$.

The same equation can be used [13.41] to establish the average number in the accumulator when only noise is present. For this case, the probabilities, $P_i$, are iden-

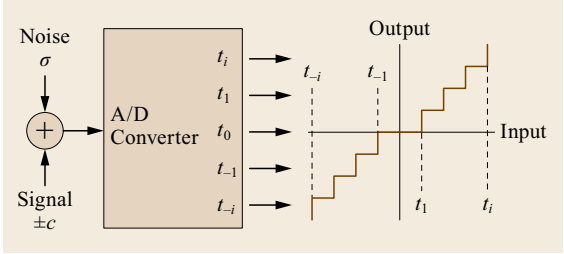

**Fig. 13.15** ADC signal and noise model (after [13.41])

tical as $c = 0$, then [13.35]

$$E(N_{\text{noise}}) = \bar{N}_{\text{noise}} = n \sum_i \begin{Bmatrix} w_i P_i(s=0)\, p_+ \\ -w_i P_i(s=0)\, p_- \end{Bmatrix} = 0\,. \tag{13.21}$$

The variance of the accumulator number after $n$ independent experiments represents the post-correlation noise variance (note the use of the square of the values in the weight vector) [13.36]

$$E(N_{\text{noise}}^2) = n \sum_i \begin{Bmatrix} w_i^2 P_i(s=0)\, p_+ \\ +w_i^2 P_i(s=0)\, p_- \end{Bmatrix} = 2n \sum_i \left\{ w_i^2 P_i(s=0) \right\}. \tag{13.22}$$

Based on these expressions, the quantization loss can be computed and depicted in Fig. 13.16.

It shall be outlined that the curves are only valid for infinite (very high) sampling rates. Thus, the results are too optimistic in comparison to the case of a finite sampling rate [13.9]. In [13.9], similar curves are shown for a narrow-band and a wide-band receiver. All curves for the ADC losses approach the two-level (1 bit) case, that is, a loss of 1.961 dB, at low values of normalized threshold $\Delta/\sigma$. For high normalized thresholds, the loss curves for ADCs which have a level at zero grow without bound, whereas the ADC loss curves stay bounded

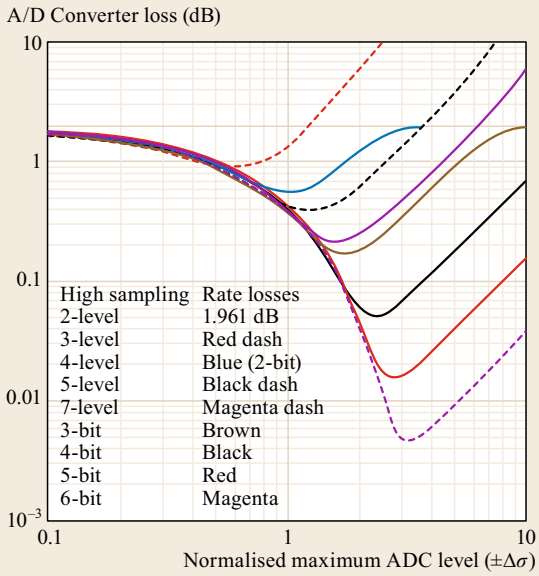

**Fig. 13.16** Losses in A/D converters with linear weighting (after [13.41])

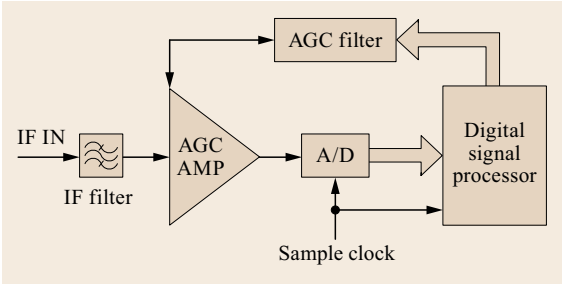

**Fig. 13.17** AGC control circuit (after [13.12])

for the case that no level at zero is present, that is, 1 bit, 2 bit, 3 bit.

### Automatic Gain Control

In receivers with multibit ADC implementation, the dynamic range of the signal has to be controlled. The goal is that the signal amplitude is conditioned in such a way that the amplitude range falls on average between maximum and minimum thresholds of the ADC. This signal conditioning is obtained by the integration of an amplifier with a variable gain, the so-called automatic gain control (AGC), into the front end (Fig. 13.17). The AGC is driven in a closed-loop feedback control circuit. Some type of measure is needed in the digital domain after the ADC. The measure may be processed when feedback steered the AGC amplifier. Usually, the root-mean-square noise power amplitude is measured and fedback. Monitored AGC levels can be used to detect interference on the GNSS signal.

## 13.2.4 Oscillators

A GNSS receiver tracks the carrier and code phase of the received signal in reference to the receiver's local oscillator. If either the satellite oscillator or the receiver oscillator shows excessive phase noise, the signal-processing performance of the PLL and DLL with very low cost performance crystal oscillators (CXOs) may be degraded. Concerning phase noise, the PLL is the most critical element, because a replica of the carrier frequency has to be stabilized in the first RF stages, which is at least a factor of 100 larger than the code-chipping rate in comon GNSS signals. For some receiver operations which require a long-term clock stability, atomic clock technology on chip scale is available since 2008. A miniaturized cesium oscillator called the chip scale atomic clock was developed by Symmetricom [13.45].

The basic types of oscillators used in today's GNSS receivers and their key properties are briefly discussed in this section. For a more comprehensive discussion of time and frequency standards, the readers are referred to Chap. 5 of this Handbook.

### Crystal Oscillators

CXOs use a piece of deformable quartz to generate a precise mechanical oscillation which, at the same time, is converted into an electrical signal. CXOs are built on the principle of the piezoelectric effect. The electrical field interacts with the quartz element and induces mechanical oscillations which can be measured by a pick-off. Because of the mechanical oscillation, a CXO can also be understood as a micromechanical proof mass, which is sensitive to g-load and linear vibration spectra.

Several design versions of CXOs are available (Fig. 13.18). The simplest devices are the low-end crystal oscillators which are used in wrist watches. They provide stability down to $10^{-5}$ over 1 s. Very important for GNSS receivers are the temperature-compensated crystal oscillators (TCXOs). TCXOs can be produced with the help of a low-cost industrial process. Because their temperature-dependent drift is corrected by a calibration model on the software level and the available performance is between $10^{-6}$ and $10^{-8}$ which is sufficient for GNSS receiver signal processing and local clock generation. Higher performance CXOs are also available. In order to get rid of the temperature-dependent drift, the approach is here to install the crystal in an oven. This will provide a very well defined thermal environment. Such crystals are called ovenized crystal oscillators (OCXOs). On the short-term (1 s) scale, theses OCXOs could provide stabilities like rubidium clocks down to $10^{-13}$. However, cost, linear dimension, and power consumption prevent the use of OCXOs in commercial GNSS receivers. They are used in special applications, for example, in GNSS reference stations to provide a more precise standalone time and frequency reference.

The relative stability of a frequency source is characterized by [13.46]

$$y = \frac{\delta f}{f} , \tag{13.23}$$

where $y$ is the fractional frequency stability, $\delta f$ is frequency error or jitters, and $f$ is the nominal frequency to be generated. Frequency stability is not a static measure, but it depends on the application time interval (short term versus long term) on the temperature during operation and on the applied acceleration ($g$-load).

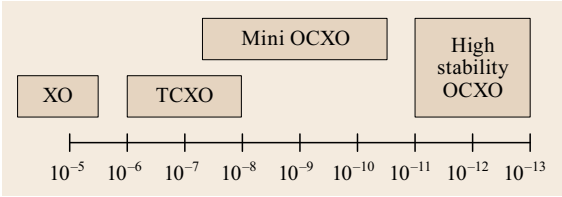

**Fig. 13.18** Overview on crystal oscillator technologies for the short term (< 1 s)

The temperature-dependent frequency error may be described by a polynomial

$$\frac{\delta f}{f} = a + b(T - T_0) + c(T - T_0)^2 , \tag{13.24}$$

with $T$ denoting the actual temperature, $a$ the bias error, $b$ the linear temperature-dependent term, $c$ the quadratic temperature-dependent term, and $T_0$ the reference temperature, for example, for a laboratory calibration. A typical value for temperature sensitivity of a CXO could have a magnitude of $b = 10^{-5}$–$10^{-6}\,\mathrm{K}^{-1}$ for a specified range of $-40\,^\circ\mathrm{C} \le T \le 80\,^\circ\mathrm{C}$.

Another error term, called the $g$-sensitivity of the crystal, is dependent on the applied acceleration along a sensitive axis of the CXO [13.47]. The error equation is of the form

$$\frac{\delta f}{f} = K\frac{a}{g} . \tag{13.25}$$

The $K$-factor describes the sensitivity to acceleration $a$ and $g$ is the gravity acceleration at the Earth surface which is used for normalization in this equation. CXOs for low dynamics ($K = 10^{-8}$) and high dynamics ($K = 10^{-10}$) environments are available [13.47].

Besides these systematic errors, a CXO also shows significant stochastic errors [13.46] which could impair the signal processing in a GNSS receiver.

The consequence of this oscillator phase and frequency noise is that, in a more detailed analysis, the clock error is not really a bias, but a filtered stochastic process and has to be considered with specific dynamics and statistical properties. As a rule of thumb, it is assumed that the clock problem is solved by estimating the clock bias in the absolute or differential navigation solution. This is not really the case, when working with low-cost performance crystals, performing applications in high dynamics and heavy vibration environments, and doing high-precision carrier-phase processing by use of surveying-type receivers. The effect of oscillator phase noise leads to PLL-tracking errors, and if it gets excessive, even to cycle-slips and loss-of-lock.

The variance of frequency stability $y$, the so-called *Allan* variance [13.46], is given by the expression

$$\sigma_y^2(\tau) = \mathrm{Var}\left(\frac{\delta f}{f}\right)_\tau , \tag{13.26}$$

where $\tau$ is the time constant for performing an average of $y$ by low-pass filtering or integration.

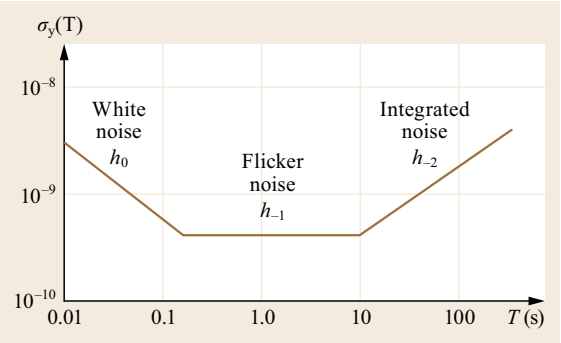

**Fig. 13.19** Allan variance pattern as a function of averaging time

**Table 13.1** Typical Allan variance parameters for different frequency sources (after [13.48])

| Frequency source | White noise $h_0$ (s) | Flicker noise $h_{-1}$ (-) | Integrated noise $h_{-2}$ ($s^{-1}$) |
|---|---|---|---|
| TCXO | $10^{-21}$ | $10^{-20}$ | $2\cdot10^{-20}$ |
| OCXO | $2.5\cdot10^{-26}$ | $2.5\cdot10^{-23}$ | $2.5\cdot10^{-22}$ |
| Rubidium | $10^{-23}$ | $10^{-22}$ | $1.3\cdot10^{-26}$ |
| Cesium | $2\cdot10^{-20}$ | $7\cdot10^{-23}$ | $4\cdot10^{-29}$ |

In a more explicit form, the Allan variance is given as

$$\sigma_y^2(\tau) = \frac{h_0}{2\tau} + 2\ln(2)h_{-1} + \frac{2\pi^2}{3}\tau h_{-2}\,, \tag{13.27}$$

where $h_0$, $h_{-1}$, and $h_{-2}$ represent individual noise contributions that dominate the stability of a frequency source at specific time scales (Fig. 13.19). Typical values of the Allan variance parameters for common oscillator types are collated in Table 13.1.

The power spectral density of the Allan variance, which is of importance in the following analysis, is commonly represented by [13.49]

$$S_y(\omega) = h_0 + \frac{h_{-1}}{\omega} + \frac{h_{-2}}{\omega^2} \tag{13.28}$$

or

$$S_{f_0}(\omega) = 4\pi^2 f_0^2\left(h_0 + \frac{h_{-1}}{\omega} + \frac{h_{-2}}{\omega^2}\right)\,. \tag{13.29}$$

The latter expression already considers the fact that we have to synthesize a reference frequency $f_0$ in a GNSS receiver for the carrier and code. In order to arrive at the carrier and code level, the frequency expression has to be integrated

$$S_\phi(\omega) = \frac{S_{f_0}}{\omega^2}\,. \tag{13.30}$$

Because the GNSS user is interested in the $1\sigma$ phase error in radians, the impact of the loop filter has to be considered

$$\sigma_\phi^2 = \frac{1}{2\pi}\int_0^\infty S_\phi(\omega)|1-H(\omega)|^2 \mathrm{d}\omega\,, \tag{13.31}$$

where $H(\omega)$ is the transfer function of the loop. This means, the Allan variance power spectral density contributes only to the phase-tracking errors, which are outside the passband of the loop filter (ideal filter assumed). In the case of a second-order loop, that is,

$$|1-H(\omega)|^2 = \frac{\omega^4}{\omega_\mathrm{L}^4+\omega^4}\,, \tag{13.32}$$

the phase-tracking error caused by Allan noise in the steady state is obtained as

$$\begin{aligned}\sigma_\phi^2 = {} & 2\pi f_0^2 h_0 \int_0^\infty \frac{\omega^2}{\omega_\mathrm{L}^4+\omega^4}\mathrm{d}\omega \\ & + 2\pi f_0^2 h_{-1}\int_0^\infty \frac{\omega}{\omega_\mathrm{L}^4+\omega^4}\mathrm{d}\omega \\ & + 2\pi f_0^2 h_{-2}\int_0^\infty \frac{1}{\omega_\mathrm{L}^4+\omega^4}\mathrm{d}\omega\,,\end{aligned} \tag{13.33}$$

where $\omega \approx 1.9B_\mathrm{L}$ (at a loop-damping factor $\xi = 0.707$) and $B_\mathrm{L}$ is the single-sided noise bandwidth of the loop. Evaluation of the integrals leads to the following expression [13.49]

$$\sigma_\phi^2 = 2\pi^2 f_0^2\left(\frac{\pi^2 h_{-2}}{\sqrt{2}\,\omega_\mathrm{L}^3} + \frac{\pi h_{-1}}{4\omega_\mathrm{L}^2} + \frac{h_0}{4\sqrt{2}\omega_\mathrm{L}}\right)\,. \tag{13.34}$$

The second effect is the induced phase noise on the CXO caused by vibrations of the user platform. The final phase noise-tracking error depends on the $g$-sensitivity of the oscillator and the power spectral density of the vibrations. For this case, the expression is of the form

$$\sigma_\phi^2 = 2\pi f_0^2 k_\mathrm{g}^2 \int_0^\infty G_g(\omega)\frac{\omega^2}{\omega_\mathrm{L}^4+\omega^4}\,\mathrm{d}\omega\,, \tag{13.35}$$

where $k_\mathrm{g}$ denotes the g-sensitivity of the oscillator and $G_\mathrm{g}(\omega)$ is the single-sided vibration power spectral density (measured in units of $\mathrm{g}^2/(\mathrm{rad/s})$). Representative

g-sensitivity values are given by

$$k_g = \begin{cases} 1 \cdot 10^{-9}\,\mathrm{g}^{-1} & \text{low dynamics receiver ,} \\ 3 \cdot 10^{-10}\,\mathrm{g}^{-1} & \text{high dynamics receiver .} \end{cases} \tag{13.36}$$

In this case, an analysis is difficult to perform, because the result depends heavily on the vibration spectrum under which the user has to operate on a specific platform or vehicle. In harsh dynamic environments, the tracking error caused by vibrations can become significant, again with the consequence that loss of lock can occur.

#### Chip-Scale Atomic Clock (CSAC)

Besides crystal oscillators chip-scale atomic clocks (CSACs) are commercially available. The CSAC technology was developed in a Defense Advanced Research Projects Agency (DARPA) program in several project phases in 2001. The production started in 2008. The highly portable atomic clock consists of a physics package including the cesium cell, shielding, and a lid. The system elements are integrated on a printed circuit board (PCB). Currently [13.45], the size is about $4.0 \times 3.6 \times 1.3\,\mathrm{cm}^3$, the weight is 0.035 kg, and the power consumption is 120 mW while in operation. The cesium atoms are excited by a laser beam of a vertical-cavity surface-emitting laser (VCEL). The laser output signal (the resonant line) is detected by a photodiode. The stability of the clock in terms of Allan deviation is $1.5 \cdot 10^{-10}$ over 1 s and $5 \cdot 10^{-12}$ over 1000 s which outperforms a typical TCXO. An additional advantage is the low sensitivity with respect to acceleration and vibration levels in comparison to a CXO. The temperature sensitivity is less than $5 \cdot 10^{-10}$ over the entire operating temperature range (−10 °C to +70 °C). A low (about $10^{-10}$) sensitivity concerning input voltage variations and applied magnetic fields can be observed. CSAC technology will evolve to a smaller size, lower power consumption, and lower cost. The advantage of CSAC technology as a frequency source for GNSS receivers is due to the ability to acquire or re-acquire even longer codes with a short time-to-first-fix (TTFF) based on a very stable time scale. Because of lower phase noise in the tracking loops, it allows for longer integration times (coherent integrations) in signal processing. Because of its precision, a CSAC can be used for clock-coasting to substitute for the clock-error term in the estimation filter. A lower number of visible satellites are required in such a case.

### 13.2.5 Chip Technologies

In miniaturization and integration of GNSS receivers, the state of chip technologies plays an important role. Mainly the form factor, the power consumption, and production cost of a receiver depend on the current state of semiconductor technology and the semiconductor processes which can be applied. In a GNSS receiver, chip technologies are used in the RF domain, in the SPU, and in the navigation processing unit (NPU). Additionally, memory units, like read-only memory (ROM) and random access memory (RAM), and (if applicable) cryptographic units depend on microchip designs. The degree of very large scale integration (VLSI) decides on the use of the GNSS function in mass market devices, that is, in mobile phones, personal digital assistants (PDAs), automotive systems.

The development trend in VLSI GNSS chips is worthwhile to consider: even in the GNSS, mass market domain chip technology is lagging behind the leading-edge semiconductor development by 2–3 innovation cycles or technology nodes. The reason is that the market size of GNSS receivers is significantly lower than the market size of systems like PCs, mobile computing and communication devices. According to Intel, one billion devices like notebooks were used in the portable PC market in 2005. The forecast for 2015 for various ways of ubiquitous computing is above 10 billion units. In comparison to this, about 6 billion mobile communication devices are on the market [13.50]. About 1 billion civil GPS C/A-code chips are in use today (2013). Clearly, the non-GNSS information technology markets drive the development efforts in chip complexity (> 50 million transistors per die) and the minimum feature size down, for example, to 22 nm (Intel Atom) processor [13.50]. Another problem area exists for VLSI chip integration in the area of, for example, military receivers which have to fulfill higher military specifications (MIL-SPECs). Because with the decreasing feature size, only a few international foundries are able to produce the leading edge $SiO_2$-integrated circuits. The investment in these foundries is getting more and more expensive, for example, because of more advanced lithographic tools [13.51] and larger diameter wafer-processing facilities. It gets difficult for semiconductor companies in the defense sector to keep their pace. This has led to the interesting situation that in terms of high integration mass market products are outperforming silicon integration in the military receivers.

The basic functional silicon element is called a die (or sometimes called the bare chip). Because of packaging and pins, a die is only a fraction of a chip. It is diced out of the wafer. On a chip, there could be many dies with different functions. Sometimes such systems are called systems-on-a-chip (SoC).

#### Digital Chip Technologies

The processing requirement (based on experience) of a six-channel GPS C/A-code receiver is of the or-

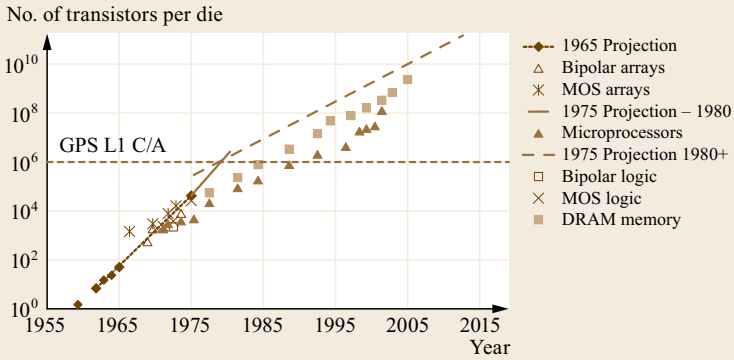

**Fig. 13.20** Complexity (number of transistors per die) of MP and memory (after [13.51], courtesy of the Institute of Electrical and Electronics Engineers (IEEE))

der of 80–100 MIPS. In information technology, it is questioned if the parameters MIPS (mega instructions per second) for measuring processing power are adequate. However, we will use it here to define orders of magnitude. For a processing power of 100 MIPS, an equivalent of one million transistors on a $SiO_2$ die are needed. Interestingly, these values hold for an Intel 486 up to an Intel Pentium PC processor. Since these processor generations were available, it was possible to implement the signal processing for the C/A-code on a PC (software receiver).

The dramatic progress of semiconductor technology in digital chips is always referred to *Moore's law*. Gordon E. Moore was a pioneer in early integrated circuit development working for Fairchild Semiconductors. In 1968, he had been a co-founder of Intel. He observed that every 2 years the number of components on a silicon area doubled (Fig. 13.20) and that the overall processor power increases in a similar manner (Fig. 13.21). In 1965, he published his work known as *Moore's Law* and gave a forecast over the next 10 years. Around 1975 [13.51], the rate of integration complexity slowed down. The reason was that in the first phase it was tried to make use of wasted area on the silicon chip. This possibility was exhausted around the mid-1970s. It is clear that Moore's law is an empirical rule. It was gained by several factors: leading manufactures like Intel tried to keep close to it, competitive manufactures did the same, and the semiconductor design tools were developed with respect to Moore's target.

Since a decade a discussion has taken place about when *Moore's law* will finally end. There is evidence that it will end, because circuits cannot get smaller than atoms, lithographic techniques become more and more critical because the structures get smaller than the wavelength of light, quantum effects get more and more pronounced with finer structures. However, several opportunities exist [13.52] to shift the limit: diversification (power and polymer electronics) and performance enhancement (multicore processing, photonics, graphene transistors).

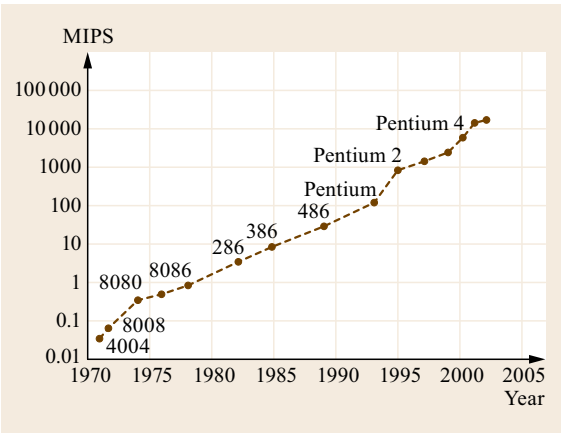

**Fig. 13.21** Growing processor performance (after [13.51], courtesy of IEEE)

Based on the discussion of Intel [13.33] and the semiconductor community, the prediction is the following: Moore's law will continue up to 2015+ and the size of structures will be reduced by a factor of 2 every 6 years (Fig. 13.22).

The width of smallest structures achieved was 65 nm in the year 2005 and 22 nm in the year 2011. The latter is 2013 in production for PC processors. Research [13.33] for the upcoming years 2015+ will be in the area of 10 nm, 7 nm, 5 nm where lithography, interconnections, materials, and other improvement areas are investigated.

A further element of Moore's law is that the semiconductor complexity (number of transistors) will increase by a factor of 4 every 6 years, processing performance increase by a factor of 150 at the same power consumption level until 2015+. The cost per transistor is halved every 2 years.

The same processing performance at decreasing power consumption will be obtained: for a GNSS dig-

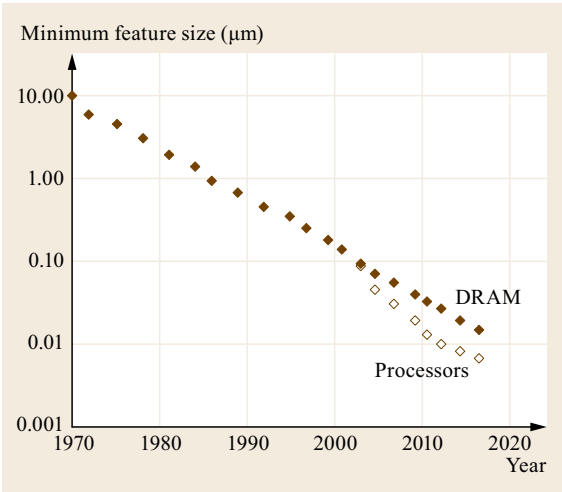

**Fig. 13.22** Decreasing minimum feature size in μm (after [13.51], courtesy of IEEE)

ital chip, this could mean that today 100 MIPS will consume 100 mW and in 2015+ 100 MIPS will consume 1 mW only.

### RF Chip Technologies

The RF semiconductor technology and its future development is a driver for the front-end architectures. Moreover, many new integrated or low-cost applications became only possible by means of RF chips. The current development tendency is toward lower power consumption, while integrating RF parts and enabling multifunctional operations.

As outlined before, digital electronics is governed by Moore's law. In the digital domain, the integration of a high number of transistors on a chip is important. Electrically, the silicon (tri-gate) metal oxide field effect transistor (MOSFET) is dominant. In semiconductor-based RF electronics Moores's law and VLSI are less important. Historically, RF semiconductors were developed till the 1980s for military systems like radars. Based on the hype in the field of mobile communication around 1990, the RF chips market moved clearly for various consumer applications.

The main requirement on an RF transistor is its fast reaction on a change of the input signal [13.53]. The two basic areas to achieve this are transistor design and selection of the suitable semiconductor material. Nowadays, RF transistors are used in a range between 0.5 and 100 GHz. In general, two [13.53] basic transistor concepts have been developed. The field-effect transistor (FET) and the bipolar transistor (BT). In an FET, the output current (drift current) is controlled by an orthogonal field. Conductivity is controlled by the potential of the gate. Three types of FETs are known [13.53]: metal–semiconductor FET (MESFET), high electron mobility transistor (HEMT), and metal–oxide semiconductor FET (MOSFET). In bipolar transistors, the output current is controlled by voltage across the p–n junction. Two types [13.53] have been developed. The bipolar junction transistor (BJT) and the hetero junction bipolar transistor (HBT). The performance [13.53] of the RF transistor is described by their ability to amplify, gain, frequency limits, output power and minimum noise figure (Table 13.2). For GNSS receivers, the noise figure $F$ of the LNA is important. Additionally, the power consumption of the RF chip and its production costs are relevant.

It should be outlined that the noise figures $F$ presented in the table refer to a single transistor. Because in an LNA, several transistors are integrated, the total noise figure could be higher. The following materials are considered: iridium phosphide (InP), silicon (Si), gallium arsenide (GaAs), and silicon germanium (SiGe). The physical gate length in a microwave silicon ASIC was in the year 2001 on a level of 90 nm and in the year 2016 it will be 11 nm.

Complementary metal oxide semiconductor (CMOS) is the cheapest and widely used silicon semiconductor process to develop digital, that is, logic chips. In CMOS, p-channel and n-channel MOSFETs are used on a common substrate. RF CMOS chips support frequencies up to 3 GHz which is more than sufficient for GNSS LNAs in L-band. For low-end single-chip integrations, RF-CMOS is important because digital functions and RF functions can be integrated within the same semiconductor process.

### Digital Signal-Processing Units

The digital SPU is traditionally decomposed into different processors (Fig. 13.23). The reason for this hybrid architecture is that we need, on the one hand, very fast parallel operations to be applied on the fast data stream which is output by the ADC. The ADC output data rate can be on multiple 10 MHz level depending on the bandwidth of the signal, receiver, and the applied sampling rate. On the other hand, we have to process signals of medium speed like the integration and dump data (output of the correlators) which are typically less than

**Table 13.2** Minimum noise figures $F$ for different RF transistor materials (after [13.53])

| Transistor type | $F$ (dB) at 2 GHz | $F$ (dB) at 5 GHz |
|---|---|---|
| InP HBT | 0.4 | 1.1 |
| Si BJT | 0.8 | 1.2 |
| GaAs HBT | 0.9 | 1.2 |
| SiGe HBT | 0.1 | 0.5 |
| GaAS MESFET | 0.1 | 0.2 |

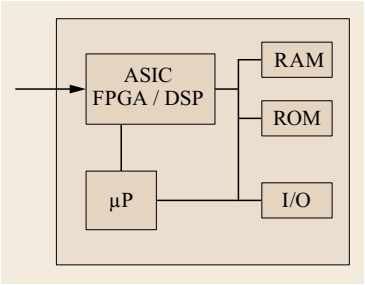

**Fig. 13.23** Generic structure of digital GNSS receiver section

the kHz level. Additionally, we have signals with low speed such as the tracking loop processing (< 100 Hz) and navigation processing (< 10 Hz). Besides data rate consideration, the complexity of mathematical functions and the necessary instruction set are also issues.

The generic standard partitioning of the SPU is to implement the fast (and more elementary operations) process on a digital signal processor (DSP) (Table 13.3). The DSP could be augmented by one or several embedded field programmable gate arrays (FPGAs). An FPGA can be re-programmed and, thus, allows for a higher flexibility. However, it is expensive and power consumption is significant. Instead of the FPGA, an ASIC can be used, which is the cheapest way to implement the digital signal processing logics but it is only reconfigurable in a limited way. Additionally, an MP or core processing unit (CPU) is always present in the SPU. The MP (µP) is controlling the entire SPU and the input/output (I/O) functions. In a software receiver, it is tried to comprise all processing functions in software running on a general purpose computer.

A DSP is, in principle, a specialized MP adapted to the typical requirements of fast real-time digital signal processing like digital filtering or fast Fourier transform (FFT) computation. A standard application is the ability to process correctly and with high data throughput *fast multiply and accumulate* (*MAC*) functions like finite impulse response filters (FIR) with many coefficients $\alpha_k$

$$y_k = \sum_{k=0}^{m} \alpha_k x_{-k} \qquad (13.37)$$

The providers of DSPs are limited. The big players are Texas Instruments (TI), Analog Devices (ADI), and Freescale (formerly Motorola). A DSP that has been used from the beginning on in GNSS receivers is the Texas Instruments TMS320 family [13.55]. Over the years, many generations and variants were available. These DSPs provide a processing power between 60 and 2000 MIPS, make use of a 24 bit fixed point or 32 bit floating-point architecture, and provide standard functions for digital filtering. The TMS320 can be programmed in C, C++, and Assembler.

**Table 13.3** Partitioning of GNSS receiver processing (after [13.54])

| Processing task | Processing hardware |
|---|---|
| Autocorrelation | ASIC/FPGA/DSP (CPU) |
| Acquisition | DSP/CPU |
| Tracking | DSP/FPGA/CPU |
| Navigation | CPU (DSP) |

On the CPU side, some GNSS receivers make use of ARM processor chips. ARM stands for the advanced reduced instruction set (RISC) machines [13.56]. From the beginning, in the early 1980s, eight versions of ARM processors have been developed. ARM version 6 and later provide a clock rate of 750–2000 MHz, a 32/64 bit architecture and a computational performance between 60 and 180 MIPS.

General purpose machines (GM), which have been used for the building of software receivers, belong in many cases to the PC processor family like Intel Core 2 (e.g., use of the Lippert Toucan board, 2 GHz CPU clock rate, 40 W power consumption). Other high-end options are the use of the 3.2 GHz cell broadband engine which is said to have a higher processor speed (factor 30 in comparison to Core 2). The cell broadband engine is used in the PLAYSTATION 3 but is a candidate for future software receivers.

### GNSS Receiver Integration Levels

Apart from functional solutions, several architectural concepts can be applied for the receiver implementation (Table 13.4). The architectural design used depends mainly on the target of the development (prototyping, geodetic receiver, chip-set, single chip), on the available investment budget and last but not least on the time schedule for the development. Higher integration has several advantages [13.57]: smaller form factor by reducing the number and size of parts, higher reliability by removing solder points of pins, lower power by removing the resistance of pins and electrical circuits, and reduced production cost in the application of semiconductor manufacturing. Higher integration will improve digital performance because of shorter electrical lines and higher processing speeds. However, in higher integration, interference between the RF and digital section can become an issue.

The individual architectures are briefly described below:

- *Discrete printed circuit board* (PCB) *design*: This architecture requires the largest area and the highest number of parts but allows for the use of high-performance discrete devices. Having the least initial production costs, it is very suitable for low- or medium-size productions. It is the technology

**Table 13.4** Receiver integration levels (after [13.57])

| Integration level | Architecture | Technologies | Relative R and D cost | Market |
|---|---|---|---|---|
| Separate LNA/RF/ASIC/μP | Discrete PCB | GaAs, SiGe, Bipolar Si, CMOS | 1 | High-precision, scientific applications |
| (LNA+RF)/ASIC/μP | Hybrid MMIC or RF Chip PCB | GaAs, SiGe, Bipolar Si, CMOS | 1.5–2 | High-end, surveying, aviation |
| (LNA+RF)/(ASIC+μP) | Dual chip PCB | Bipolar Si, SiGe, CMOS | 3–4 | Low-end, handhelds, cars |
| (LNA+RF+ASIC+μP) | Single chip | CMOS | 6–10 | Ultimate mass market, E-911 |

for prototyping and early bread-boarding receivers. LNA and RF filter are usually integrated together in the L-band antenna.

- *Hybrid monolithic microwave integrated circuit* (MMIC): This can be seen as a merge between the discrete PCB and chip-set design for medium-size production. This approach was used in surveying type of receivers in the 1990s by employing high-performance front ends (multiple step down-converters).
- *Dual chip design on PCB*: This architecture is based on an integrated RF chip and on an integrated digital chip. This chip-set will result in lower size, power consumption and price at the expense of higher initial costs and, therefore, is only applicable to consumer market applications, where highest integration and extremely low-power consumption is not a driver. Usually, simplified front-end techniques (single-step to baseband) are used.
- *Receiver single-chip integration*: Integration of the RF unit and the SPU into a single chip results in the cheapest (production cost) and smallest solution with the lowest power consumption. Because of the very high initial cost, for example, for a semiconductor design in 65 nm CMOS, the single-chip solution is only applicable to ultimate mass market. The key for the implementation of a single-chip receiver is that the semiconductor process (low-cost CMOS) for the RF part is the same as for the digital part.
- *Multifunctional chips*: Sharing the chip area with other functional elements like the communication channel. In future, it could be the dominant technology in mass market applications.

### 13.2.6 Implementation Issues

From the previous section, it became clear that a GNSS receiver is more or less a high-speed calculating machine. Thus, the classification of a receiver as a hardware receiver or a software-defined receiver has mainly to do with the kind of processing architecture which is used. The signal-processing logics and data flow to be handled are the same for all the different processing architectures. The signal structure to be processed is defined in the respective interface control documents (ICDs). We will briefly discuss the advantages and disadvantages of the three main processing architectures:

- *Software-defined radio based on a general purpose machine*: The advantages are the use of a fully programmable MP, that is, no hardwired silicon is used. The general purpose machine (GM), like PC-based MP, or DSP is accomplishing all the digital signal and navigation processing and is highly reprogrammable by use of higher programming languages, for example, C/C++. The software receiver was in its early stage a research project pursued by some universities. The rationale for industry to keep this development in focus is that modern portable navigation device (PNDs) will have in future even faster and more powerful CPUs and larger memory. Using a single CPU will help to reduce the number of different chips in PNDs.
  The disadvantages of the software receiver are that the processing load on the GM is highly critical, and also the power consumption is high. Because of the GM board, the resulting system is form-factor intensive. Software testing and validation is also a tremendous issue. It seems to be clear that the GM-based software receiver will penetrate the high-end market of hardware GNSS receivers like reference stations because these applications are independent of form factor and power-consumption requirements.
- *Software-defined radio based on FPGA*: The typical baseband processor in this configuration is based on the partitioning of functions on two processing cores: CPU and FPGA. Both elements are integrated on the same PCB and communicate together. Fast operations are done on the FPGA, whereas lower speed operations and system control are done on the CPU.
  The advantages here are that re-programmability leads to a configurable receiver architecture and re-

duced development costs because of easy bug fixing by afterward software update capability.
The disadvantages lie in the relatively high production cost (> 2000 US $ procurement cost for the bare FPGA board), especially for large and multiple FPGAs on a single board. Additionally, special software development tools (e.g., Verilog/VHDL, Handel-C) are necessary. The board size determines the form factor of the receiver. Also, relatively high power consumption depending on the number of CPUs and FPGAs and digital clock rate could result.

- *Hardware-defined based on ASIC*: In a hardware receiver, the code replica generation, the mixing with the trigonometric reference signals (early, punctual, late), and the integration and dump operations for a bank of, for example, 12 channels are conventionally implemented in a hard-wired logic on an ASIC.
The advantages of the ASIC approach are low production cost for silicon (CMOS) in very large volumes. The power consumption of highly integrated semiconductors is the lowest option available for GNSS receivers. Large-scale integration leads also to a small form factor.
The major disadvantages are low flexibility because of the fixed and hardwired chip design. If new navigation signals are transmitted and/or signal designs are modified, the chip is not usually adaptable to such changes and the receiver, has to be bought anew. For mass market receivers this is not posing a big issue because the innovation cycle is only several years, for example, in mobile phones. For more expensive hardware-based receivers (like surveying and military receivers), the not reconfigurable ASICs are an issue. Usually, backward compatibility is expected in the case of new signal structures. A certain way out of the problem is to use a DSP besides the ASIC and to attribute some functions on the DSP. Again for ASIC design, special development tools, for example, hardware development languages (HDLs), are necessary. High development cost due to additional chip runs in the case of bug fixing or architecture changes could result. The development and design costs for a VLSI chip are the highest in comparison to other implementation schemes.

The three basic implementation schemes which were described may be compared with each other in terms of power efficiency and area efficiency (Table 13.5; [13.54]). MOPS means mega operations per second and area refers to the chip area necessary to provide the required complexity for the provision of the processing power envisaged. It is notable that between a general purpose software receiver processor and an ASIC, a disadvantage of $10^4$ exists in power efficiency. The area efficiency of an ASIC is by a factor of about $10^5$ superior in comparison to a general purpose machine. It follows from this that PC, ASIC, FPGA solutions are justified solutions, but we have to be clearly aware of their advantages and disadvantages. It is a naive thinking that Moore's law will solve all the processing problems: if PC processors get better by using higher integrated CMOS, the same will hold for ASICs. Thus, to assume that a competition exists between software- and hardware-based receivers, in all the market segments is not a very valid assumption. For pure software receivers a growing niche market may be identified at the high end, in prototyping and research applications.

## 13.3 Multifrequency and Multisystem Receivers

In the former, the subsystems of a GNSS receiver were described in a more generic way. No effort was made, besides the discussion of front-end group delay, to look into architectures which make use of multifrequency and multisystem GNSS. Using more systems and more frequencies will lead to higher complexity: multifrequency antenna and front end, more complex frequency plans, faster ADC data streams, and higher parallel processing power requirements on the SPU because of more parallel channels. In this section, we intend to briefly present the major design characteristics for a GNSS receiver in the context of GPS modernization, Galileo, GLONASS, and BeiDou development.

### 13.3.1 Civil Receivers for GPS Modernization

#### Considerations for L2 Civil Signal

With the launch of the GPS Block IIR-M satellites (since 2003), the L2 civil signal (L2CS), which is the second civil GPS frequency in the context of GPS modernization, is transmitted. The detailed design of the signal was initially described in the ICD-GPS-200D. The spectral characteristics of L2CS are not so different from the C/A-code on L1. In general, the L2CS is generated through chip-by-chip multiplexing of a code of medium length (CM: 10.230 chips, period of 20 ms) and a long code (CL: 767.250 chips, period of 1.5 s). Longer codes are used in comparison to the C/A-code

**Table 13.5** Power efficiency and area efficiency of different receiver implementations (after [13.54])

| Receiver type | Platform | Characteristic | Power efficiency | Area efficiency |
|---|---|---|---|---|
| Software defined | PC or DSP | Programmable | 10 mW/MOPS | 1 MOPS/mm$^2$ |
| Software defined | FPGA | Reconfigurable | 0.1 mW/MOPS | 100 MOPS/mm$^2$ |
| Hardware defined | ASIC | Dedicated | 0.001 mW/MOPS | $10^5$ MOPS/mm$^2$ |

in order to reduce cross-correlation between different codes. The final chipping rate after multiplexing is 1.023Mc/s as in the L1 C/A-code case.

Thus, an L2CS receiver channel is very similar to an L1 C/A-code receiver. In general, the same front-end concept may be used in terms of filtering and bandwidth as in a C/A-code receiver. However, a synthesizer at L2 = 1227.6 MHz and a respective down converter to a reasonable IF (or the same IF as used for L1) is necessary. The main challenge for the implementation of the L2CS lies in the digital domain. The direct acquisition of the long code (CL) seems to be impractical without a precise GPS time estimate of the receiver [13.58]. Therefore, a pre-acquisition of the C/A-code L1 and/or the moderate-length code (CM) L2 with the subsequent handover of timing and frequency information seems to be reasonable. As outlined in [13.58], three implementation options exist:

- CM only for signal tracking and data demodulation
- CL only for signal tracking and CM for data demodulation
- Use of both CM and CL in a combined mode to track CL for the ranging signal and CM for data demodulation.

Another focus could be the implementation of long coherent integration (over 1.5 s or multiples of it) during autocorrelation processing because of the data-less CL channel property. Extremely long coherent integration poses higher requirements on the oscillator phase noise (oscillator quality), because the phase changes during the integration interval. The same holds for signal dynamics (motion of receiver): loop aiding from the CM tracker could be necessary. In principle, the L2CS has the ability to replace the semicodeless P(Y) techniques in high-end receiver integrations after December, 2020. Beyond this date, no further guarantee for the P(Y)-code is given by the US government. The GPS-ICD-200 published the signal design for the P-code, but no guarantee was given for codeless and semicodeless techniques.

### Considerations for L5 Frequency

The third civil frequency in the GPS modernization program is the L5 signal which was mainly intended to support safety-of-life applications in aviation and other similar fields. The L5 signal design is described in the ICD-GPS-705 in detail. It was firstly transmitted with the launch of the Block IIF satellites beginning in May, 2010 and will be transmitted from the GPS III constellation. The signal is transmitted in L-band on L5 = 1176.45 MHz in a bandwidth of about 24 MHz and has a chipping rate of 10.23 Mc/s. Some additional features which are important for L5 receiver implementation are that besides the spreading code a secondary Neuman–Hoffman (NH) code is used. The concept is to achieve better cross-correlation properties by increasing slightly the spectral line spacing of the periodic spreading codes. Additionally, a QPSK modulation is basically used, where the Q-channel is again a data-less channel, and, in the I-channel, navigation data (L5 data message) is present. The navigation data is forward error correction (FEC) coded to a rate of 100 sbs (symbols per second). A 24 bit cyclic redundant code (CRC-24) is added to the navigation data.

The main issue comes from the fact that the L5 signal is collocated with other civil and military signals namely distance measurement equipment (DME), tactical air navigation (TACAN) and joint tactical information distribution system (JTIDS) together with the multifunctional information distribution system (MIDS) and near-band radars. These signals cause pulse type interference for the L5 receiver channel. Civil C/A-code receivers are not designed to work in pulse-type interference environments. However, in future GNSS receivers, the capability to mitigate this type of interference is needed. This holds especially for the new aviation frequencies GPS L5 (and Galileo E5) but may pose a problem also for the wide-band Galileo E6 frequency band, where in some European countries, high-power civil and military radars and amateur TV coexist.

Following [13.58], some major changes in the L5 front end with respect to a GPS L1 C/A receiver have to be made: an RF pulse limiter to provide burn-out protection for RF components in the case of strong pulses, an RF bandpass filter of 20 MHz bandwidth on L5 = 1176.45 MHz, an additional frequency synthesizer and down converter from L5 to IF, and an analog or digital pulse blanker for the suppression of the pulse interference.

The basic change with respect to a conventional front end is the implementation of a pulse detector and pulse blanker into the signal flow between AGC and ADC in the L5 front end (Fig. 13.24).

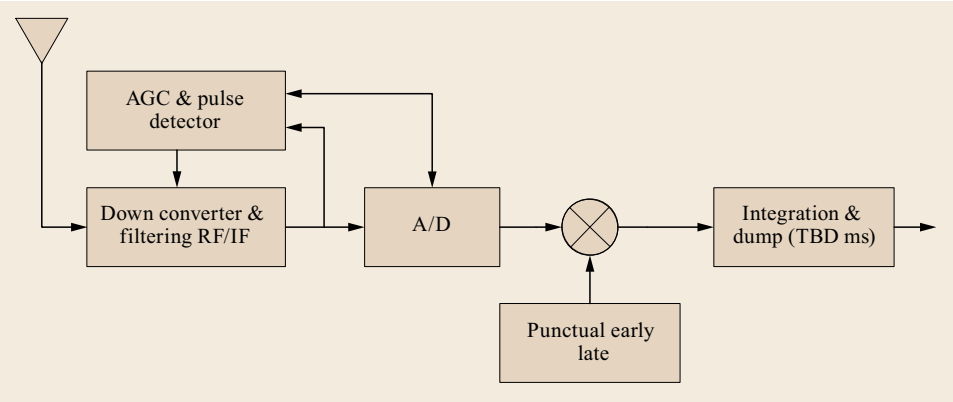

**Fig. 13.24** Pulse blanking receiver architecture (Radio Technical Commission for Aeronautics (RTCA) SC-159 L5 concept)

In general, the effects of pulsed interference on the GNSS receiver can be completely different [13.59], dependent on the characteristics of the interfering pulsed signal (peak, power, duty cycle, pulse duration) and on the receiver implementation (technology and design of front end, AGC, single- or multiple-bit ADC, correlation and tracking software). Depending on their peak power level pulsed interference leads to the following problems in a GNSS receiver:

*Strong pulses* will, on the one hand, saturate the front-end components and, on the other hand, saturate the ADC [13.59]. Typical GNSS receiver front-ends have only a restricted linear region to transfer the antenna power to the quantization result of the ADC. Outside the linear region, the front-end saturates, that is, it is not able to follow higher power variations (will output a constant gain). After a very strong pulses, it could occur that the front end will not recover (or takes long to recover), even if the pulse is zero. Recovery times in the microsecond range are possible for power levels of $> 20$ dB above saturation. A typical value for a commercial front end is 40 ns/dB [13.59]. The front-end behavior in the case of pulses depends to a large extent on the front-end technology used (bipolar transistors, MMIC, RF chip, etc.).

In addition to front-end problems, strong pulses could saturate the ADC, if the signal level is above the maximum threshold. ADC saturation leads to the positive fact that no high-pulse energy enters into the SPU, but the useful GNSS signal is completely lost.

*Weak pulses* are those which will not saturate the front end and the ADC [13.59]. However, they cause degradations in the receiver-tracking performance. Weak pulses add more or less noise $I_0$ to the thermal noise floor. As in the case of narrow- or wide-band interference, the $C/N_0$ is degraded to

$$(C/N_0)_{\text{eff}} = \frac{C}{N_0 + I_0} \,, \tag{13.38}$$

where $I_0$ depends on the power spectral density of the pulsed signal and on the type of correlator. Demodulation of data is also very sensitive [13.59] on the pulse duration, especially for cases of the high symbol rate (small pre-detection integration time relative to pulse duration).

In principle, three solutions to mitigate pulse-type interference are known:

- Pulse clipping: the power above the ADC threshold is removed
- Pulse suppression: the pulse is driven to the noise level with fast ADC and a wide-band front end
- Pulse blanking: pulse is detected in the front end, signal and noise are driven to zero, and ADC generates only zeros.

In any solution, the degradation of the $C/N_0$ will result. Because blanking suppresses the interfering signal but at the same time completely suppresses the thermal noise, it is superior to the other two methods. A pulse blanker may be implemented in a simple analog way (suboptimal) or in a more advanced digital approach (optimal). Analog pulse blanking is done based on power measurements, careful AGC (fast enough) operation, and proper threshold setting of the ADC. Digital implementation requires multiple bit ADC, processing of ADC output levels in real time, and optimal parameter estimation.

The performance in terms of $C/N_0$ of blanking pulse-type interference is given by the expression [13.59]

$$\begin{aligned}(C/N_0)_{\text{eff}} &= 39.5 + 20\,\log(1 - \text{PDC}_\text{B}) \\ &\quad - 10\,\log\left(1 - \text{PDC}_\text{B} + \sum_{i=1}^{N} 10^{\frac{R_i}{10}}\right) \\ R_i &= P_i + 97\,\text{dBm} + 10\,\log(dc_i)\,,\end{aligned} \tag{13.39}$$

where $PDC_B$ is the pulse duty cycle of blanker for strong pulses, $N$ is the number of low-level undesired pulses, $P_i$ is the peak-received power of low-level pulses, and $dc_i$ is the duty cycle of low-level pulses.

### 13.3.2 Galileo Receivers

The architecture of Galileo receivers is basically not too different from GPS receivers. Depending on the target Galileo service (open service, commercial service, public regulated service), the receiver is potentially a single- or a multifrequency wide-band receiver. Aside from the PRS service, it seems to be clear that a Galileo receiver will always make use of a GPS single- or multifrequency implementation. Thus, it will be in most cases not a standalone Galileo but a hybrid GPS/Galileo receiver.

Thus, in implementing the Galileo functions into the RF front end and in the SPU, a basic decision has to be made by the designer about the Galileo services to be used and the frequency bands to be processed. After this decision is taken, the Galileo specific signal processing and data modulation have to be implemented. The RF front-end chain has to be adapted to the bandwidth of the specific Galileo signals. In particular, the bandwidth requirements are very high, if we consider, for example, the AltBOC(15,10) as a unified signal on E5 or the $BOC_{cos}(15,2.5)$ which is the PRS component of the E1. The AltBOC(15,10) has a bandwidth of 50 MHz (the entire signal components are transmitted in a 90 MHz bandwidth) and if this is Nyquist sampled, it will result in an extremely fast digital data stream of $> 100$ Mbit/s (baseband sampling) to be digitized and processed in the SPU. The design of the DLLs and PLLs will be more or less conventional.

A Galileo high-end receiver will potentially make use of several front ends where the RF bandwidth is dependent on the selected signal (E1, E5a+b, E6) combination. As outlined earlier, RF semiconductor technologies are available to build a highly integrated RF unit. New challenges arise mainly in the digital part of the receiver (including the ADC) because of high digital data rates to be processed. Special requirements in the digital domain are the acquisition and processing of various BOC($n$,$m$)-type signals. Open service Galileo receivers will be focused to acquire and process the composite MBOC $= \left(\frac{10}{11}\right)$ BOC(1,1) $+ \left(\frac{1}{11}\right)$ BOC(6,1). Additionally, several data-free carriers (pilot signals) have to be processed. Robust detector designs are necessary to avoid ambiguities which could result from side-lobe tracking of the binary offset carrier (BOC) autocorrelation functions. A basic method is called *bump-jumping* which works with five correlation points. Another new element is the decoding of the various data messages in the Galileo data structure. After frame synchronization on some of the new message types (e.g., F/NAV), de-interleaving, Viterbi decoding, data decryption, and CRC check-sum computation have to be performed. Another issue is to perform hybrid GPS/Galileo positioning making use of the Galileo/GPS time offset (GGTO).

In the Galileo, the coexistence of the E5 and E6 signals with other service signals has to be considered. As in the case of GPS, L5-pulsed interference from DME/TACAN and/or JTIDS/MIDS is to be expected. In some European countries, high-power civil and military pulsing radars are transmitting into the E6 band. Additionally, amateur TV transmissions are locally present. In order to utilize E5 and E6, the techniques of analog or digital pulse blanking and other interference mitigation methodologies have to be implemented.

In a multifrequency GPS/Galileo receiver, ephemeris, positioning, and timing data will be available from many different satellite sources. Simplified acquisition strategies could thus be implemented. If the receiver position, ephemeris data, and clock error are known from, for example, GPS, then Galileo signal search could be skipped by the calculation of the Doppler and code phase from an available GPS navigation solution. If this is not possible, handover to Galileo signal acquisition unit has to be done.

### 13.3.3 GLONASS Receivers

The historical difference between GPS and GLONASS was that GLONASS used an frequency division multiple access (FDMA) scheme in contrary to GPS which uses code division multiple access (CDMA). In the context of GLONASS modernization, it is planned to transmit various CDMA signals (like GLONASS-K1, K2, KM) step by step. The implementation will need several years until 2025+. However, because of obvious backward compatibility issues, the FDMA signals will also be present in future.

The processing of FDMA signals in a receiver on the analog and digital levels has a basic impact on the receiver design and performance [13.60]. In the case of FDMA, the RF front end has a much higher complexity than that of CDMA. The number of components is higher and the frequency synthesizer is much more difficult to implement. The cost and effort of designing the GLONASS RF chip are also higher than that of the single-carrier frequency CDMA. The front end is also the driving factor of the power consumption and the form factor of the receiver. The requirements for the FDMA synthesizer [13.60] are to elaborate an optimal frequency plan, the selection of proper ref-

erence frequency/division ratios, minimize the phase noise penalty, and minimize the number of components at the same time. The integration of GPS and/or Galileo to GLONASS in the receiver adds even more complexity to the synthesizer.

A second problem area is that the designer has to minimize the group delay dispersion in the RF front end (which is present for each individual satellite) by the appropriate design of (band pass) filters which provide small delays without temperature variation. Special calibration loops are necessary for high precision. The presence of differential group delay between GLONASS satellites will degrade the performance of the navigation solution.

### 13.3.4 BeiDou/Compass Receivers

Due to signal characteristics of BeiDou-1 service signals, BeiDou-1 receivers were at least of backpack size, which is not sufficient for handheld versions in comparison to the other two existing systems. However, because of clear similarities in the signal structures of BeiDou-2 and Galileo, the architectural design of a BeiDou-2 receiver became similar to a Galileo receiver. In June 2004, the first generation of handheld BeiDou-2 receivers came out of Taipei by miniaturization of devices.

Similar to GLONASS receivers, the use of a specific reference frame in BeiDou which is different from GPS/Galileo may be a problem in designing a multisystem receiver. The regional short message service of BeiDou, which allows the user and the station to exchange short message (currently 120 Chinese characters per message), adds complexity to the receiver, and therefore potentially higher costs. Furthermore, a vague policy of BeiDou signal design, for example, modulation schemes, and navigation message contents, and formats was also a barrier in GNSS receiver industry to get into the market. However, the BeiDou B1 signal interface control document, released in December 2012, has boosted new development activities of worldwide GNSS chipset and receiver manufacturers [13.61]. An initial and logical step in developing such a device or component is to reuse existing technology widely proven by previous design examples. For an example, STMicroelectronics introduced the socalled Teseo-II chip which was designed based on STA8088 originally built for GPS, GLONASS, and Galileo. The final solution employs two chips (the Teseo-II itself and an additional STA5630 tuner) and can do positioning with BeiDou only or BeiDou + GLONASS. The receiver software integrates the new constellation with the existing ones (GPS, Galileo, GLONASS, and regional systems), such that the selection of various GNSS configurations is actually possible [13.62]. For another example, Broadcom offers the GNSS location chip with BeiDou support. They have introduced the BCM47531, a GNSS chip that generates positioning data from five satellite constellations simultaneously – GPS, GLONASS, QZSS, SBAS, and BeiDou. The newly added BeiDou constellation increases the satellite visibility to a smartphone, enhancing navigation accuracy, particularly in urban settings where buildings and obstructions can affect performance.

It is noted that transportation authorities of China built up a mandate that certain commercial vehicles in parts of the nation should use the BeiDou system. This is similar as the activity of Russian government for GLONASS. This and the completion of BeiDou constellation will be an important driver to increasing of a BeiDou receiver-equipped navigation system on their market [13.63].

### 13.3.5 Military GPS Receivers

After the initial operational capability (IOC) of GPS was reached in December, 1993, military receivers which were delivered to US and NATO forces were furnished with the precise positioning service-security module (PPS-SM). PPS-SM was a first generation crypto module [13.64] to allow a military receiver to get access to the Y-code. The security module was a central processing chip in the receiver. It provided, on the one hand, the interface to the crypto key loader at the receiver housing. On the other hand, it steered the distribution of cryptographic information inside the receiver. Military receivers of this generation made use of P-code reference generators in all of the channels. In order to add a Y-code capability to each of the channels, the crypto information was directed to the P-code channels via so-called auxiliary output chips (AOCs) [13.65]. Additionally, Selective Availability (SA) parameters were handed over to the navigation processer which allowed a receiver for authorized users (PPS) to remove SA from the navigation solution. Many military receivers were manufactured in accordance with the PPS-SM standard in the 1990s (e.g., Rockwell Collins MAGR, PLGR, GEM I-IV, Trimble FORCE, etc.).

The problem faced over the years was that all these receivers (delivered by different manufactures) came up with different interfaces, form factors and test standards. Thus, in 1998, the Chairman of the Joint Chiefs of Staff issued a deployment mandate for modular standard and new security module architecture. This new modular standard [13.64] is called the GPS receiver application module (GRAM). It includes a new security architecture which is called selective availability antispoofing module (SAASM).

In general, GRAM is a new DoD/industry standard for embedded GPS which is aiming at a modular and open system architecture with standardized electrical, functional, and software interfaces including standardized procedures for verification and testing. The goal is an exchangeable receiver for system integrators, that is, the same receiver architecture with different form factors. Military receivers in *six* form factors are supported: a standard electronic module, format E (SEM-E) for aviation, a versa module euro (VME) card bus implementation for Navy ships, a Personal Computer Memory Card International Association (PCMCIA) for mobile terrestrial applications, a synchronous serial interface (SSI) capable form factor for handheld receivers like the defense advanced GPS receiver (DAGR) and two form factors for guided munitions.

The GRAM concept should allow for fast and cost-effective upgrades and should lead to a defined market for military GPS products. Following the public domain information given in [13.65, 66], the SAASM chip is a systems on the chip (SoC) layout where several functional silicon dies are integrated: a key data processor (second generation crypto module), an advanced MP, RAM and ROM storage units, and the code block including the digital logics for acquisition and correlation.

## 13.4 Technology Trends

Independent of the specific receiver (civil low-end, civil high-end, military, etc.), a general trend in GNSS receiver technology will be ongoing miniaturization. Higher VLSI will result in lower weight, smaller size, and lower power consumption. In the past, higher integration led to lower production and acquisition cost for the chips and finally the receivers. However, leading-edge VLSI (65 nm and below) is depending on market size for the class of receivers. We will see in all receiver domains hybrid receivers which will use GPS and one or more other GNSS system. Another general trend is that more correlators (up to massively parallel) will be used per channel in order to enhance sensitivity and help to mitigate multipath effects by more advanced mitigation techniques. Because many new signals are potentially available, more flexible or generic implementation concepts could become an issue.

### 13.4.1 Civil Low-End Trends

The civil low-end receiver technologies are deployed into the mass market where 1 billion (2013 estimate) GPS chips are in use in mobile phones, automotive equipment, mobile computers, and other consumer products. Implementation of GNSS ASICs in 65 nm CMOS has happened. The question is if and when will the step to next technology node happen, for example, 45 nm CMOS. In this receiver categories, power efficiency and area efficiency are main drivers of the implementation. Integrated single chips where analog RF and digital CMOS are integrated together are already a standard. In order to enhance the sensitivity down to signal levels of −190 dBW, massively parallel correlators or comparable FFT techniques are in use for acquisition.

Apparently, a single-frequency dogma is persistent: currently only single-frequency L1 chips and/or dies are developed. The main argument against dual frequency is that the analog CMOS RF modification necessary for, for example, L2 or L5 is a significant cost driver (cost factor of 2). For the digital subsystem, no major cost impact exists. Overall, a more expensive chip will result which is not demanded by the mass market customers. It is argued that no requirement for higher performance by adding a second frequency is present in the mass market.

Another problem area is the question how many GNSS systems should be supported on the same chip. This question cannot be finally answered. It has to do with the computational limits and finally power consumption of the single chip. A trend seems to be that, in any way, there will be a GPS L1 implementation as a basis for the chip. A regional treatment of costumer expectations could lead to the design option that we will have GPS/Galileo for the European market, GPS/GLONASS for the Russian, and GPS/BeiDou integrated hybrid chips for the Chinese markets.

Another open question at the low end is: If really an upcoming competition by pure software solutions against hardware implementation would take place?

### 13.4.2 Civil High-End Trends

At the civil high-end, highest power efficiency and high area efficiency are not the main design drivers. Although the large-scale integration proceeds also in this area, the degree of integration is lagging behind the low end by one or two innovation cycles. The trend is clearly to use all GNSS systems on all available frequency bands, that is, to provide a multisystem and multifrequency receiver. Such receivers will utilize more than 220 channels. They have a complex front-end ASIC, a powerful digital ASIC and an MP to run differ-

ent application specific software for real-time kinematic (RTK) positioning or PPP (precise point positioning). Most receivers are optimized for high-precision carrier-phase measurements with mm precision. A more precise oscillator is a requirement to keep the phase-noise effects small in working with small tracking loop bandwidth. In order to enter new markets, theses high-end receivers will be provided in the form of modules. At the high end, the software-defined radio based on a general purpose computer has potential market opportunities in cases where high adaptability and flexibility with respect to future ICD updates and changes of the signal formats are the requirements.

### 13.4.3 Trends in Military and/or Governmental Receivers

The current generations of GRAM/SAASM receivers which are mandatory since 2002 in the USA and their allied forces make all use of the P(Y)-code. Since the launch of the first GPS IIR-M, the new military M-code is transmitted. Thus, it is quite straightforward for the DoD to develop receivers which have M-code capability. The development program is called modernized user equipment (MUE). A request for proposal (RFP) was launched in 2004 by the US government with the goal to develop a so-called YMCA engine. The RFP called for a proof of concept and the development of ASICs and/or modules plus cost estimation. Since October 2007, three contracts had been awarded to develop the YMCA [13.67] receiver: ground-based-GRAM-M SSI (Rockwell Collins), GRAM SEM-E/M Card (Raytheon), single YMCA ASIC/SoC (L-3/interstate electronics). Besides this GRAM form-factor, it was announced to develop a common GPS module (CGM) which is making use of the latest semiconductor technology. Another interesting trend is the development of the MicroDAGR by Rockwell Collins. The MicroDAGR, with 0.175 kg, is a smaller version of the handheld DAGR which has a weight of 0.450 kg. It is a fusion of a military handheld GPS with mobile multimedia features. Some of these features are a digital camera, MP3 player, and a colored touch screen which are integrated. The motivation for the MicroDAGR is to prevent the use of small-sized commercial GPS receivers by troops in military theatres.

## 13.5 Receiver Types

In this section, we give a brief and systematic overview about the main types of GNSS receivers. The section is written without making any claim for completeness because over the years so many different specialized receivers were developed.

### 13.5.1 Navigation Receivers Handheld

Navigation receivers of handheld type have the appearance of a mobile radio. They make use of an integrated antenna, an integrated battery, a simple keyboard, and a monochrome or colored LCD display. On the architecture side in the civil domain, 12-channel L1 C/A-code receivers are in use. In the future, other GNSS systems will be integrated on the L1 frequency on a regional market-oriented basis. Most of them have software for waypoint navigation and some have a real-time DGPS capability. Governmental–military receivers make use of a security module like PP-SM or SAASM. Handheld receivers are characterized by low cost (about 200 US $ at the low end), and are used in the land, marine, and aviation domain.

### 13.5.2 Navigation Receivers Non-Handheld

The appearance of nonhand-held navigation receivers is, in most cases, a sensor (black box) with specific interfaces for marine, land, and aviation applications. In the civil market, 12-channel L1 C/A-code GPS receivers are available. For these receivers, small form factor and low power consumption are usually not a design driver, because they are used in large platforms like ships or commercial aircraft. In the military domain, dual-frequency P(Y)-code receivers are standard until now. Especially, in commercial aviation, these receivers are used in safety-critical operations like area navigation and precision landing. For this purpose, receivers have to undergo specific qualification and certification procedures such as MIL-STD 810, Federal Aviation Administration (FAA) TSO C-129, ARINC 743 A, RTCA DO-217, and so on. Most navigation receivers have a requirement for autonomous integrity monitoring schemes like receiver autonomous integrity monitoring (RAIM). Depending on the user community, these receivers are compatible with a variety of interfaces like Mil-Bus 1553, ARINC-429, National Marine Electronics Association (NMEA) 0183, Radio Technical Commission for Maritime Services (RTCM) SC 104, and others. Usually, a specific user dynamics in terms of linear velocity, acceleration, and jerk for the signal dynamics is specified (500–1000 m/s, 4–9 g, 4–10 g/s). Military navigation receivers fulfill a specified jamming resistance in terms of the jamming-to-signal ratio (J/S). Because of these ad-

vanced certification and standardization requirements, the acquisition cost of nonhand-held receivers is on the 10 000–30 000 US $ level.

### 13.5.3 Engines, OEM Modules, Chips, and Dies

GNSS engines, original equipment manufacturer (OEM) modules, chips, and dies are semifinished products. No housing, power supply, and control and display unit are attached to theses receivers. This class of GNSS products is integrated into higher level navigation systems which are sold in a specific market, for example, car navigation systems. Most of these receivers are parallel channel C/A-code L1 units until now. Multifrequency and multisystem modules are also available in the current years. These semifinished products usually provide flexible hardware and software interfaces which allow to output all the measured raw data and the entire navigation message.

### 13.5.4 Time Transfer Receivers

Timing receivers usually make use of a low-end 12-channel GPS L1, C/A-code chip. The timing system itself is based on a more precise clock/oscillator like, for example, a rubidium. Specific optimal estimation algorithms are applied in order to determine the clock offset and frequency offset from GPS time and synchronize to Coordinated Universal Time (UTC) (United States Naval Observatory (USNO)). Early time transfer receivers provided only a single channel because only one unknown (the time offset) has to be estimated. The user world geodetic system (WGS) 84 coordinates of the antenna had to be input. Because the GNSS chips developed in recent years make use of multiple channels, time transfer receivers with a single channel are not provided anymore. Thus, timing receivers have also a positioning capability nowadays.

### 13.5.5 Geodetic Receivers

Modern geodetic or surveying GNSS receivers have a multisystem, multifrequency design. They are able to track all current and future GNSS signals and thus provide (based on several high-end GNSS modules) more than 400 channels. Currently, most of these receivers have a semicodeless capability to make available at least P(Y)-code pseudoranges and carrier phases on L2. Surveying receivers are optimized to provide high-precision carrier-phase measurements with millimeter accuracy. This high accuracy implies the use of a more advanced antenna with a stable phase-center and a means to suppress the ground multipath. It is necessary that the surveying devices are adapted to the typical field environment of surveyors. From the form-factor side, the GNSS modules are typically integrated together with different radio modems (for the reception of RTK correction data) in the antenna pot. The antenna pot is mounted on top of a vertical rod. The rod includes a leveling device which is used to center the antenna exactly above a survey mark on ground. Attached to the rod is a CDU for system control functions. The receiver usually includes a large memory for storing all the measured data for post-processing purpose. Present surveying receivers have a RTK capability on the software level. This allows the receiver to process various differential correction formats. Sometimes the receiver is integrated together with other surveying instruments like theodolites and laser ranging equipment to a total station. The acquisition cost of GNSS surveying systems is on the level of multiple 10 000 US $.

### 13.5.6 Space Receivers

Since a decade, the use of GNSS receivers on-board of Earth satellites became a standard. GNSS on spacecraft is an inexpensive way to perform autonomous orbit and time determination (Chap. 32). Apart from the higher Doppler shifts of $\pm 40$ kHz during orbital motion at about 8000 m/s, the GNSS positioning scenario on an LEO platform is not so different from an Earth-fixed user. This situation changes, if the receiver is flown on high-flying satellites in geostationary Earth (GEO) or highly elliptical (HEO) orbits. Because the user in this type of orbit is above the GNSS constellation, it can only receive satellites which transmit on side-lobes from the other side of the Earth. A spaceborne receiver has some special features; because of the high Doppler shift, specific acquisition algorithms are necessary. For autonomous orbit determination, nonlinear Kalman filters are used. Because the user platform is flying on a high altitude, GNSS satellites are visible under the negative mask angle below the horizon. For specific missions, the Earth itself as a shading body has to be considered in the visibility analysis. Because many platforms are not flown in an Earth-pointing attitude, the receiver needs the capability (or option) to work with two GNSS antennas in order to get independent of the spacecraft attitude. Other features could be the use of radiation-hardened components and the provision of interfaces to specific spacecraft data bus systems.

### 13.5.7 Attitude Determination Receivers

For the attitude determination of a user platform, multiple antenna systems are used. The key issue of attitude determination is to measure precise carrier phases be-

tween the antenna phase centers while knowing the baseline (the distance) between them (Chap. 27). This opens the possibility of determining pitch, roll, and yaw of the platform with an accuracy of 0.1–0.01° depending on the base-line length, the carrier-phase multipath, and noise errors. In many GPS attitude determination systems, four antennas are used. Behind each antenna, a receiver is located with say a bank of six channels each. The different receivers are synchronized between each other by using a common crystal oscillator. Attitude receivers are used on terrestrial and spaceborne platforms.

# 14. Signal Processing

Jong-Hoon Won, Thomas Pany

In this chapter digital signal processing of a global navigation satellite system (GNSS) receiver is presented. It provides a high-level block diagram as well as detailed descriptions for all the internal functions of a modern digital GNSS receiver, focusing on signal acquisition and tracking, time synchronization, navigation data bit demodulation and decoding, and measurement generation. Also, several issues on the processing of upcoming GNSS signals, which may have new features like a binary offset carrier (BOC) modulation, data/pilot channels, primary/secondary codes, and so on are addressed. Furthermore, advanced topics in designing modern digital GNSS receivers such as tracking of the global positioning system (GPS) P(Y)-code, various combined processing schemes, Kalman filter-based signal tracking loops, and a vector-tracking approach are also presented.

## 14.1 Overview and Scope

The signal processing unit of a GNSS receiver processes the combined signal from all satellites plus noise and interference. This is done on one or more frequency bands. Typically, the receiver has dedicated units to process the signal from the individual satellite and frequency bands – those units are called channels.

The received signal power from the satellite is very low, usually −130 dBm or less, and the amplitude of the received signal is much smaller than the one of the received noise. One speaks of the fact that the signal is buried in the noise. Furthermore, the satellites transmit on the same carrier frequency and signals from different satellites overlap. As a matter of fact the typical received signal after amplification, downconversion and analog-to-digital conversion (ADC) looks like the data shown in Fig. 14.1. The GNSS signals are not directly recognizable within this data stream, and the signal samples look purely random.

To detect and track the GNSS signals, the receiver employs the *auto-correlation* principle. It generates a transmitted GNSS signal copy of a single satellite inside the receiver and correlates this replica signal with the received signal. If the signal parameters in terms of code phase (= signal delay $\tau$) and Doppler shift $f_d$ match reasonably well, the correlation value increases as shown in Fig. 14.2. The correlation is realized as an *integration* of the product of received and replica signal. Thus the terms correlation and integration are used synonymously within this chapter.

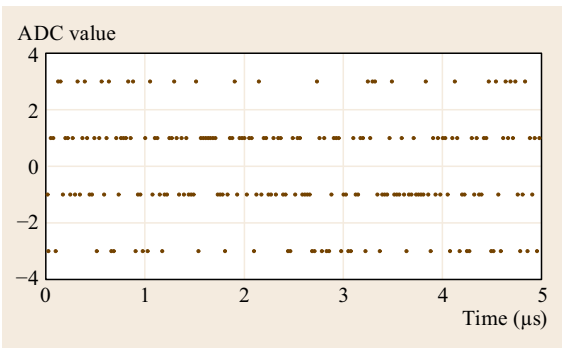

**Fig. 14.1** Output of a 2 bit ADC receiving GPS C/A signals plus thermal noise

The correlation brings the signal for the considered satellite above the noise floor, separates this signal from the other satellite signals and provides an estimate of the signal parameters including $\tau$ and $f_d$.

Figure 14.3 illustrates the schematic block diagram of a generic GNSS receiver focusing on the internal functions of a signal processing channel. GNSS signals received at the antenna are filtered, amplified, downconverted to an intermediate frequency (IF) by the radio frequency (RF) signal chain in the front end, and then applied to an ADC at the end of the RF front end to obtain digital samples. The *digital processing* of a GNSS signal in a channel starts with the detection that a signal is present (acquisition). During acquisition coarse estimates of the code delay and Doppler of the signal are determined in feed-forward manner, and then the channel switches to code and carrier tracking to refine the estimates in a feedback structure.

For tracking, several measures are necessary to ensure accuracy and stability of the tracking process. Tracking is based on generating an internal replica of the received signal and the replica is generated itself by several code and carrier numerically-controlled oscillators (NCOs). The NCO counters are converted into geometrical meaningful values (code/carrier pseudorange, Doppler) and are passed together with a signal power estimate to the navigation processor. The received signal power is permanently monitored. If it drops below a certain threshold, the channel declares a loss of lock and restarts with acquisition. During

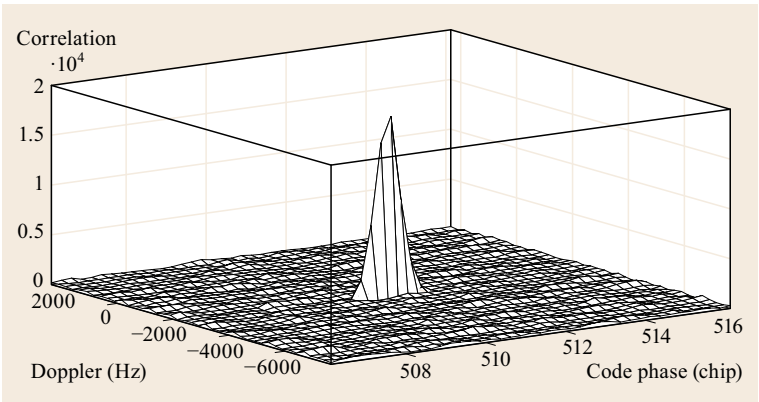

**Fig. 14.2** GPS C/A correlation function computed for PRN1 during signal acquisition

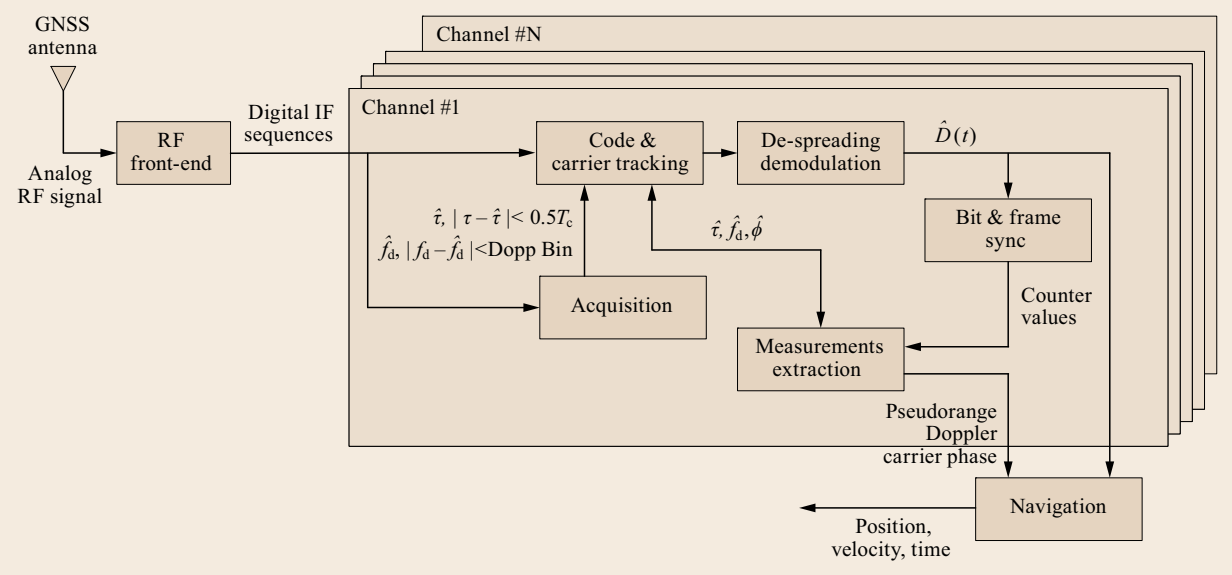

**Fig. 14.3** Block diagram of internal functions in a generic GNSS receiver architecture

tracking the channel synchronizes to the broadcast navigation data message and decodes it. The decoded bit information contains the satellite's ephemeris and almanac, system time information, and meteorological parameters. The information from code and carrier tracking blocks together with time synchronization information is used to generate the primary measurements of GNSS. Using these, finally, the navigation unit computes the GNSS navigational equation to obtain the user position, velocity and timing (PVT) information.

## 14.2 Received Signal Model

This section describes a model for the considered GNSS signals and of the resulting correlation values. These models form the basis for the tracking and acquisition analysis.

### 14.2.1 Generic GNSS Signal

Assuming a generic multiplexing scheme based on quadrature phase shift keying (QPSK) modulation, the signal transmitted at the antenna of a single GNSS satellite in one frequency band can be modeled as

$$s(t) = \sqrt{2P_c(t)}D_c(t)C_c(t)\cos(2\pi f_L t) + \mathrm{j}\sqrt{2P_s(t)}D_s(t)C_s(t)\sin(2\pi f_L t)\,, \qquad (14.1)$$

where $P$ is the signal power for the corresponding signal component, $D$ is the navigation data symbol sequence ($\pm 1$ for data channels and $+1$ for pilot channels) with a symbol duration of $T_{sym}$ in seconds, $C$ is the spreading code sequence with a chip duration of $T_c$ in seconds, $f_L$ is the carrier frequency in L-band in Hz, and subscripts c and s represent the identifiers for carriers, respectively cosine and sine. This model covers the majority of broadcast GNSS signals, and the ones not covered, such as alternative BOC (AltBOC) or code shift keying (CSK), have at least a similar structure. Also, unmodulated codes – realizing a binary phase shift keying (BPSK) modulation on a single component – or the relevant modulated codes, such as binary offset carrier (BOC) or any other code modulation for new GNSS signals, with the corresponding representative parameters can be used by modifying the spreading code sequence $C$.

The model given in (14.1) for QPSK signals can be easily modified for data-only signals or time-multiplexing signals. In the first case, the sine term is omitted, and for the second case, the sine term is replaced by a cosine and one has to make sure that $C_c$ and $C_s$ cannot be present simultaneously (i. e., $C_s(t)C_c(t) = 0$).

The received signal for $N$ visible satellites at the end of a receiver antenna can be modeled as

$$r(t) = \sum_{i=1}^{N} a_i e^{\mathrm{j}\phi_{0;i}} s_i(t - \tau_i) + n(t) \qquad (14.2)$$

where $s_i$ is the signal from the $i$th visible satellite, $a_i$ is the attenuation factor for the signal power of the corresponding satellite, and $n(t)$ is the additive noise component. The signal propagation time from the $i$th satellite to the receiver is given by $\tau_i$ expressed in seconds and $\phi_{0;i}$ is a phase delay in radians.

### 14.2.2 Signal Model at RF and IF

From (14.1) and (14.2), the received signal for a single satellite at the end of a receiver antenna can be modeled as

$$\begin{aligned} r_{\mathrm{RF}}(t;\tau,\phi_0,f_\mathrm{d},A_\mathrm{c},A_\mathrm{s}) &= A_\mathrm{c}D_\mathrm{c}(t-\tau)C_\mathrm{c}(t-\tau)\cos[2\pi(f_\mathrm{L}+f_\mathrm{d})t+\phi_0] \\ &\quad + \mathrm{j}A_\mathrm{s}D_\mathrm{s}(t-\tau)C_\mathrm{s}(t-\tau)\sin[2\pi(f_\mathrm{L}+f_\mathrm{d})t+\phi_0] \\ &\quad + n_{\mathrm{RF}}(t)\,, \end{aligned} \tag{14.3}$$

where $\tau$ is the code delay (s), $f_\mathrm{d}$ is the carrier Doppler frequency shift (Hz), $\phi_0$ is the carrier-phase delay (rad), $A$ is the signal amplitude for the corresponding signal component taking into account the signal power as well as the attenuation factor, $n_{\mathrm{RF}}(t)$ is the band-limited additive white Gaussian noise (AWGN) having a one-sided power spectral density (PSD) of $N_0$ and a bandwidth determined usually by the filter chain inside the RF front end (RF-FE) of the receiver, and the subscript RF represents the identifier for the carrier.

The received signal in (14.3) has a very high carrier frequency and most digital signal processors would have difficulty in generating such a rapidly varying digital carrier wave. Therefore, we must downconvert the frequency to something more manageable. Moreover, the signal power of the received signal is very low so that it must be increased necessarily to be processed. At the same time the effective suppression of the natural noise as well as radio frequency interference should be made. This signal conditioning process is done by a series of mixing and bandpass filtering processes at the RF-FE (Sect. 14.3.2).

Without loss of generality, after the downconversion with proper band-limited filters on multiple (or single) stages and then digitization by the ADC, a signal component of the digitized IF received signal (e.g., data channel at cosine carrier) at the end of the RF-FE can be rewritten from (14.3) in the discrete time domain given by

$$\begin{aligned} &r_{\mathrm{IF}}(k;\tau,\phi,f_\mathrm{d},A) = \\ &\quad AD(T_\mathrm{s}k-\tau)C(T_\mathrm{s}k-\tau)\cos[2\pi(f_{\mathrm{IF}}+f_\mathrm{d})T_\mathrm{s}k+\phi] \\ &\quad + n_{\mathrm{IF}}(k) \\ &\quad \text{for } k=0,1,2,\ldots\,, \end{aligned} \tag{14.4}$$

where $T_\mathrm{s}$ is the sampling time interval (s) such that $t=kT_\mathrm{s}$, and $n_{\mathrm{IF}}$ is the corresponding noise at IF. Note that $\phi$ here is the carrier-phase offset at $t=T_\mathrm{s}k$ in addition to the Doppler shift, and $\tau$, $\phi$, $f_\mathrm{d}$, and $A$ are the signal parameters of interest as functions of time $t$ to be estimated in the receiver signal processing for navigation purposes.

In fact, the process performed in the RF-FE consists of the frequency translation, signal amplitude magnification and out-of-band limiting. Note that the only parameter changed in the downconversion process of the RF-FE is the center frequency of the carrier wave. The delay effects caused by the RF-FE process are common in all the channels and will be eliminated by the navigation process in the form of common clock bias.

### 14.2.3 Correlator Model

Assuming the navigation data bit does not change in the integration time interval, the digitized received signal for a signal component (e.g., cosine) of a visible GNSS satellite can be modeled as a complex signal notation based on the signal parameters of interest [14.1]. Therefore, without the use of amplitude and navigation data bit, the locally generated replica signal at the IF can be written as

$$\hat{r}_{\mathrm{IF}}\left(k;\hat{\tau},\hat{\phi},\hat{f}_\mathrm{d}\right) = 2C(T_\mathrm{s}k-\hat{\tau})\mathrm{e}^{\mathrm{j}[2\pi(f_{\mathrm{IF}}+\hat{f}_\mathrm{d})T_\mathrm{s}k+\hat{\phi}]}\,. \tag{14.5}$$

Here, the notation for an estimator (i. e., hat) is intentionally used because the locally generated replica signal is a combination of output of estimators for the signal parameters of interest.

The correlator is a process to compute the integration of the received signal multiplied with the locally generated replica signal for a given coherent integration time. For the sake of the simplicity, let

$$\begin{aligned} r(k) &= r_{\mathrm{IF}}(k;\tau,\phi,f_\mathrm{d},A), \\ \hat{r}(k) &= \hat{r}_{\mathrm{IF}}(k;\hat{\tau},\hat{\phi},\hat{f}_\mathrm{d}), \\ \Theta &= 2\pi(f_{\mathrm{IF}}+f_\mathrm{d})T_\mathrm{s}k+\phi, \\ \hat{\Theta} &= 2\pi(f_{\mathrm{IF}}+\hat{f}_\mathrm{d})T_\mathrm{s}k+\hat{\phi}, \\ \Sigma &= \Sigma_{k=1}^{M}\,, \end{aligned} \tag{14.6}$$

then

$$\begin{aligned} &\mathrm{corr}\left[r_{\mathrm{IF}}(k;\tau,\phi,f_\mathrm{d},A),\hat{r}_{\mathrm{IF}}\left(k;\hat{\tau},\hat{\phi},\hat{f}_\mathrm{d}\right)\right] \\ &\quad = \sum r(k)\hat{r}(k)\,, \end{aligned} \tag{14.7}$$

where $\mathrm{corr}(x,y)$ is the correlation function of $x$ and $y$, and $M$ is the number of samples within the integration time $T=MT_\mathrm{s}$, which is usually shorter or equal to the navigation data bit/symbol period.

We can apply the mixing process, a form of multiplication of the received signal and the locally generated replica signal as follows

$$r(k)\hat{r}(k) = 2C(T_s k-\tau)C(T_s k-\hat{\tau}) \times \cos\Theta e^{j\hat{\Theta}} + n_{IF}(k)\hat{r}(k)\,. \tag{14.8}$$

Applying (14.4) and (14.5) into (14.8), and then integration for a given integration time yields

$$\sum r(k)\hat{r}(k) = \sum C(T_s k-\tau)C(T_s k-\hat{\tau})2\cos\Theta e^{j\hat{\Theta}} + 2\sum n_{IF}(k)C(T_s k-\hat{\tau})e^{j\hat{\Theta}}\,. \tag{14.9}$$

The first summation in (14.9) is given by

$$\sum C(T_s k-\tau)C(T_s k-\hat{\tau}) = R(\delta\tau) \tag{14.10}$$

with $R(\delta\tau)$ being the normalized correlation function of $C(T_s k)$. In the case where a BPSK signal is considered, like the GPS C/A code signal, the correlation function takes the form

$$R(\delta\tau) = \begin{cases} 1-\frac{|\delta\tau|}{T_c} & \text{for } |\delta\tau| \le T_c\,, \\ 0 & \text{for } |\delta\tau| > T_c\,, \end{cases} \tag{14.11}$$

where $\delta\tau = \tau - \hat{\tau}$ is the code delay error (s) and $T_c$ is the code chip interval (s). For BPSK signals $R$ has a triangular shape as shown in Fig. 14.2.

The second term in (14.9) can be expanded to two parts

$$\begin{aligned} &2\sum \cos\Theta\cos\hat{\Theta} \\ &= \sum\cos(\Theta-\hat{\Theta}) + \sum\cos(\Theta+\hat{\Theta}) \\ &\approx \sum\cos(\Theta-\hat{\Theta})\,, \end{aligned} \tag{14.12}$$

$$\begin{aligned} &2\sum \cos\Theta\sin\hat{\Theta} \\ &= \sum\sin(\Theta-\hat{\Theta}) - \sum\sin(\Theta+\hat{\Theta}) \\ &\approx \sum\sin(\Theta-\hat{\Theta})\,, \end{aligned} \tag{14.13}$$

where

$$\begin{aligned} \Theta-\hat{\Theta} &= 2\pi\delta f_d T_s k + \delta\phi \\ \Theta+\hat{\Theta} &= 2\pi\left(2f_{IF}+f_d+\hat{f}_d\right)T_s k + \phi + \hat{\phi} \end{aligned} \tag{14.14}$$

with $\delta\phi = \phi - \hat{\phi}$ is the carrier-phase error (rad), and $\delta f_d = f_d - \hat{f}_d$ is the Doppler error (Hz).

The term $\Theta+\hat{\Theta}$ in (14.14) contains a higher-order frequency component $4\pi f_{IF}T_s k$ and the corresponding components in (14.12) and (14.13) were filtered out by the summation operation (i. e., low-pass filter).

Additionally, applying the rule of products of sine and cosine into (14.12) and (14.13) considering the summation of (14.9) yields

$$\begin{aligned} &\sum\cos(2\pi\delta f_d T_s k + \delta\phi) \\ &= \sum\begin{pmatrix}\cos(2\pi\delta f_d T_s k)\cos\delta\phi \\ -\sin(2\pi\delta f_d T_s k)\sin\delta\phi\end{pmatrix} \\ &= \frac{\sin(2\pi\delta f_d T)}{2\pi\delta f_d T}\cos\delta\phi \end{aligned} \tag{14.15}$$

and

$$\begin{aligned} &\sum\sin(2\pi\delta f_d T_s k + \delta\phi) \\ &= \sum\begin{pmatrix}\sin(2\pi\delta f_d T_s k)\sin\delta\phi \\ +\cos(2\pi\delta f_d T_s k)\cos\delta\phi\end{pmatrix} \\ &= \frac{\sin(2\pi\delta f_d T)}{2\pi\delta f_d T}\sin\delta\phi\,. \end{aligned} \tag{14.16}$$

The substitution of the results in (14.10), (14.15) and (14.16) into (14.9) yields

$$\sum r(k)\hat{r}(k) = R(\delta\tau)\frac{\sin(2\pi\delta f_d T)}{2\pi\delta f_d T}e^{j\delta\phi} + 2\sum n_{IF}C(T_s k-\hat{\tau})e^{j\hat{\Theta}}\,. \tag{14.17}$$

Finally, taking into account the signal amplitude, data bit and noise effect, the correlator output in (14.7) can be written as

$$\begin{aligned} &\mathrm{corr}\left[r_{IF}(k),\hat{r}_{IF}(k)\right] \\ &= \bar{A}\,D\,R(\delta\tau)\,\mathrm{sinc}(\delta f_d T)e^{j\delta\phi} + \eta \\ &= I + jQ \end{aligned} \tag{14.18}$$

with

$$\mathrm{sinc}(\delta f_d T) = \frac{\sin(2\pi\delta f_d T)}{2\pi\delta f_d T}\,, \tag{14.19}$$

$$\bar{A} = \sqrt{2TC/N_0}\,, \tag{14.20}$$

where $\bar{A}$ is the amplitude of the baseband signal component assuming a normalized noise component, $C/N_0$ is the carrier-to-noise ratio (Hz), and $I$ and $Q$ represent postcorrelation values in in-phase ($I$) and quadrature ($Q$) components respectively, (this is the so

called *baseband signal* component) and can be given by

$$I = \bar{A}\, D\, R(\delta\tau)\, \mathrm{sinc}(\delta f_\mathrm{d} T) \cos(\delta\phi) + \eta_\mathrm{I}\,,$$
$$Q = \bar{A}\, D\, R(\delta\tau)\, \mathrm{sinc}(\delta f_\mathrm{d} T) \sin(\delta\phi) + \eta_\mathrm{Q}\,, \qquad (14.21)$$

where $\eta_\mathrm{I}$ and $\eta_\mathrm{Q}$ represent the noise in $I$ and $Q$ respectively, which are normalized by multiplication so that their noise power is given by

$$E(\eta_\mathrm{I}^2) = E(\eta_\mathrm{Q}^2) = 1\,, \qquad (14.22)$$

where $E(x)$ denotes the expected value of $x$ [14.2].

The early and late correlator concept is widely used in the BPSK code tracking due to the nonconvexity property of the triangular shape of code correlation function (Sect. 14.4.4 for more details including BOC signals). The correlator outputs, that is the baseband $I/Q$ values at the early, prompt and late branches are six basic signal processing elements given as a function of signal parameter errors [14.1, 2]

$$\boldsymbol{B} = \boldsymbol{h}\left(D, d; \bar{A}, \delta\tau, \delta f_\mathrm{d}, \delta\phi\right) + \boldsymbol{\eta} \qquad (14.23)$$

with

$$\boldsymbol{B} = [I_\mathrm{E}, Q_\mathrm{E}, I_\mathrm{P}, Q_\mathrm{P}, I_\mathrm{L}, Q_\mathrm{L}]^\top\,,$$
$$\boldsymbol{h} = \begin{bmatrix} \bar{A}DR\left(\delta\tau - \frac{d}{2}\right)\mathrm{sinc}(\delta f_\mathrm{d} T)\cos\delta\phi \\ \bar{A}DR\left(\delta\tau - \frac{d}{2}\right)\mathrm{sinc}(\delta f_\mathrm{d} T)\sin\delta\phi \\ \bar{A}DR(\delta\tau)\,\mathrm{sinc}(\delta f_\mathrm{d} T)\cos\delta\phi \\ \bar{A}DR(\delta\tau)\,\mathrm{sinc}(\delta f_\mathrm{d} T)\sin\delta\phi \\ \bar{A}DR\left(\delta\tau + \frac{d}{2}\right)\mathrm{sinc}(\delta f_\mathrm{d} T)\cos\delta\phi \\ \bar{A}DR\left(\delta\tau + \frac{d}{2}\right)\mathrm{sinc}(\delta f_\mathrm{d} T)\sin\delta\phi \end{bmatrix}\,,$$
$$\boldsymbol{\eta} = [\eta_{\mathrm{I_E}}, \eta_{\mathrm{Q_E}}, \eta_{\mathrm{I_P}}, \eta_{\mathrm{Q_P}}, \eta_{\mathrm{I_L}}, \eta_{\mathrm{Q_L}}]^\top\,,$$

where $d$ represents the early-to-late correlation spacing in chips (e.g., $d = 1$ for normal early-minus-late correlators).

Note that the above equation for six basic signal processing elements is for standard tracking of a BPSK signal. The number of early and late branches with a given correlator spacing is in general dependent on the modulation type of the signal (i. e., BOC), and the discriminator algorithms [14.3–6].

## 14.3 Signal Search and Acquisition

The signal search is the first phase of a GNSS receiver that determines if it receives signals from satellites at all. Due to the nature of the GNSS signals, the signal search includes a coarse estimation of the signal's Doppler and code phase. The signal search can intuitively be seen as a numerical evaluation of the signal's correlation function (14.18) in the two-dimensional Doppler and code phase space. If the peak magnitude of this function exceeds a certain threshold, then the signal is declared to be present and the position of the peak are the coarse estimates. This picture is not far from a fundamental theoretical concept, which is termed a generalized maximum likelihood ratio test [14.7].

### 14.3.1 Test Statistics

The basis for the acquisition logic are the correlator outputs (14.21). The correlator position in the code phase/Doppler domain with respect to the true values is denoted as $\delta\tau$ and $\delta f_\mathrm{d}$. The carrier phase is not considered during signal acquisition and the total power $S$ is given by

$$|S|^2 = I^2 + Q^2\,. \qquad (14.24)$$

Under the assumption of a signal being present the total power $S$ assumes the shape of a peak like the one shown in Fig. 14.2 (or multiple peaks in the case of a BOC signal shown in Fig. 14.4), which has to be detected against a more or less uniform background of noise. The total power is written as

$$|S|^2 = A^2 R(\delta\tau)^2\, \mathrm{sinc}(\delta f_\mathrm{d} T)^2 + \text{noise}\,. \qquad (14.25)$$

The expected value of the noise is easily evaluated, as terms linear in $\eta_{\mathrm{I,Q}}$ vanish. Thus we have

$$E[\text{noise}] = E[\eta_\mathrm{I}^2 + \eta_\mathrm{Q}^2] = 2\,. \qquad (14.26)$$

In the theory of signal detection, signal acquisition has to decide which of the following hypotheses is true:

$H_0$: Considered satellite signal is not present
$H_1$: Considered satellite signal is present.

Typically, signal acquisition is carried out for each satellite signal separately. The acquisition engine evaluates the total power $S$ for a certain range of Doppler and code-phase values, searches the peak within this area and compares the value of the peak against a threshold $\gamma$. If the peak exceeds the threshold, the hypothesis $H_1$ is declared to be true, otherwise $H_0$. To increase the sensitivity one can increase the *coherent* integration time $T$ of (14.7), up to a limit determined by the computational resources (gate count in the case of a GNSS chip set or

central processing unit (CPU) load for software-based receivers), the oscillator stability, user dynamics or by the length of the broadcast navigation data bits/symbols or secondary codes. Usually it is in a range of 1–20 ms. A further sensitivity increase is achieved by a *noncoherent* integration; that is to compute the correlation function several ($= \nu$) times and to average them. Under some reasonable assumptions like constant Doppler and uniformly distributed carrier phase for each coherent integration interval, it can be shown mathematically that coherent plus noncoherent integration is in fact an optimal strategy [14.7]. In the following we assume that $S_{\mathrm{nc}}$ represents the coherent plus noncoherent integration result

$$S_{\mathrm{nc}} = \sum_{n=1}^{\nu} |S_n|^2 \qquad (14.27)$$

and that $n$ denotes subsequent coherent integrations each over an interval of $T$. The total integration time is $T_{\mathrm{tot}} = T\nu$.

Mathematically speaking, the function $S_{\mathrm{nc}}$ is the sum of $2\nu$ squared zero-mean Gaussian random variables under the assumption $H_0$, and $S_{\mathrm{nc}}$ follows a central chi-squared distribution $Q_{\chi^2;\alpha}$ with $\alpha = 2\nu$ degrees of freedom. The number of degrees of freedom $2\nu$ is explained by recalling that each coherent integration has a contribution from the real $I$ and the imaginary $Q$ part. Using the definitions of [14.8] we have

$$P(S_{\mathrm{nc}} > \gamma | H_0) = Q_{\chi^2;2\nu}(\gamma) \,. \qquad (14.28)$$

The term $P(S_{\mathrm{nc}} > \gamma | H_0)$ denotes the false alarm probability, that is the chance that the receiver incorrectly detects a signal even if none is present.

Under $H_1$, the probability distribution of $S_{\mathrm{nc}}$ is a noncentral chi-squared distribution $Q_{\chi^2;\alpha;z}$ and the noncentrality parameter $z = 2\nu TC/N_0$ relates to the carrier-to-noise ratio $C/N_0$ and the number of noncoherent integrations $\nu$

$$P(S_{\mathrm{nc}} > \gamma | H_1) = Q_{\chi^2;2\nu;2\nu TC/N_0}(\gamma) \,. \qquad (14.29)$$

The term $P(S_{\mathrm{nc}} > \gamma | H_1)$ is the detection probability, that is the ability of the receiver to detect signals that are actually present.

As an example the total power $\sqrt{S_{\mathrm{nc}}}$ of a Galileo E1 composite binary offset carrier (CBOC) signal is shown in Fig. 14.4. Essentially the BOC(1,1) component of the CBOC signal determines the visual appearance, with the BOC(6,1) component being much smaller. The chosen acquisition settings $T = 8$ ms and $\nu = 5$ correspond to a medium to high sensitivity acquisition unit capable of detecting signals as low as approximately 30.5 dB-Hz as will be shown with equation (14.31). It can be seen that an unobstructed but low-elevation satellite signal has a clear peak, even showing the BOC(1,1) side lobes. Legacy GPS C/A receivers operating with $T = 1$ ms and $\nu = 1$ would not be able to detect this signal reliably and have difficulties acquiring signals near the horizon due to the diminished receiver antenna gain at low elevations.

Due to the squaring operation in the noncoherent integration, the noise floor gets positively biased. The ratio of the peak minus this bias divided by the standard

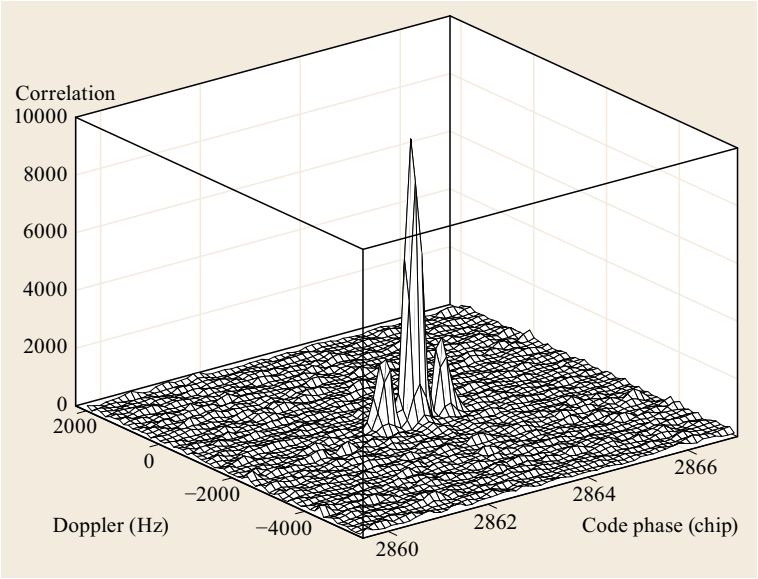

**Fig. 14.4** Example of an E1C correlation function for a Galileo satellite at low elevation

deviation of the noise is called *signal-to-noise* ratio (SNR). For $\nu > 7-9$ the central limit theorem applies. Then the probability distributions can be approximated by Gaussian ones $Q_{N;\mu;\sigma}$, with $\mu$ being the mean value and $\sigma$ the standard deviation. Thus we can write

$$P(S_{\mathrm{nc}} > \gamma | H_0) \approx Q_{N;2\nu;\sqrt{4\nu}}(\gamma) \,,$$
$$P(S_{\mathrm{nc}} > \gamma | H_1) \approx Q_{N;2\nu(1+TC/N_0);\sqrt{4\nu+8\nu TC/N_0}}(\gamma) \,. \tag{14.30}$$

With these approximations, we can establish a relationship between the carrier-to-noise ratio $C/N_0$ and the SNR value, which is useful to assess the sensitivity of an acquisition engine. As a first starting point, an SNR of 13 dB is required to detect a signal. A more precise description of the acquisition sensitivity will be given later. The SNR value derives from $C/N_0$ under these approximation as

$$\mathrm{SNR} = \frac{2\nu TC/N_0}{\sqrt{4\nu}} = TC/N_0 \sqrt{\nu} \,. \tag{14.31}$$

One realizes that for large $\nu$ the SNR increase due to further noncoherent integration is twice as slow as for an increase in the coherent integration time $T$. This phenomenon is usually called *squaring loss*. For example, doubling the integration time increases the SNR value by 3 dB, and doubling the number of noncoherent integrations increases the SNR by 1.5 dB.

### 14.3.2 Acquisition Module Architecture

A block diagram of a modern GNSS acquisition engine is shown in Fig. 14.5. Acquisition is typically a process that takes place only when needed. In this case the IF sample selector cuts out a certain time span of GNSS signal samples from the received signal data stream. Two important preprocessing steps may take place, if the signal environment requires this.

For high-sensitivity acquisition, it may happen that strong and weak signals are received simultaneously. For the example of an indoor receiver, one can think of a situation where a strong signal comes through the window and a weak signal has first to penetrate a wall before reception by the antenna. Unfortunately, the pseudo-random noise (PRN) codes from different satellites are not completely orthogonal; their cross correlation is slightly different from zero. Thus the correlation (total power) function $S_{\mathrm{nc}}$ not only contains the possibly present autocorrelation peak but also many cross-correlation peaks. The ratio between the autocorrelation peak and the largest cross-correlation peak under the assumption of equal power is called *cross-correlation protection*. It is a measure of how much signal power difference can be tolerated by the receiver still being able to differentiate the true autocorrelation peak from the unwanted cross-correlation peaks.

For the GPS C/A code it is around −22 dB. When the acquisition function $S_{\mathrm{nc}}$ of the weak signal is computed it might be contaminated by cross-correlation peaks from the strong signal (if the strong signal is e.g., 22 dB or more stronger than the weak signal). In that case it is beneficial to cancel (subtract) the strong signals from the incoming composite signal before computation of $S_{\mathrm{nc}}$. This is possible with good precision, as a replica of a strong signal, whose parameters (code delay, Doppler, carrier phase and amplitude) can be accurately estimated, can be well reproduced inside the acquisition engine [14.9].

If the receiver is located inside a harsh RF environment (e.g., inside a mobile phone) a lot of interference, especially tone interference (isolated frequency peaks) is present. It might for example be caused by harmonics of the reference oscillator, local oscillators or any other clock signals inside the system. Those spikes in the spectrum have to be canceled by either fast Fourier transform (FFT) techniques or adaptive notch filters.

Finally, the computation of (14.27) takes place and a search and decision logic selects the correct peak. To gain some sensitivity and to increase the robustness,

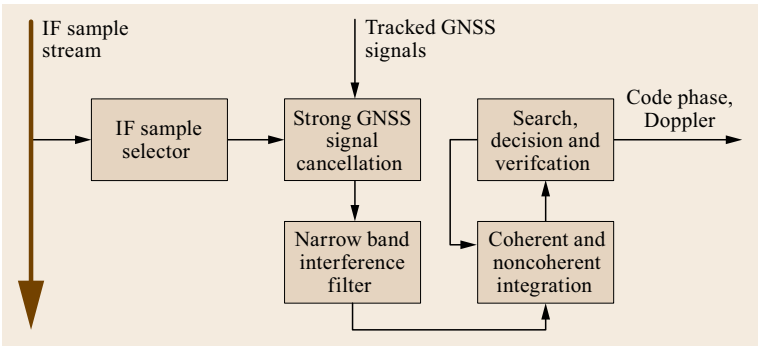

**Fig. 14.5** Block diagram of a GNSS signal acquisition engine

a search and decision logic may select for example the ten highest peaks and then recompute (14.27) only for those code-phase and Doppler values, eventually using a larger number of noncoherent integrations. This is called *acquisition verification*. Verification is implicitly also done during the tracking process (a channel will not be able to track a false acquisition result for a longer time span), but verification in the tracking channels takes much more time and usually only a limited number of tracking channels are available.

### 14.3.3 Coherent Integration Methods

This section describes the computation of correlation values $I$ and $Q$ via numerical integration over the coherent integration time $T$, thus the evaluation of (14.18). This is the part of acquisition consuming most of the resources as it works with the native sample rate. In comparison, noncoherent integration or detection consume much fewer resources. The coherent integration is done by units called *correlators*.

The implementation of correlators for the acquisition unit differs from the tracking channel implementation as a wide Doppler range is considered, a wide code-phase range (typically the whole PRN code period) is considered and the accuracy requirements in terms of code-phase resolution or Doppler resolution are rather low. Thus different methods for code and Doppler correlation are considered.

#### Code Correlation

There are three main methods available to realize the coherent integration in code phase for acquisition purposes:

- Re-use of tracking channels for signal acquisition
- Parallel correlation with a matched filter structure
- Precorrelation FFT techniques.

The first method has historical importance or is used for special receivers focusing on a low-resource implementation. A tracking channel is programmed to continuously (but slowly) increase the code phase until the correlation peak is detected (obviously, the tracking channel has to be on the right Doppler frequency). This method is called *serial search* and may come along with Tong detectors [14.10] as a means to verify signal detection and to increase the sensitivity.

The second method is to set up a digital filter, whose filter coefficients are the PRN code values themselves (*matched filter*). The PRN code is resampled to the incoming sample rate. This filter is fed with the Doppler-compensated incoming signal. It can be very efficiently realized in hardware using a pipelined structure [14.11]. The incoming signal is fed serially into the filter. Once initialized (i. e., after one PRN code period has been fed in), the structure outputs one value of the correlation function for each incoming sample. With each cycle, the output correlation function is shifted in code phase by one sample. The code-phase resolution in chips is given by the ratio of the PRN code rate divided by the sample rate.

The third method exploits the Fourier convolution theorem, which states that the computation of a correlation function in the time domain can be expressed as a multiplication in the frequency domain [14.7]. This drastically reduces the number of required operations and is the method of choice if a software-based solution is targeted. Various methods like zero padding or resampling exist to cope with the fact that an FFT approach intrinsically works with periodic signals [14.7]. The code-phase resolution in chips is again given by the ratio of the PRN code rate divided by the sample rate.

#### Doppler Correlation

The code correlation methods from before have to be carried out after Doppler removal. In the most simple way, a carrier NCO is used for this purpose. The term *carrier NCO* is used to denote the responsible unit to generate a sine/cosine wave with a certain phase and frequency. The received signal samples are multiplied with carrier NCO samples (sine and cosine part) and the code replica samples before carrying out the coherent integration. If the selected carrier NCO frequency matches the true Doppler frequency, the correlation value becomes a maximum; the Doppler has been removed.

A certain Doppler search strategy has to be employed to change the carrier NCO frequency in a proper way, each time one PRN code sequence has been searched. This is done until the signal is detected. To give an example, the receiver may start with the lowest possible frequency of for example −6 kHz and gradually increases the frequency in steps of 500 Hz until the highest possible frequency of for example 6 kHz is reached. This approach can be slow if the Doppler search range is wide, but it is suitable if the Doppler is approximately known (e.g., in case of reacquiring a signal).

A more efficient way to search a wide Doppler range is to use *postcorrelation FFT* techniques [14.12]. They exploit the fact that the multiplication with the carrier NCO together with the integration resemble the definition of the discrete Fourier transform. If the integration over $M$ samples is subdivided into $N$ chunks,

then one may write

$$\begin{aligned}
&\sum_{k=1}^{M} s_k \exp\left(2\pi \mathrm{j}\hat{f}_\mathrm{d} T_\mathrm{s} k\right) \\
&\quad = \sum_{n=1}^{N} \sum_{k=(n-1)\frac{M}{N}+1}^{\frac{nM}{N}} s_k \exp\left(2\pi \mathrm{j}\hat{f}_\mathrm{d} T_\mathrm{s} k\right) \\
&\quad = \sum_{n=1}^{N} \left[ \exp\left(2\pi \mathrm{j}\hat{f}_\mathrm{d} T_\mathrm{s} (n-1)\frac{M}{N}\right) \right. \\
&\qquad \left. \times \sum_{k=1}^{\frac{M}{N}} s_{k+(n-1)\frac{M}{N}} \exp\left(2\pi \mathrm{j}\hat{f}_\mathrm{d} T_\mathrm{s} k\right) \right] \\
&\quad \approx \sum_{n=1}^{N} \left[ \exp\left(2\pi \mathrm{j}\hat{f}_\mathrm{d} T_\mathrm{s} (n-1)\frac{M}{N}\right) S_n \right] . \qquad (14.32)
\end{aligned}$$

Here $s_k = r(k)C(T_\mathrm{s}k - \hat{\tau})$ is a placeholder for the received signal multiplied with the code replica and

$$S_n = \sum_{k=1}^{\frac{M}{N}} s_{k+(n-1)\frac{M}{N}} \exp\left(2\pi \mathrm{j}\tilde{f}_\mathrm{d} T_\mathrm{s} k\right) . \qquad (14.33)$$

The short coherent integrations $S_n$ are performed all with the same carrier NCO frequency $\tilde{f}_\mathrm{d}$ being an integer multiple of $N/(MT_\mathrm{s})$. For example, if a coherent integration time of $MT_\mathrm{s} = 4\,\mathrm{ms}$ is targeted, one can compute eight correlation functions $S_n$, each based on $NT_\mathrm{s} = 0.5\,\mathrm{ms}$ of a GNSS signal assuming $\tilde{f}_\mathrm{d} = 0\,\mathrm{Hz}$. Applying for each code phase bin separately an eight-point FFT gives the 4 ms correlation function for the Doppler values of $\hat{f}_\mathrm{d} = -250\,\mathrm{Hz}, -187.5\,\mathrm{Hz}, \ldots, 187.5\,\mathrm{Hz}$. This is computationally much more efficient than doing a full 4 ms correlation for all eight Doppler bins. There is a certain correlation loss $L_\mathrm{PC}$ involved depending on the difference of $\hat{f}_\mathrm{d}$ and $\tilde{f}_\mathrm{d}$, evaluated as

$$L_\mathrm{PC} = 20\log_{10}\left|\mathrm{sinc}\left[NT_\mathrm{s}\left(\hat{f}_\mathrm{d} - \tilde{f}_\mathrm{d}\right)\right]\right| , \qquad (14.34)$$

which assumes in this example for a maximum difference of 250 Hz a value of $-3.96\,\mathrm{dB}$. To which extend this loss can be tolerated is application dependent.

In the case where the code correlation is performed with FFT methods, a very efficient way exists to search different Doppler bins. Before multiplying the Fourier transform of the received signal with the transformed replica signal, the transformed replica signal is circularly shifted by a certain number of samples. A shift of one sample corresponds to a Doppler step of $(LT_\mathrm{s})^{-1}$ Hz with $L$ being the length of the FFT. Thus all Doppler bins can be searched and only the multiplication and the inverse FFT (but not the forward FFTs) have to be carried out for each Doppler bin.

It should be mentioned that a number of further advanced FFT algorithms have been developed mostly by David Akopian, which are summarized in [14.7] for example. They include a lossless postcorrelation FFT method as well as an highly efficient algorithm applicable if the code search range can be limited. The use of Fourier methods in the one or other form within an acquisition unit is inevitable if numerically optimal performance is sought.

### 14.3.4 Search Space

Acquisition is a two-dimensional search in the code phase/Doppler dimension. A reduction of the search space not only saves computational resources but also increases the sensitivity. A suitable resolution for the code phase and Doppler grid has to be chosen.

#### Code Direction

The search in code direction typically covers the full PRN code period because a precise time with an accuracy of better than the PRN code period (e.g., 1 ms) is usually not available at startup. Furthermore, matched filter techniques or FFT techniques prefer to work with the whole PRN code sequence. Two notable exceptions from this rule should be mentioned.

The first case considers encrypted GNSS signals. Typically they are based on very long PRN codes, which provide some protection against PRN code decoding and dissemination. For example, the GPS P(Y)-code is one week long and cannot be acquired in this way. If direct P(Y)-code acquisition is targeted (and not a handover from the GPS C/A code), then a smaller fraction of the P(Y)-code is search in larger piece of incoming signal (or vice versa). The length of the larger portion has to reflect the receiver uncertainty of its prediction of the code phase.

Second, modern GNSS signals typically consist of a primary and a secondary code. The direct acquisition of the combined code (which has a typical length of 10–100 ms) is usually difficult due to computational limitations but mostly due to user dynamics and receiver clock instability. Instead one considers only the primary code. The secondary code can be regarded as a navigation data bit/symbol.

The code phase resolution has to be high enough in order not to miss the correlation peak. In the worst case, the peak is right in the middle of two correlation values. For a BPSK signal, a minimum of $r = 2$ samples per chip shall be used, while for a BOC$(n, m)$ signal a number of $r = 4n/m$ samples per chip is required. This is illustrated with Fig. 14.6 where the worst case of maxi-

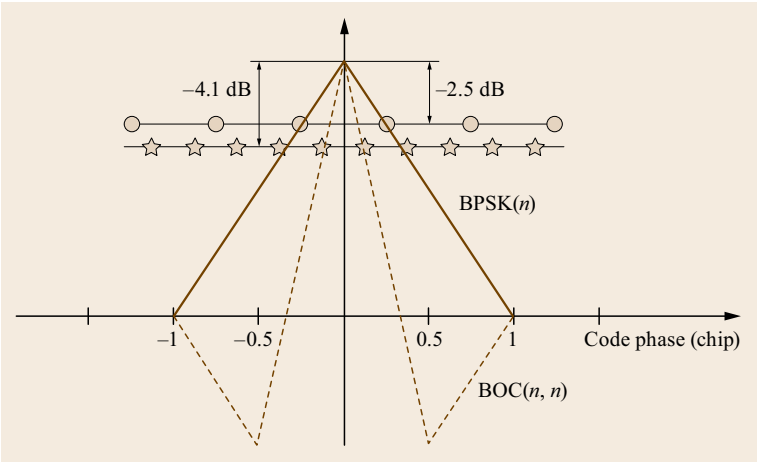

**Fig. 14.6** Impact of finite code resolution for a BPSK($n$) and a BOC($n, n$) signal using 2 and 4 samples per chip, respectively

mum code phase mismatch for the suggested resolution settings is shown. The figure shows one BPSK and one BOC correlation function with the main peak just between two code phase bins denoted as circles for the BPSK signal and stars for the BOC signal.

For a BPSK signal, the maximum loss is then

$$20\log_{10}\left(1-\frac{1}{2r}\right) = -2.5\,\text{dB}\,. \tag{14.35}$$

For BOC($n, m$) signals, it is

$$20\log_{10}\left(1-\frac{1}{2r}\frac{2n+m}{m}\right), \tag{14.36}$$

which evaluates to $-4.1\,\text{dB}$ for a BOC($n, n$) signal. These are worst-case losses and average mismatch losses are smaller. If they are too high for a certain application, then the resolution $r$ needs to be increased at the cost of higher computational demands.

#### Doppler Direction

The Doppler search range has to be wide enough to cover the user velocity, satellite velocity and the receiver clock drift. On the L1 frequency it is on the order of $\pm 6\,\text{kHz}$ for a static receiver with an oscillator having at least temperature-compensated crystal oscillator (TCXO) quality (expressed as an absolute frequency stability over the operating temperature range of 1 ppm).

Once the receiver clock drift has been estimated, it usually remains stable for hours (if the operating temperature is sufficiently stable). If the user position and velocity is approximately known and an almanac is available, the Doppler search range can be narrowed down to the order of $\pm 100\,\text{Hz}$.

If the clock drift is unknown, it can be coarsely estimated from a single first satellite signal, provided that an approximate position plus velocity and an almanac are available. Only for this first signal, the full Doppler search range has to be employed. The following signals can then be found in a narrow Doppler range.

The correlation value of (14.25) depends on a sinc function of the Doppler frequency error as drawn in Fig. 14.7. Thus the Doppler resolution should be at least $\Delta f_\text{d} = 1/T$ (shown as circles in Fig. 14.7), which gives a maximum loss of

$$20\log_{10}\operatorname{sinc}\frac{\Delta f_\text{d} T}{2} = -3.9\,\text{dB}\,. \tag{14.37}$$

A finer resolution is preferable if the required computational resources are available.

### 14.3.5 Acquisition Performance

The acquisition performance is expressed in signal processing terms as the probability of detection (for a given signal power and false alarm rate) and the time needed

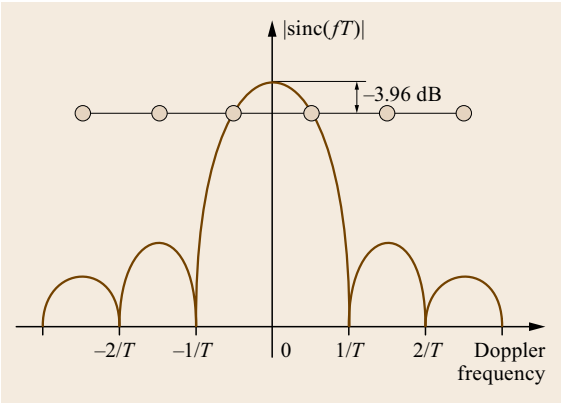

**Fig. 14.7** Impact of a finite Doppler resolution during acquisition. *Circles* are spaced at $\Delta f_d = 1/T$

to perform the operation. The time needed contributes to the time-to-first-fix (TTFF) and depends on the number of correlation values to be computed.

As the search space of Sect. 14.3.4 usually includes many, let's say $N_G$, bins, it is useful to distinguish single-bin and system probabilities. Single-bin probabilities are used in (14.28)–(14.30) and refer to the case that only a single correlation value is considered (either the signal is present in this test bin or not). System probabilities $P'$ consider the whole search space instead. According to [14.13] they are related to the single-bin probabilities by the following equations

$$P'(S_{nc} > \gamma|H_0) \approx 1 - [1 - P(S_{nc} > \gamma|H_0)]^{N_{uc}} ,$$
$$P'(S_{nc} > \gamma|H_1) \approx P(S_{nc} > \gamma|H_1) . \quad (14.38)$$

To discuss system probabilities, the concept of the number of uncorrelated search bins $N_{uc}$ is important. Usually the correlation values are statistically correlated, especially if a fine code phase of Doppler resolution is used. Only if two test bins are separated far enough they can be considered as statistically uncorrelated. $N_{uc}$ is approximately given as

$$N_{uc} = \Delta T f_c T \Delta f_d , \quad (14.39)$$

where $\Delta T$ is the search range in time (code phase direction) in seconds, $f_c$ is the chipping rate of the PRN code in chips per second, $T$ is the coherent integration time in seconds and $\Delta f_d$ is the Doppler range in Hz.

Choosing a proper system false alarm rate $P'(S_{nc} > \gamma|H_0)$ to achieve a minimum detection probability $P'(S_{nc} > \gamma|H_1)$ for a given signal power is highly application dependent. Both are linked to each other via the threshold $\gamma$ and cannot be optimized simultaneously.

If we assume that the search space contains $N_G$ grid points (usually $N_G > N_{uc}$) and the system needs $D_W$ seconds to compute $M_G$ values of $S_{nc}$, then the whole grid is searched in $D_W N_G / M_G$ seconds.

One may, however, decide to perform an acquisition test $S_{nc} > \gamma$ every time the $M_G$ values are available. Then the mean time $T_M$ needed to acquire a single GNSS signal can be computed under several assumptions as [14.13]

$$T_M = \left(\frac{2 - p_d}{2 p_d}\right)\left(\frac{k\left[1 - (1 - p_{fa})^{M_G}\right] + 1}{M_G}\right) N_G D_W . \quad (14.40)$$

The definitions $p_d = P(S_{nc} > \gamma|H_1)$ and $p_{fa} = P(S > \gamma|H_0)$ are used. The symbol $k$ is a penalty factor used to characterize the time needed to detect a false acquisition. If a false signal is incorrectly detected, the system is assumed to spend $kD_W$ seconds to detect its error and then to continue with the normal acquisition procedure. We assume that the true signal parameters lie exactly on one of the grid points and that the correlation values for all other grid points follow a $H_0$ distribution. In other words, if the signal is present on one grid point, it is not present on all the others. We also assume that the position of the true grid point is uniformly distributed over all grid points. Finally, for (14.40) it is assumed that the correlation values on different grid points are uncorrelated, that is $N_G = N_{uc}$.

### 14.3.6 Handling Data Bits and Secondary Codes

Possibly present data bits or data symbols and secondary codes represent a certain challenge during signal acquisition. Those data bits and their exact transition times are generally unknown to the acquisition engine. Whereas the secondary code is known, the code phase within the secondary code is generally unknown during acquisition. Thus the secondary code has a similar effect on acquisition as an unknown data bit. In the following we use the term data bit but do mean data bits (or data symbols in the case where a forward error correction scheme is used) or secondary code chips.

One may easily envisage a situation where a data bit transition occurs in the middle of a coherent integration interval and the first and second half of the correlation cancel each other.

One method, which is called the half-bit method, to cope with this unknown transitions is to subdivide the signal into two interleaving sequences of segments with each of the duration of half the data bit. One of the sequences is then free of transitions. The acquisition engine works on both sequences thereby doubling the number of search bins. It will detect the signal only in one sequence.

Data bit transitions correlate with a residual Doppler frequency within the received navigation signal. For example, a data bit transition in the middle of the integration interval and a residual Doppler frequency of $1/(2T)$ nearly cancel each other. This effect can be exploited especially if a large number of noncoherent integrations is used. Then one can show that the average loss induced by randomly occurring data bit transitions is −2.14 dB for a data bit length of 20 ms and a coherent integration time of 16 ms [14.9]. This loss is an average value over all Doppler frequencies and over the whole primary code-phase range. Although the loss for individual bins might be higher, simply ignoring those data bit transitions is a viable approach during acquisition.

## 14.4 Signal Tracking

After the coarse estimate of initial code delay and carrier Doppler by the acquisition block, the signal tracking is performed to obtain fine estimates of signal parameters of interest. A number of traditional signal tracking loop architectures such as phase-locked-loop (PLL) for carrier-phase tracking, frequency-locked-loop (FLL) for carrier Doppler frequency shift tracking, and delay-locked-loop (DLL) for code delay tracking are widely used as engineering standards in modern digital GNSS receivers.

### 14.4.1 Architecture

In fact, the main purpose of a signal tracking loop is to adjust the input of the local replica signal generators to match the received signals. This is done by adjusting the input of the NCO, which is the rate of change of the signal parameter of interest. This means that the tracking loop is implemented in a form of feedback systems that are closed by the NCO. The signal tracking loop can be considered as the special case of an output feedback control system that has an integrator in the feedback loop as an actuator to track the input signal. Thus, the resulting tracking loop filter is a type of proportional and integrate (PI) controller in control theory. In a PLL (or FLL) the output of the discriminator is the phase (or frequency) error estimate of the input carrier signal, while the code delay error estimate is for a DLL.

Figure 14.8 shows a high-level block diagram of a single-channel signal tracking engine in typical digital GNSS receivers.

The single tracking loop in a single channel of a GNSS receiver is composed of correlators, discriminators, loop filters and NCOs for the code and carrier tracking loops, where the digitized IF signal sequences are applied to the input. The programmable designs of the integration time interval in correlators, the type of discriminators as well as the order and bandwidth of loop filters determine characteristics of the signal tracking loop in terms of the steady-state error and the robustness to dynamic stress [14.10]. The carrier Doppler aiding to code tracking and/or external velocity aiding to the carrier tracking loop can be employed to enhance the signal tracking performance. The lower feedback in Fig. 14.8 illustrates the carrier tracking loop in a traditional digital GNSS receiver, while the upper part is the code tracking loop.

The operation of the signal tracking engine is as follows. The carriers in the digital IF signal sequences are wiped off by the replica carrier signals to produce the $I$ and $Q$ signal components. The replica carrier signals are synthesized by the carrier generator for which the input is the carrier NCO output. The $I$ and $Q$ signal compo-

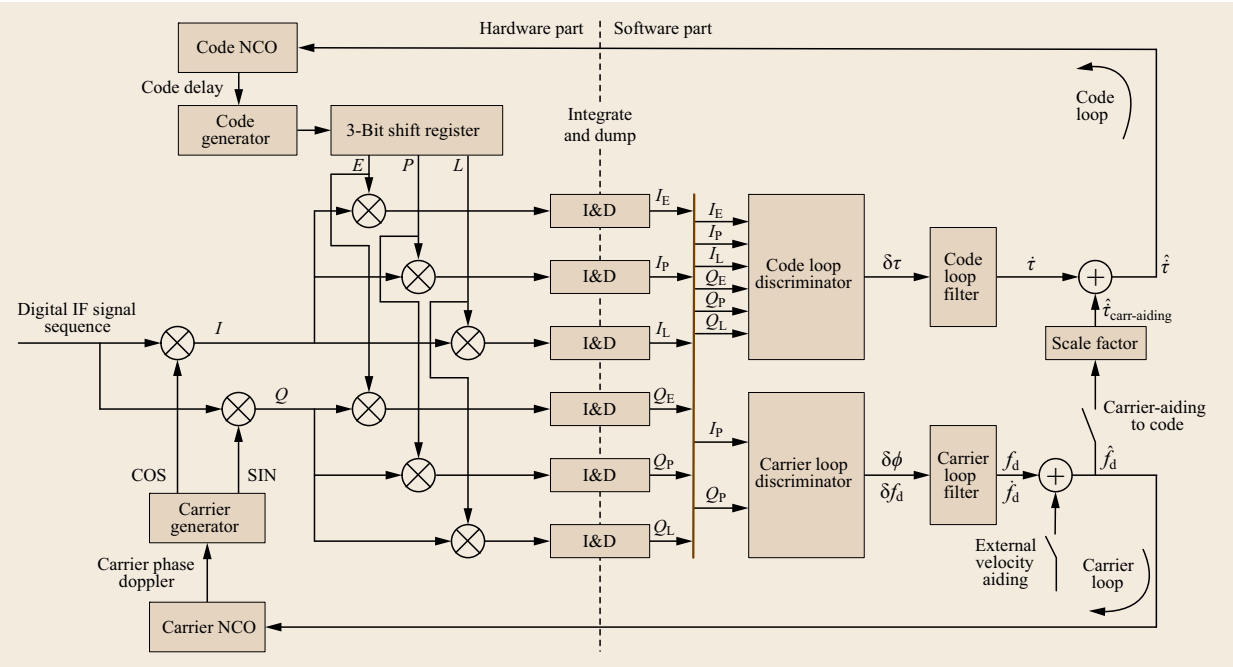

**Fig. 14.8** Block diagram of a GNSS signal tracking engine

nents are then correlated with the replica codes at early, prompt, and late branches (for the most simple case of standard tracking of a BPSK signal). They are, similar to the previous case, synthesized by the code generator with a 3 bit shift register for which the input is the code NCO output. In the closed loop operation, the carrier and code NCOs are controlled by the carrier and code tracking loop, respectively.

Normally, the correlator output at prompt branches is used in the carrier tracking whereas the correlator output at early and late branches are used in the code tracking. In particular, the arctangent of $Q/I$ is used in the carrier discriminator to determine the carrier angle (i. e., phase $\delta\phi$) of the incoming signal with respect to the in-phase ($I$) replica signal of the prompt. For code tracking, the combination of outputs at early and late branches (e.g., early-minus-late) is used in the code discriminator to estimate the delay $\delta\tau$ of the incoming codes with respect to the replica codes. Therefore, the absolute value of $I$ at the prompt branch should be maximum (for PLL), and the vector sum of $I$ and $Q$ at early and late branches should be balanced (for DLL) when the replica signal is successfully aligned to the incoming signal. Finally, the sign of $I$ represents the navigation data bit/symbol.

### 14.4.2 Tracking Loop Model

A basic model for a single-channel signal tracking loop in a GNSS receiver is shown in Fig. 14.9. Note that the input of the signal tracking loop is the signal (i. e., wave) in the continuous time domain, $r(t;\theta(t))$, which is nonlinear in the signal parameter of interest, $\theta$, and its output is the corresponding estimated signal, $\hat{r}(t;\hat{\theta}(t))$. Depending on the type of loop, the parameter $\theta$ may either be the code phase $\tau$ (DLL), the Doppler shift $f_d$ (FLL), or the carrier phase $\phi$ (PLL).

The discriminator output is the signal parameter error, $\delta\theta$, obtained by comparing the incoming signal and the local replica signal. In fact, this process is accomplished by the combination of the correlator outputs, that is the baseband $I$ and $Q$ signal components computed by the nonlinear operation with the received signals and the locally generated replica signals as in (14.23). This discriminator output contains noise that should be efficiently filtered out by the loop filter. Therefore, the tracking process is sensitive in terms of noise effects and dynamic responses rather than the coarse acquisition process. Note that the output of the loop filter is the rate of change information of the signal parameter of interest, $\dot{\theta}$, which is then integrated in the NCO to predict the signal parameter estimate, $\hat{\theta}$, for the next step. This signal parameter estimate is used in the local signal generator to produce the estimated local replica signals for the correlation.

In order to obtain a mathematical description of the tracking loop suitable for subsequent design and analysis, it is desirable to approximate linearly the nonlinear operation of the actual tracking loop. Under the assumption that the tracking error is small enough and that the input noise is uncorrelated with the locally generated replica signal, the linearized tracking loop in the Laplace domain is obtained for actual input signal parameters as shown in Fig. 14.10, where $s = \sigma + j\omega$ denotes the Laplace operator. The difference between Fig. 14.10 and Fig. 14.9 is that the nonlinear operation of the correlator and discriminator for the incoming and local replica signals is substituted by a simple comparator with the linear dependence on signal parameters, where $\theta(s)$ and $\hat{\theta}(s)$ represent the input of the tracking loop and the output from the NCO.

In this linear model we assume that the comparator measures the difference of these two signal parameters to provide the input signal $\delta\theta$ to the loop filter. Assum-

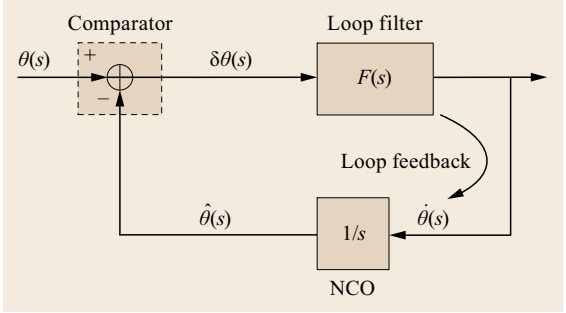

**Fig. 14.10** Linear model of a signal tracking loop in the Laplace domain

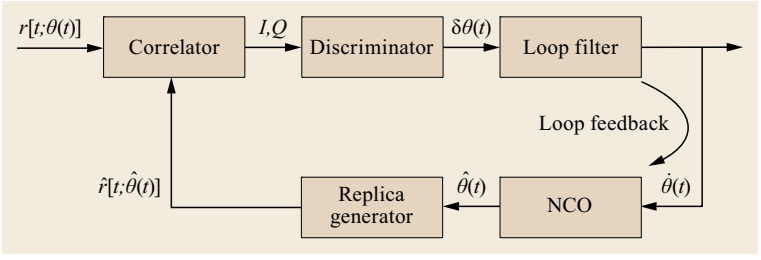

**Fig. 14.9** Nonlinear model of a signal tracking loop in the time domain

ing noise contaminated signal parameters, the output of the comparator is modeled by

$$\delta\theta(s) = \theta(s) - \hat{\theta}(s)\,, \tag{14.41}$$

where $\theta(s) = \theta_0(s) + n_\theta(s)$ is the sum of the nominal value $\theta_0$ of $\theta$ and the corresponding noise $n_\theta$.

The loop filter transfer function $F(s)$ is defined as

$$F(s) = \frac{\dot{\theta}(s)}{\delta\theta(s)}\,, \tag{14.42}$$

where $\dot{\theta}(s)$ and $\delta\theta(s)$ represent the Laplace transforms of the input $\dot{\theta}(t)$ and the output $\delta\theta(t)$ respectively.

The NCO is a simple integrator, therefore its transfer function $N(s) = 1/s$, and its output is modeled by

$$\hat{\theta}(s) = \frac{1}{s}\dot{\theta}(s)\,. \tag{14.43}$$

Assuming a unity gain for the discriminator and NCO, the overall loop transfer function $H(s)$ is given by

$$H(s) = \frac{\hat{\theta}(s)}{\theta(s)} = \frac{N(s)F(s)}{1+N(s)F(s)} = \frac{F(s)}{s+F(s)} \tag{14.44}$$

and its error transfer function $H_e(s)$ is also given by

$$H_e(s) = 1 - H(s) = \frac{s}{s+F(s)}\,. \tag{14.45}$$

Then, the input signal $U(s)$ (e.g., a unit step, ramp, acceleration, etc.) generates the error function given by

$$\varepsilon(s) = H_e(s)U(s)\,. \tag{14.46}$$

The steady-state error can be found by applying the final value theorem of the Laplace transform to (14.46) given by

$$\varepsilon(s=0) = \varepsilon(t=\infty) = \frac{\frac{\mathrm{d}^n G}{\mathrm{d}t^n}}{\omega_0^n}\,, \tag{14.47}$$

where $n$ is the loop filter order and $\mathrm{d}^n G/\mathrm{d}t^n$ is the maximum line-of-sight dynamics. If, for example, $n = 2$, then $\mathrm{d}^2 G/\mathrm{d}t^2$ represent the line-of-sight acceleration. For a $n$th order tracking loop, the natural frequency is denoted by $\omega_0$ and can be computed by using (14.48).

Note that the above steady-state error is a function of the loop filter order $n$; therefore, the type of steady-state error for the signal tracking loop is dependent on the loop filter order.

The equivalent noise bandwidth of $H(s)$ is defined as

$$B_n = \int_0^\infty |H(\mathrm{j}\omega)|^2 \mathrm{d}\omega \;\approxeq\; \begin{cases} \frac{\omega_0}{4} & n = 1\,, \\ \frac{\omega_0}{1.89} & n = 2\,, \\ \frac{\omega_0}{1.2} & n = 3\,, \end{cases} \tag{14.48}$$

where $\omega$ is the angular frequency (rad).

### 14.4.3 Correlators

The correlation process (also known as predetection integration process) in (14.18) is performed by correlators. This is done by two steps:

- The integration and dump for a given interval at hardware correlators after mixing (i. e., multiplying) incoming and local replica signals
- The accumulation of the integration and dumped values for the next $N$ samples in the software.

In this way the receiver's signal processor can extend the integration time with a minimum on hardware resources; for example a 1 ms integration and dump is done with hardware correlators and the accumulation of the next 20 samples for 20 ms of integration time (GPS C/A code) is done in the software. The integration and dump interval, which is normally set to be at least equal to or larger than a single code epoch interval in the tracking loops, multiplied by the $N$ accumulation time in software, determines the bandwidth of the predetection process. The resultant integration time should be as long as possible for the high sensitivity in weak or interfered signals and as short as possible for the robustness to high signal dynamics.

The resulting outputs of correlators are six basic signal processing elements as in (14.23), in particular for BPSK-like signals, which are inputted into the discriminator to produce the signal parameter errors. Depending on the code type and the code tracking algorithm, a larger number of correlator channels can be used in addition to the six basic signal processing elements.

### 14.4.4 Discriminators

The purpose of a discriminator is to extract the signal parameter error information from the correlator outputs $I$ and $Q$ at the early, prompt, and late branches, which are nonlinear functions of the signal parameters of interest to be estimated as in (14.23). The output of the nonlinear discriminator function is the combination of the correlator outputs that is linearly increasing with the input signal parameter error within the linear region, such that the discriminator senses the amount of error in the replica signal with respect to the incoming signal (so-called $S$-curve). The output of the discriminator is then provided to the NCO for the next step in a negative feedback to control the code/carrier generators. This discriminator output may contain a greater noise effect, therefore the loop filter are employed before the NCO in the feedback in order to efficiently suppress the noise effect.

The type of discriminator algorithm determines the type of tracking loop (i. e., PLL, FLL or DLL) as well as relevant characteristics (i. e., phase reversal sensitivity, signal amplitude sensitivity, computational load, pull-in-range, etc.).

### PLL and FLL Discriminators

The carrier loop discriminator determines characteristics of the carrier tracking loop as a carrier-phase tracking loop or a carrier Doppler tracking loop.

For the carrier-phase tracking loop, there are mainly two types: a pure PLL and a Costas PLL. The pure PLL is sensitive to the presence of bit/symbol modulation on the signal. The Costas PLL is insensitive to that if the integration time of the correlator to produce the baseband $I$ and $Q$ does not straddle the data bit/symbol transitions. Both discriminators produces the carrier-phase error (but with different pull-in-ranges) that are used as input to the PLL filter to reduce the noise.

For the carrier Doppler tracking loop, the FLL discriminator produces the carrier Doppler frequency errors that are also used as input into the FLL filter for the same reason.

The carrier-phase tracking loops are more accurate but more sensitive to dynamic stress than the carrier Doppler tracking loop. There is a trade-off between these three methods as shown in Table 14.1. For better accuracy, a PLL for pilot channel or a Costas loop for data channel with lower order and narrow bandwidths should be employed, and vice versa for better robustness to dynamics.

The basic idea of the carrier loop discriminator starts from $Q/I$ at the prompt branch in (14.23) to extract the signal parameter error information (i. e., the carrier-phase error). Under the assumption of no noise in (14.23), the carrier-phase error can be obtained by

$$\frac{Q}{I} = \frac{\sin(\delta\phi)}{\cos(\delta\phi)} = \tan(\delta\phi) \approxeq \delta\phi \quad \text{for } \delta\phi \approx 0\,. \tag{14.49}$$

Taking the arctangent in both sides, we obtain

$$\tan^{-1}\left(\frac{Q}{I}\right) = \delta\phi\,. \tag{14.50}$$

For pure PLLs, the arctangent in (14.50) is substituted by a four-quadrant arctangent in order to remain linear over the full input error range of $\pm 180^\circ$, whereas arctangent for Costas PLLs remains linear over half of the input error range ($\pm 90^\circ$) [14.10]. There are other similar PLL discriminator functions with less computational burden, such as $\text{sign}(I)Q \approxeq \delta\phi$ or $IQ \approxeq 2\delta\phi$, but the slopes of the discriminator outputs are proportional to signal amplitude, which causes nonoptimal properties depending on the signal-to-noise ratio. Beside the algorithm described before, there are several variants of PLL and FLL discriminator algorithms that produce slightly different characteristics in terms of coherent/noncoherent, normalization, and computational complexity [14.10].

**Table 14.1** Trade-off in GNSS receiver carrier tracking loop design

| Loop property | For robustness to dynamics | For accuracy |
|---|---|---|
| Carrier tracking loop type | FLL | PLL (for pilot channel) or Costas (for data channel) |
| Loop filter order | High | Low |
| Loop noise bandwidth | Wide | Narrow |

By applying $I$ to a deadbeat detector (like a signum function), we can obtain the navigation message bits/symbols. However, due to the $\pm 180^\circ$ of phase reversal in Costas PLLs, the ambiguity in the detected navigation symbols exists. This is solved later in the frame synchronization process by using the known preamble bits at the beginning of each subframe (Sect. 14.5.3).

The pull-in range of a PLL is the set of all the initial conditions that lead to phase lock, provided that a stable singular point exists [14.14]. Within this pull-in range the discriminator output is approximately linearly proportional to the input error, and the loop filter can operate correctly to reduce the tracking error finally reaching the zero-crossing point. Therefore, the input value to the loop filter at the initial stage should be sufficiently converged within this pull-in range for the correct loop filter operation; that is the acquisition output (e.g., the coarse code delay and Doppler) should be sufficiently accurate. If this cannot be achieved, the channel has to be operated in FLL mode until the Doppler error gets small enough. Additionally, this pull-in range is significantly related to the dynamic range of the loop filter.

In order to derive the FLL discriminators, we start from the definition of the Doppler frequency, which is the difference between two adjacent phases of baseband samples within the same data symbol [14.15]

$$f_\mathrm{d} \equiv \frac{(\phi_{k+1} - \phi_k)}{T}\,, \tag{14.51}$$

so that the Doppler error, the output of the FLL discriminator, is obtained by applying $\delta$ to both sides

$$\delta f_\mathrm{d} \equiv \frac{(\delta\phi_{k+1} - \delta\phi_k)}{T}\,. \tag{14.52}$$

Here $k$ is used to index baseband samples and $T$ is the coherent integration time.

Applying the tangent function to the right-hand side of (14.52) and using the relationship between $\delta\phi$ and the baseband $I$ and $Q$ signal components in (14.50), we obtain

$$\begin{aligned}\tan(\delta\phi_{k+1}-\delta\phi_k) &= \frac{\tan\delta\phi_{k+1}-\tan\delta\phi_k}{1+\tan\delta\phi_{k+1}\tan\delta\phi_k}\\ &= \frac{\frac{Q_{k+1}}{I_{k+1}}-\frac{Q_k}{I_k}}{1+\left(\frac{Q_{k+1}}{I_{k+1}}\right)\left(\frac{Q_k}{I_k}\right)}\\ &= \frac{I_kQ_{k+1}-I_{k+1}Q_k}{I_kI_{k+1}+Q_kQ_{k+1}}\\ &= \frac{\text{cross}}{\text{dot}}\end{aligned} \tag{14.53}$$

with

$$\begin{aligned}\text{cross} &= I_kQ_{k+1}-I_{k+1}Q_k\,,\\ \text{dot} &= I_kI_{k+1}+Q_kQ_{k+1}\,.\end{aligned}$$

Finally, the combination of dot and cross divided by $T$ represents the Doppler frequency error

$$\frac{\tan^{-1}\left(\frac{\text{cross}}{\text{dot}}\right)}{T} = \delta f_\text{d}\,. \tag{14.54}$$

Intrinsically, the FLL tracks the carrier frequency and not the carrier phase so that the FLL discriminator is insensitive to $\pm 180°$ phase reversals but its integration time must not straddle the navigation data bit/symbol transitions. If not, the phase jump caused by 180° phase reversals acts as a high-frequency component that affects the rest of the processing. Beside the algorithm described before, there are several variants of FLL discriminator algorithms that produce slightly different characteristics in terms of optimality depending on the signal-to-noise ratio, the pull-in range corresponding to the integration time and computational complexity [14.10].

Note that the pull-in range of the FLL discriminator is inversely proportional to the integration time because of the fact that the FLL discriminator output is obtained by using two consecutive pairs of carrier-phase discriminator outputs divided by the integration time.

#### DLL Discriminator

The basic idea of the code loop discriminator is almost the same as the PLL discriminator, but it uses the early and late branches rather than the prompt branch of the carrier loop. In fact, the PLL discriminator is obtained from the first- and/or second-order derivative of the maximum likelihood estimation (MLE) cost function, while the cost function for the code delay, which is a triangular shape of correlation function, is not differentiable at the peak when no error exists. Therefore, half-chip early and half-chip late sampling of the triangular correlation function divided by the given sampling interval, which is an approximate first-order derivative of the cost function, is used.

Figure 14.11 shows how the early, prompt, and late correlators change as the offset of the locally generated code replicas are advanced with respect to the incoming satellite's code signal and the corresponding normalized early-minus-late discriminator output for the relevant five cases of replica code offsets.

If the replica code is aligned, then the early and late branches are equal in amplitude and no error is generated by the discriminator. If not, the early and late samples are not equal by an amount proportional to the code offset, so that the DLL discriminator outputs the relevant error, which is then fed into the closed loop operation through the loop filter to filter out the noise effect.

There are several variants of DLL discriminator algorithms that produce slightly different characteristics in terms of required coherent-noncoherent integrations, accuracy, availability depending on the carrier-lock condition, correlator spacing and computational complexity, described in [14.10]. The most common one is a normalized early-power minus late-power code discriminator

$$\delta\tau = \frac{\alpha_\text{d}}{2(2-d)}\frac{I_\text{E}^2+Q_\text{E}^2-I_\text{L}^2-Q_\text{L}^2}{I_\text{P}^2+Q_\text{P}^2}\,, \tag{14.55}$$

which is in first-order linearly proportional to the code tracking error. The constant $\alpha_\text{d}$ has to be chosen depending on the modulation scheme to achieve unity slope.

In addition, due to the approximation of the nonconvexity cost function by the early and late correlator concept, the correlation spacing $d$ plays an important role in the DLL performance. For example, narrowing the correlator spacing $d$ is beneficial in the reduction of tracking errors in the presence of both noise and multipath whereas a wider precorrelation bandwidth is required, coupled with higher sampling rates and higher processing speed as well as losing the robustness to dynamics [14.16].

### 14.4.5 Loop Filters

One of the most important factors in the signal tracking software is to obtain a loop filter, $F(s)$ in (14.42). Since the discriminator output contains much noise, the purpose of the loop filter is to reduce noise in order to produce an accurate estimate of the original signal.

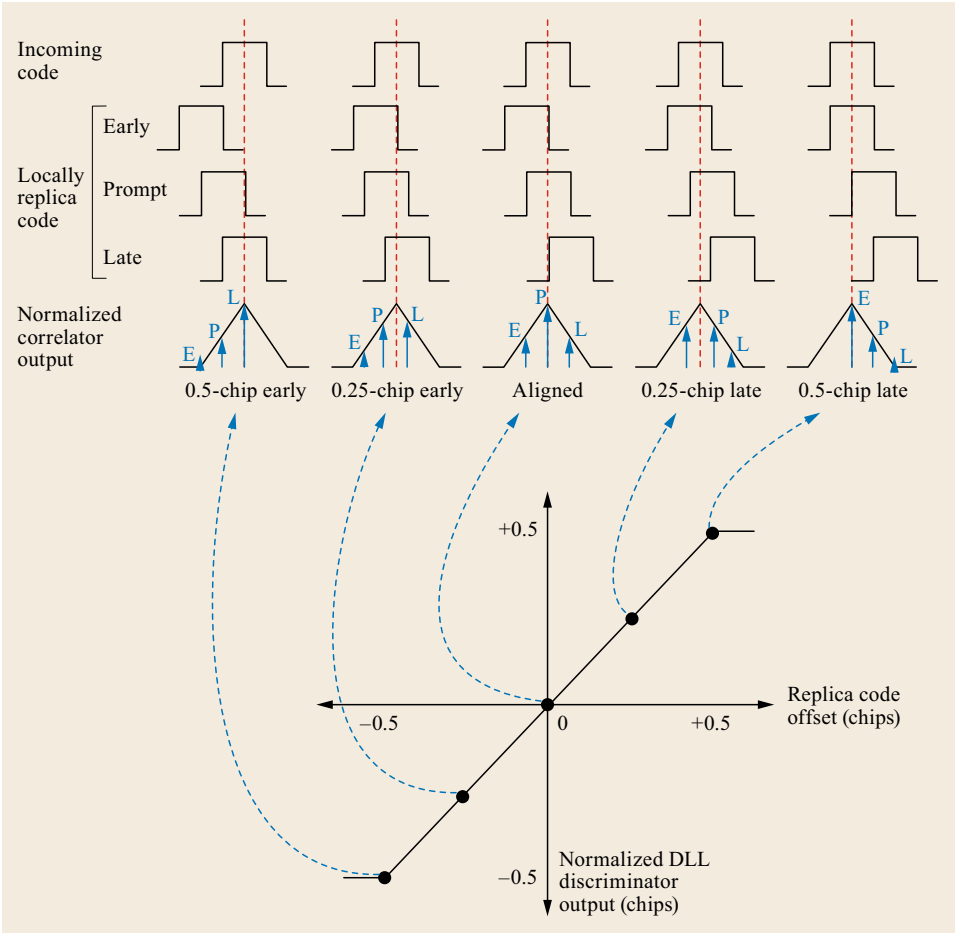

**Fig. 14.11** Early-minus-late DLL discriminator (after [14.10])

The design criteria for the loop filter is to design an optimal filter to minimize the root mean square (RMS) noise error based on the constraint of a transient error specification. This means that the RMS error due to the noise interference in steady state should be minimized in terms of the NCO (code or carrier) phase jitter, while the transient error in the signal (code or carrier) phase due to dynamics should also be maintained at a specific amount at the same time.

There are many different approaches to designing a digital loop filter. One of the design approaches, which is widely used, is to design the overall signal tracking loop in the continuous time domain with existing knowledge of analog loop filters, and then to implement this in the discrete time domain.

One solution for this is offered by the variational method for optimization via a Lagrangian multiplier. An optimal solution for the loop filter in the continuous time domain is given by a function of the loop noise bandwidth as in (14.48), which limits the noise in the loop and can be interpreted as a normal filter coefficient such as a decay ratio, damping ratio, or natural frequency [14.17].

Figure 14.12 shows block diagrams of first-, second- and third-order loop filters. Note that an integrator ($= 1/s$) for the NCO is located additionally in the open loop; the order of a loop filter determines the order of $H(s)$, not $F(s)$, that is for an $n$ th order tracking loop the denominator of the transfer function $H(s)$ is an $n$ th order function of $s$.

The signal tracking loop obtained in the continuous time domain as a differential equation is then transformed into the corresponding discrete equivalent in a difference equation by applying the digital integration method (also known as the $z$-transform method). This is done by replacing $s$ in the continuous transfer function with a function of $z$.

Under the assumption of a simple integration method, the closed-loop transfer function, $H(s)$, can be represented in state-space form for any order of loop

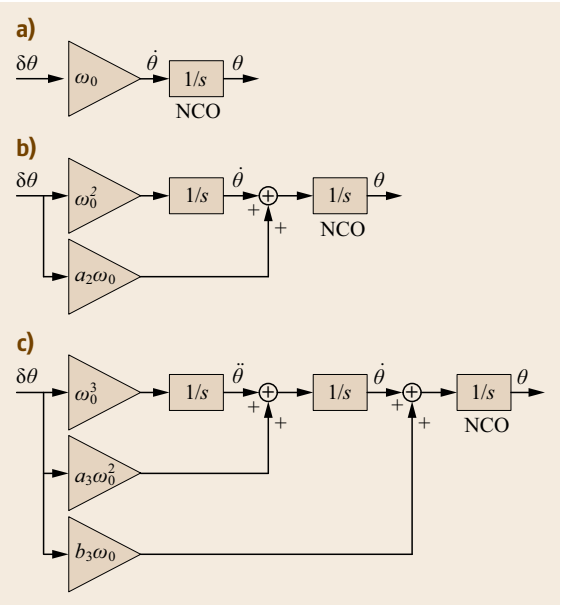

**Fig. 14.12a–c** Block diagrams of loop filters: **(a)** first order, **(b)** second order, and **(c)** third order (after [14.10])

filters

$$\begin{aligned} \boldsymbol{x}_{k+1} &= \mathbf{F}\boldsymbol{x}_k + \mathbf{L}\delta\theta_k \,, \\ \boldsymbol{y}_k &= \mathbf{C}\boldsymbol{x}_k + \mathbf{D}\delta\theta_k \,, \end{aligned} \tag{14.56}$$

where $\boldsymbol{x}$ is the state vector, $\boldsymbol{y}$ is the system output, $\delta\theta$ is the discriminator output, $\mathbf{F}$ is the transition matrix, $\mathbf{L}$ is the filter gain matrix, and $\mathbf{C}$ and $\mathbf{D}$ are the corresponding matrices to obtain the system output from the system state vector and input vector. All of these are dependent on the selected filter order and loop bandwidth.

In a similar way, the open-loop transfer function $F(s)$ in (14.42) can also be expressed in a state-space form for any order of loop filters.

Note that only the second equation of (14.56) is used within a real receiver implementation and links the discriminator output $\delta\theta$ to the NCO (code or carrier) phase and rate contained in $\boldsymbol{x}_k$.

Characteristics of the loop filters of three different orders are summarized in Table 14.2. In the implementation of $F(s)$, a subscript $L$ like $(\cdot)_\mathrm{L}$ is intentionally used to distinguish state-space matrices from continuous time symbols. Note that the state vector of the open loop is the rate information of the closed loop, therefore the order of $\boldsymbol{x}_\mathrm{L}$ is one order less than $\boldsymbol{x}$ due to the NCO in the closed loop; for an example of third-order loop $\boldsymbol{x} = [\theta, \dot{\theta}, \ddot{\theta}]^\top$ and $\boldsymbol{x}_\mathrm{L} = [\dot{\theta}, \ddot{\theta}]^\top$. In the general case of signal dynamics specifications the first-order loop filter is widely employed in the DLL with a Doppler aiding, whereas the second- and third-order loop filters are eventually used in the FLL and PLL respectively.

Note that the tracking loops in the continuous time domain are unconditionally stable by nature but the corresponding discrete equivalents are a kind of sampled data system that is never unconditionally stable. This is due to the fact that high-gain loops in the discrete time domain always result in instability because of the inherent transportation lag, which is a major potential drawback of this kind of system. Moreover, the stability issue becomes serious when the normalized bandwidth (i. e., $BT$ = the product of the loop bandwidth and the loop update time interval) in the discrete systems is insufficiently small compared to a certain threshold. Therefore, the stability issue is an important factor in any kind of digital signal tracking loop.

As a result, the key point in designing a tracking loop filter is to determine both the filter order and the filter noise bandwidth to accommodate user dynamic stress specification based on the noise statistics given by RF specifications of the receiver as well as the integration time [14.17].

### 14.4.6 NCO and Code/Carrier Generator

The signal parameter error sensed at the discriminator is filtered by the loop filter, which produces the signal parameter rate. This signal parameter rate is then applied to the NCO, which is a digital signal generator creating a synchronous, discrete-time, discrete-valued representation of a waveform. The NCO increases or decreases by the rate information as necessary to adjust the local replica signal generator phase with respect to the incoming signal phase. Therefore, mathematically, the NCO can be regarded as a simple integrator that gets the rate and then produces the phase. The obtained phase is then applied to the carrier generator to generate the appropriate carrier wave for the next step. A similar metric is also applied to the code NCO and generator.

Figure 14.13 illustrates a block diagram of the carrier NCO and its digital frequency synthesizer waveform, for example, high and low frequency trigonometric functions. One replica carrier cycle and one replica code cycle repeat each time when the corresponding NCO overflows. In particular for the carrier NCO, a map function that converts the amplitude of the NCO staircase phase output into the appropriate trigonometric function [14.10] is used even in modern digital real-time receivers due to computational efficiency. However, due to the evolution of digital processing techniques and the recent emergence of a software-defined-radio approach for GNSS receivers, a very high resolution NCO to generate a continuous

**Table 14.2** Loop filter characteristics

| | First order | Second order | Third order |
|---|---|---|---|
| Loop filter transfer function | $F(s) = \omega_0$ | $F(s) = \frac{a_2\omega_0 s + \omega_0^2}{s}$ | $F(s) = \frac{b_3\omega_0 s^2 + a_3\omega_0^2 s + \omega_0^3}{s^2}$ |
| Implementation of $F(s)$ | | $\boldsymbol{x}_\mathrm{L} = [\dot{\theta}]$<br>$\mathbf{F}_\mathrm{L} = [1]$<br>$\mathbf{L}_\mathrm{L} = [T\omega_0^2]$<br>$\mathbf{C}_\mathrm{L} = [1]$<br>$\mathbf{D}_\mathrm{L} = [a_2\omega_0]$ | $\boldsymbol{x}_\mathrm{L} = [\dot{\theta}, \ddot{\theta}]^\top$<br>$\mathbf{F}_\mathrm{L} = \begin{bmatrix} 1 & T \\ 0 & 1 \end{bmatrix}$<br>$\mathbf{L}_\mathrm{L} = [Ta_3\omega_0^2 \quad T\omega_0^3]^\top$<br>$\mathbf{C}_\mathrm{L} = [1 \quad 0]$<br>$\mathbf{D}_\mathrm{L} = [b_3\omega_0]$ |
| Closed-loop transfer function | $H(s) = \frac{\omega_0}{s + \omega_0}$ | $H(s) = \frac{a_2\omega_0 s + \omega_0^2}{s^2 + a_2\omega_0 s + \omega_0^2}$ | $H(s) = \frac{b_3\omega_0 s^2 + a_3\omega_0^2 s + \omega_0^3}{s^3 + b_3\omega_0 s^2 + a_3\omega_0^2 s + \omega_0^3}$ |
| Implementation of $H(s)$ | $\boldsymbol{x} = [\theta]$<br>$\mathbf{F} = [1]$<br>$\mathbf{L} = [T\omega_0]$<br>$\mathbf{C} = [1]$<br>$\mathbf{D} = [0]$ | $\boldsymbol{x} = [\theta, \dot{\theta}]^\top$<br>$\mathbf{F} = \begin{bmatrix} 1 & T \\ 0 & 1 \end{bmatrix}$<br>$\mathbf{L} = [Ta_2\omega_0 \quad T\omega_0^2]$<br>$\mathbf{C} = [1 \quad 0]$<br>$\mathbf{D} = [0]$ | $\boldsymbol{x} = [\theta, \dot{\theta}, \ddot{\theta}]^\top$<br>$\mathbf{F} = \begin{bmatrix} 1 & T & 0 \\ 0 & 1 & T \\ 0 & 0 & 1 \end{bmatrix}$<br>$\mathbf{L} = [Tb_3\omega_0 \quad Ta_3\omega_0^2 \quad T\omega_0^3]^\top$<br>$\mathbf{C} = [1 \quad 0 \quad 0]$<br>$\mathbf{D} = [0]$ |
| Loop noise bandwidth | $B_n = \frac{\omega_0}{4}$ | $B_n = \frac{\omega_0}{1.89}$ | $B_n = \frac{\omega_0}{1.2}$ |

waveform based on a powerful processor is employed for the GNSS signal processing.

### 14.4.7 Aiding

As shown in Fig. 14.8 the use of aiding information on each tracking loop in a closed-loop operation enhances its performance. The aiding information is a rate of change of the corresponding signal parameter of interest; that is the velocity aiding is applied in order to enhance the tracking performance of the code delay or the carrier phase.

#### Carrier-Doppler Aided Code Tracking

There are two sources for measuring distance between the satellite and the user. The range information of the carrier phase is equivalent to the code delay at a much smaller noise level plus a bias. Therefore, the Doppler information from the carrier tracking loop can be used for estimating the code rate information after a proper scaling. In this case the loop bandwidth of the code tracking loop can be extremely narrowed. A reversal way to attempt to aid the carrier Doppler tracking by using the code rate would not be feasible due to the weak link property of the carrier tracking loop in terms of the receiver dynamics and thermal noise effects in comparison to the code tracking loop [14.10].

#### External Doppler-Aided Carrier Tracking

Alternatively, most of the signal dynamics can be captured by external aiding sensors – mostly inertial measurement units. Therefore, the velocity information from an external aiding sensor can be used for the carrier tracking with a quite narrow loop bandwidth. The velocity information obtained by an external sensor in the navigational frame is converted into the line-of-sight domain between the user and satellites, which is then applied to the carrier Doppler tracking in each channel. This external velocity aiding to the Doppler tracking will also help the code tracking in such a way as stated before.

### 14.4.8 Switching Rule

The signal processing starts with the acquisition. If a signal is present, which can be detected by testing the signal power, the signal processing enters the FLL, continuously checking the code lock. If the code and frequency are then locked the processing moves to the PLL, continuously checking the phase lock. If either phase lock or code lock is lost, then the processing goes back and proceeds again. This can be done by resetting (or reconfiguring) the weight factor of the PLL and FLL (Sect. 14.7.4).

However, for a short period immediately after the tracking loops start, they are especially sensitive due to the large uncertainty in the signal parameter estimates obtained from the acquisition (e.g., 180° for carrier phase, several hundreds Hz for Doppler and a half-chip for code). Therefore, the bandwidth of each tracking loop should be chosen to be sufficiently larger than the actual noise bandwidth of the input signal in the initial stage, in order for system robustness at the beginning. This is because of the fact that the signal tracking loop is a kind of multi-input multi-output (MIMO) system, which has three distinct input and outputs such as carrier phase, Doppler, and code delay, but each tracking loop is designed separately on the assumption of a single-input single-output (SISO) system with no error for other loops. This is only valid generally in steady state; for example a DLL is derived assuming PLL and FLL are perfectly working ($\delta\phi = 0$ and $\delta f_\mathrm{d} = 0$), and PLL and/or FLL are designed in a similar way. Therefore, at the initial stage, each tracking loop has a certain amount of error that may be correlated with the error of other loops.

Furthermore, due to the nature of system dynamics, both the carrier tracking loop and the code tracking loop are sophisticated systems that will take a while to converge within the small error bound in the steady-state region after the transient time.

Figure 14.14 shows the independent step responses of the PLL, FLL and DLL with commonly used bandwidths in the proper region. Note that the settling time of the FLL is quite a bit longer than those of the PLL and DLL (e.g., the settling time of the FLL is larger than 4–5 s, whereas the PLL and DLL have a quite shorter settling time of less than 1 s). The FLL plays an important role in the tracking loop in the initial stage in terms of aiding capability to DLL and PLL. This is because the minimum required $C/N_0$ of FLL is low in comparison to the PLL and the Doppler-aided code delay estimate from the FLL is much less noisy than the unaided DLL; in another words, the PLL and DLL begin to work correctly after the FLL works properly.

These facts should be taken into account in an appropriate way such that a wide bandwidth is preferable to be accepted especially at the beginning of the loop filter operation and then switched to narrower ones after the transient time to retain the robustness. In particular, the bandwidth switching of PLL from wide to narrow should not be faster than the time when the FLL converges sufficiently to a steady state. If not, the phase error of $\pm 90°$ will occur and the PLL may not work correctly. A third-order PLL assisted with a second-order FLL for the unaided carrier tracking, together with a quite narrowband first-order DLL aided by Doppler from the carrier tracking loop is used for civilian purpose GNSS receivers.

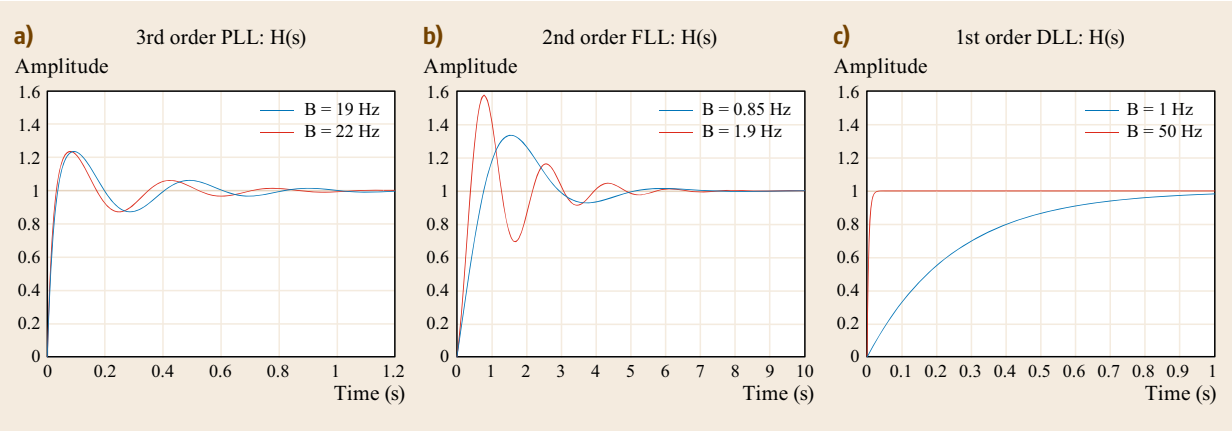

**Fig. 14.14a–c** Step response of tracking loops: **(a)** the third-order PLL, **(b)** the second-order FLL and **(c)** the first-order DLL (after [14.18])

### 14.4.9 BOC Tracking

Some of the upcoming GNSS signals have been designed to implement a BOC modulation that offers improved performance in terms of code tracking accuracy, robustness to interference, and interoperability, while offering a spectral separation from BPSK-like signals due to its split spectrum [14.19]. However, the main drawback of BOC-like signals is their multipeak autocorrelation function yielding multiple zero-crossing points in the code discriminator function that implies possible biased tracking (or false acquisition) if no special care is considered [14.3]. Therefore, the BOC ambiguity problem should be solved to force the receiver signal processor to lock onto the central peak. Several schemes for unambiguous tracking of BOC-like signals have been reported [14.3–6]. One of the most obvious ways for this is the bump-jump method. It uses two correlation channels like very early (VE) and very late (VL), in addition to the typical correlation channels early (E), prompt (P), and late (L) where the VE and VL correlators are separated from the P correlators by a code delay very close to half the inverse of the offset carrier frequency, that is one peak apart [14.4, 5]. In this method the tracker is controlled to jump in the appropriate direction when the VE and VL correlation values are consistently higher than the P correlation values. The number of correlation channels for VE and VL may increase with appropriate code delays as the order of BOC-like signals (e.g., MBOC or Galileo PRS) increases.

### 14.4.10 Tracking Performance

Under the assumption of no multipath, the dominant sources of tracking error in a tracking loop of a GNSS receiver are composed of tracking jitter and dynamic stress error (induced by signal dynamics). The tracking loops may maintain their lock when the tracking errors are sufficiently well controlled to be less than thresholds corresponding to the rule-of-thumb design strategy of tracking loops; the 3-$\sigma$ tracking jitter has to be reliably less than the pull-in range of the corresponding discriminator in order to guarantee more than 99.7% of lock condition. If this rule of thumb is violated, the satellite signal will most likely be lost [14.10]. The rule of thumb is written as

$$3\sigma_{\mathrm{XLL}} = 3\sigma_{\mathrm{j,XLL}} + \varepsilon_{\mathrm{D,XLL}} \leq T_{\mathrm{XLL}} \,, \tag{14.57}$$

where $\sigma_{\mathrm{XLL}}$ is the 1-sigma PLL, FLL or DLL tracking error, $\sigma_{\mathrm{j,XLL}}$ is the 1-sigma phase, Doppler or code delay jitter from all sources except dynamic stress error, and $\varepsilon_{\mathrm{D,XLL}}$ and $T_{\mathrm{XLL}}$ are the dynamic stress error and the rule-of-thumb threshold obtained from the pull-in range of discriminator in the corresponding tracking loop, respectively (see [14.10] for more details in mathematical expression of each error source).

Figure 14.15 illustrates the tracking error with respect to $C/N_0$. There are six key factors in the tracking loop jitter plots (Table 14.3). The tracking loop should be designed to have low minimum $C/N_0$ to lock onto the signal, to have small noise jitter error, a narrow spreading width and a large design margin. Unfortunately, no method to simultaneously fulfill all these requirements exists.

Depending on the type of tracking loop, the main sources of tracking error as well as the tracking threshold are different. The tracking jitter of a PLL consists of the thermal noise error, oscillator's Allan variance error, vibration-induced oscillator error, ionospheric scintil-

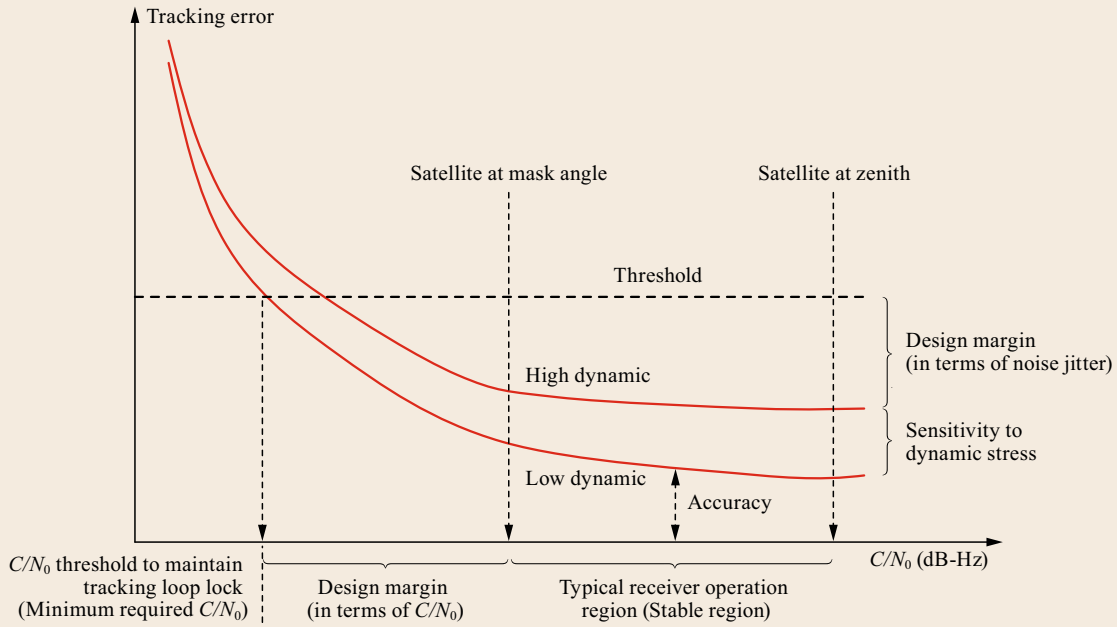

**Fig. 14.15** An illustrative example of tracking loop error versus $C/N_0$

**Table 14.3** Key factors in tracking loop jitter line

| Key factors | Description |
|---|---|
| Minimal required $C/N_0$ | The intersection point of noise jitter line with the threshold line; allowable $C/N_0$ |
| Accuracy | A noise jitter at a certain $C/N_0$ in stable region |
| Dynamic stress sensitivity | Spreading width of noise jitter lines; sensitivity of tracking loop to dynamic stress; if the tracking loop is designed to be robust to signal dynamics the spreading width of noise jitter lines might be narrow for given dynamics |
| Design margin (in terms of noise jitter) | Threshold minus noise jitter at a certain $C/N_0$; signal tracking loop stability margin |
| Design margin (in terms of $C/N_0$) | Start point of stable region minus required minimal $C/N_0$ |
| Stable region | Typical operating range of tracking loops; noise jitter line is aligned almost horizontally and produces a reasonable accuracy |

lation error, and so on. The tracking jitter of FLL and DLL consists mainly thermal noise error.

The tracking threshold of a Costas PLL is normally 45° for a data channel and a pure PLL for a pilot channel has a 90° threshold.

The thermal noise error of a PLL is a function of the loop bandwidth and $C/N_0$, while the FLL and DLL additionally require the contributions of the integration time $T$ and the correlator spacing $d$, respectively. Both are also related to their tracking thresholds. Also, the thermal noise error of the tracking loops is slightly dependent on the discriminator algorithm employed and affected by the squaring loss that is dependent on the integration time $T$. The larger the $C/N_0$ is or the narrower the loop bandwidth is, the less thermal noise error is effectively achieved. Furthermore, a longer integration time or a smaller correlator spacing results in a better tracking accuracy in terms of thermal noise.

It should be noted that, in particular, the thermal noise error of a DLL is affected by the shape of the power spectral density of the signal weighted with $(f - f_L)^2$. This weighted power spectral density is the Fourier transform of the second derivative $R''(\tau)$ of the autocorrelation function and its integral over frequency is called the *Gabor bandwidth*. This means BOC-like signals, occupying the same bandwidth as BPSK-like signals but having more signal power at the spectrum edge, have a larger Garbor bandwidth [14.20] and thus a sharper correlation peak. Therefore, the BOC tracking accuracy is better than that of BPSK-like signal.

The vibration-induced oscillator jitter of a PLL is caused by external vibration, which can be modeled by the oscillator's g-sensitivity, the vibration intensity and the frequency range of vibrations for different orders of loop filter as well as different carrier frequencies [14.21]. This can be a major problem for dynamic applications. Vibration isolators in mounting the oscillator should be taken into account to reduce its impact on PLL.

The oscillator's Allan variance jitter of a PLL is a natural phase noise resulting from frequency instability, which can be modeled by three (so-called) clock parameters ($h_{-2}$, $h_{-1}$, $h_0$) and the averaging time, depending on the oscillator grade for different orders of loop filter as well as different carrier frequencies [14.21, 22]. The oscillator's Allan variation jitter is proportional to the carrier frequency. The use of a high-grade oscillator is important in reducing the oscillator's Allan variation jitter.

The dynamic stress error is due to the relative motion between user and satellites, therefore it is a major problem for high-dynamic users, principally degrading the tracking performance. It is dependent on the signal dynamics, which is proportional to the carrier frequency, and the loop bandwidth for different orders of loop filter. The first-order loops are sensitive to velocity stress, while the second- and third-order loops are sensitive to acceleration and jerk type stress respectively. It can be reduced if a lower carrier frequency and narrower loop bandwidths are used.

The ionospheric scintillation error of a PLL is due to ionization density irregularities, making signals change phase unexpectedly and varying rapidly in magnitude (see Sect. 6.3.3 of this Handbook). Ionospheric scintillation effects vary with an 11-year period of solar activity, mainly in low (tropical) and high latitude regions. The ionospheric scintillation effect can be modeled by an amplitude fade scintillation and phase variation scintillation. The strength of the amplitude scintillation is typically quantified by a metric called $S_4$-index, which is the ratio of the standard deviation of the signal power to the mean signal power computed over a period of time [14.23]. In order to effectively track scintillating GNSS signals, it was demonstrated that a third-order PLL with $T \approx 10\,\text{ms}$ and $B \approx 10\,\text{Hz}$ provided good values for tracking of GPS L1 C/A code receivers in the presence of scintillations [14.24]. If the receiver application does not require carrier-phase lock, a FLL is preferable instead of a PLL since the FLL is more robust than a PLL during scintillation. Also a variable bandwidth PLL, designed to maintain lock during ionospheric scintillations, could be a good solution [14.25].

More detailed information on the tracking performance will be provided in Sect. 14.6.

## 14.5 Time Synchronization and Data Demodulation

By demodulating the navigation data message, the receiver is able to obtain all the necessary information for positioning (e.g., satellite ephemeris or atmospheric model parameters) and is also able to retrieve the transmission epoch of the satellite signal in an absolute sense.

The tracking process inside the receiver tries to steer $\delta\tau$ as defined in (14.10) towards zero. Thus the code phase $\hat{\nu}$ of the replica signal, defined as

$$\hat{\nu}(k) = T_s k - \hat{\tau} \tag{14.58}$$

follows the code phase $\nu$ of the received signal, defined as

$$\nu(k) = T_s k - \tau\,. \tag{14.59}$$

The code phase is per definition equal to the transmission epoch of the signal in the nominal satellite timescale modulo the code period. Thus by knowing the code phase, the transmission epoch of the GNSS signal received at the epoch $k$ is known modulo the code period.

To get the transmission epoch in absolute time, the number of code periods having already been broadcast by the satellite since a certain reference epoch (e.g., nominal week number 0 and second 0) has to be known. This number is sometimes called *code ambiguity*. The necessary information to achieve this is embedded in the navigation data message. For GPS it is composed of a week number and a so-called *Z-count* defining the time within the week in multiples of 6s. The latter term is called *time of week*. Other GNSSs use similar definitions. Overall those data fields define the transmission time of a certain bit boundary within the navigation message. Bit boundaries coincide with PRN code boundaries. After decoding the time information for this reference PRN code boundary, the channel keeps track of the received code periods and is always able to tell the transmission time in an absolute sense.

The process of resolving the code ambiguity can often be done without the message itself. The ambiguity

is rather long (typically at least 1 ms ≈ 300 km). Thus if the same satellite is tracked on a different frequency (e.g., already on L1), then the ambiguity on L5 for example can be easily derived from the first frequency. Other methods rely on consistency considerations making use of approximate user coordinates and satellite ephemeris data.

### 14.5.1 Bit/Symbol Synchronization

The binary units that are used to represent the navigation data message $d(t)$ are called bits or symbols. The term symbols is used in the case where the message employs a *forward error correction* scheme (like for the GPS civil navigation message (CNAV) on L2 or L5, or all Galileo messages). Otherwise the term bits is used (e.g., for the GPS NAV message on L1).

The number of primary code periods within one bit/symbol is an integer but can be larger than 1. Furthermore, a so-called secondary code sequence can be used, which alternates the sign of the primary code periods within one bit/symbol.

For the example of the GPS L5 data component, the secondary code is 1111001010. A 1 indicates to reverse the sign of the primary code, a 0 to keep the primary code sign. The length of the secondary code generally equals the bit/symbol duration. For the GPS L5 data component, the primary code has 10 230 chips, a duration of 1 ms and a data rate of 100 sps.

In case of the GPS C/A code signal on L1, the primary PRN code repeats 20 times within one data bit, which results in a trivial secondary code (= 00000000000000000000). All C/A code PRN sequences have the same sign within one bit.

A secondary code can also be present on pilot signal components.

The process of bit/symbol synchronization is sometimes also called secondary code synchronization. Once it has been achieved, the secondary code can be removed from the correlation values, which can then be added up coherently. This allows for increasing the coherent integration time from, for example, 1 ms to 10 ms, which is usually beneficial for the tracking process in terms of sensitivity and accuracy (the squaring loss decreases). Furthermore, the carrier phase can be retrieved unambiguously in the full range of ±180° as the sign of the secondary code is known.

A useful illustration of this process is shown in Fig. 14.16. Here the in-phase component of the data and pilot component of a rather clean Galileo E1 open service signal are plotted as a function of time. Phase lock has already been achieved and most signal power is in the in-phase component. The coherent integration time for data and pilot is here 4 ms corresponding to the primary code period.

At $t \approx 8.1$ s the receiver achieved secondary code synchronization on the pilot channel. Before this epoch the secondary code (= 00111000000010101101100 10) can be identified even visually on the pilot. After synchronization, the channel removes the secondary code from the correlation values, and corrects for the initially incorrect phase offset of 180°. The pilot correlation values change from being negative to the positive side.

There are several different algorithms possible to achieve secondary code synchronization. They can be grouped into the following categories:

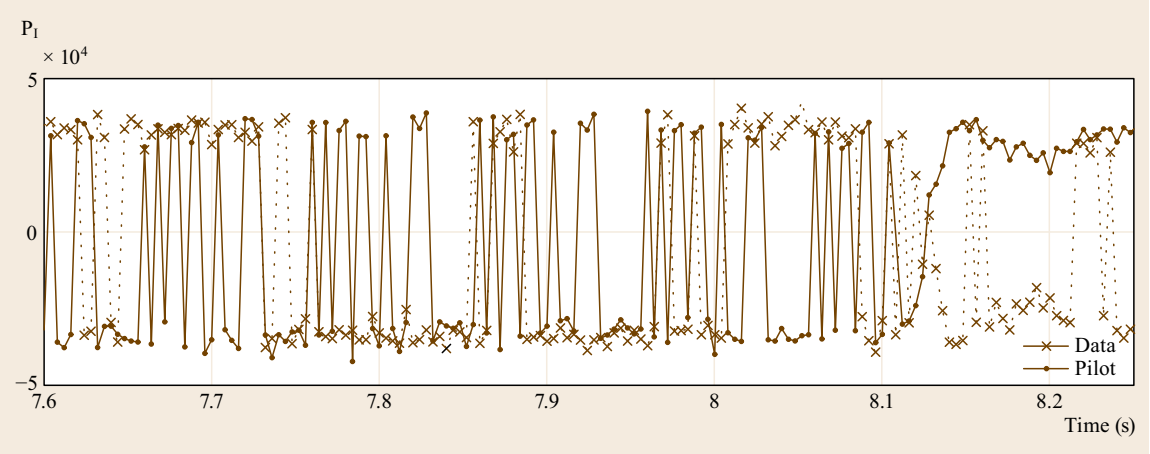

**Fig. 14.16** Prompt correlator in-phase values while symbol synchronization is achieved on the pilot for an E1 Galileo open service satellite signal

- Histogram method (GPS C/A or Russian Global Navigation Satellite System (GLONASS) only)
- Postcorrelation search
- Dedicated tracking verification channels.

The histogram method works for all signals with a trivial secondary code. The algorithm detects bit transitions between primary code boundaries using for example the bit-transition-sensitive discriminator explained later in (14.61). Assuming a certain run time $R$ of the algorithm (e.g., for 1 s runtime, $R = 1000$ in the case of GPS C/A), a histogram is set up with the number of bins $L$ equal to the number of primary codes within one data bit (e.g., $L = 20$ in the case of the GPS C/A signal). Each bin $n$ counts the events of $\mathrm{dot}_{k \bmod L = n} < 0$ using the definition (14.61). Here $k \bmod L$ denotes $k$ modulo $L$. At the true bit transition bin $n_\mathrm{t}$, there will be on average $R/(2L)$ counts. The other bins generally contain zero counts for high signal power. It is relatively easy to find appropriate thresholds to identify the correct bin transition epoch.

For the postcorrelation method, the tracking channel produces prompt $I/Q$ correlation values based on a coherent integration time equal to the primary code period. Let now $s_k$ denote the secondary code sequence. Assuming again a certain runtime $R$ of the algorithm, the following test metric can be used to identify the true bit/symbol transition

$$\hat{n}_\mathrm{t} = \arg\max_{n_\mathrm{t}} \sum_{k=1}^{R/L} \left| \sum_{l=1}^{L} \left( I_{P,Lk+l-n_\mathrm{t}} + \mathrm{j} Q_{P,Lk+l-n_\mathrm{t}} \right) s_l \right|^2 . \tag{14.60}$$

The postcorrelation method can be extended to estimate also residual Doppler frequency errors, which are typically present at this point of signal tracking as the Doppler estimate from the acquisition engine is rather crude [14.26].

The disadvantage of the postcorrelation and the histogram method is that the underlying tracking channel operates with the short coherent integration time determined by the primary code period. It is often only 1 ms, which makes it difficult to track the signal in for example moderate indoor conditions or under canopy. A solution to circumvent this problem can be realized if an abundance of tracking channels is available (which is not a problem for today's application specific integrated circuit (ASIC) or CPU technology). Then not only one tracking channel is started per acquired PRN code, but $L$ channels are started and each channel assumes a certain bit/symbol transition epoch (the number of hypothesizes equals to $L$). Each channel employs a much longer integration time (e.g., 20 ms). The channel with the correct hypothesis will finally turn out the highest estimated signal power and after that the other channels are stopped.

### 14.5.2 Data Bit/Symbol Demodulation

Once bit/symbol synchronization has been achieved, the navigation data message can be stripped off from the received signal. This is rather straightforward and three major scenarios can be considered.

The most direct way occurs if a pilot signal is present and phase lock has been achieved (e.g., Fig. 14.16). Then the in-phase prompt correlator values $I_{\mathrm{P},k}$ of the data-bearing component correspond to the bits or symbols (the index $k$ is used to enumerate the sequence of values). Usually a positive in-phase correlator value is attributed to a bit value of 0 and a negative correlator value to a bit value of 1. The case of a zero in-phase correlator value is very unlikely to occur and can be handled either way.

The second scenario is the case of no pilot signal being present but phase lock having been achieved using a Costas PLL. The bits/symbols can be again retrieved from the sign of the in-phase prompt correlator values $I_{\mathrm{P},k}$, but one doesn't know if the navigation message is inverted or not. A possible inversion is resolved later in the decoding process.

Finally, the third scenario corresponds to the case where frequency lock is achieved but no phase lock. Then the sign of the in-phase prompt correlation values cannot be used directly for demodulation. Instead one computes phase transitions between two epochs like the dot term of the FLL discriminator,

$$\mathrm{dot}_k = I_k I_{k+1} + Q_k Q_{k+1} . \tag{14.61}$$

If the dot term is positive, the assumed bit/symbol sequence keeps the same sign, if it is negative the sign changes. Like for the second scenario, one does not know if the resulting bit/symbol sequence is inverted or not. Furthermore an erroneous estimate of one transition inverts the whole resulting bit/symbol stream from that epoch on. Frequency tracking can be applied for lower received signal powers compared to phase tracking. But still the frequency tracking errors need to be reasonable, in order not to mix up residual frequency contributions with bit/symbol transitions.

The bit/symbol error rate can be evaluated analytically if one assumes perfect phase or frequency tracking. In that case, bit/symbol errors occur due to the fact that $I_{\mathrm{P},k}$ and $Q_{\mathrm{P},k}$ are nonzero Gaussian random variables. If the noise exceeds the signal amplitude, bit/symbol errors occur. For the first and second sce-

nario, the bit/symbol error rate (BER) is given by

$$\mathrm{BER}_{\mathrm{PLL}} = \frac{1}{2}\mathrm{erfc}\,\sqrt{TC/N_0} \tag{14.62}$$

with $\mathrm{erfc}(x) = 1 - \mathrm{erf}(x)$ denoting the complementary error function. For the third scenario the bit/symbol transition error rate (TER) is given by

$$\mathrm{TER}_{\mathrm{FLL}} = \frac{1}{2}\exp(-2TC/N_0)\,. \tag{14.63}$$

Generally, the thermal noise contribution to the bit/symbol error rate is rather small and errors are more likely to occur due to tracking errors, occasional blocking of the line-of-sight or signal fading effects. Those contributions can, however, not be tackled in a simple analytic way [14.27].

### 14.5.3 Frame Synchronization

The various navigation messages have their own structure, but the data is generally organized in blocks called frames, pages, subframes or similar. One core task of the decoder is to identify the beginning of such a block. This is facilitated by a so-called preamble. The preamble is a well-defined bit/symbol sequence broadcast at the beginning of the block. A few exemplary preambles are shown in Table 14.4.

For most navigation messages (e.g., GPS C/A NAV, GLONASS, Galileo, Beidou), the preamble can be found in the bit/symbol stream directly after demodulation. That is, no forward error correction scheme as described in Sect. 14.5.4 is employed for it. Prominent exceptions are the satellite-based augmentation system (SBAS) and the GPS L2/L5 CNAV messages, where the forward error correction scheme also includes the preamble. In that case, the Viterbi decoder has to be applied first, before searching the preamble.

If the absolute sign of the navigation message is not determined by the demodulation, two hypotheses for the preamble have to be tested. The normal and the inverted preamble have to be searched.

Once the preamble has been identified, a predefined number of bits/symbols representing the block of the navigation data message is passed to the decoder. If the inverted preamble has been found, the block has also to be inverted. If the decoder is able to validate this block of data, by for example employing parity checks, the channel achieves *frame synchronization*. Usually a few trials are necessary, as the preamble is rather short and it is likely that also part of the block data is mistaken for it.

**Table 14.4** Navigation message preambles for GNSS signals near the L1 frequency

| Message | Preamble |
|---|---|
| GPS NAV L1 | 1000101100 |
| GLONASS | 11111000110111010100000010010110 |
| Galileo INAV E1 | 0101100000 |
| Beidou D1 | 11100010010 |

### 14.5.4 Bit Error Correction

To improve the resilience of the receiver against bit/symbol errors caused by distortions in the signal propagation channel, various measures have been employed by the GNSS signal designers. Those techniques reduce the bit error rate (error correction) and provide means to verify that bits have been received correctly (error detection):

- Parity bits
- Forward error correction
- Interleaving.

For example, the smallest data block of the GPS C/A NAV message (called a word) consists of 30 bit and six of them are parity bits. The underlying algorithm to compute parity is given in [14.28]. For more recently designed navigation messages, parity is often computed using cyclic redundancy checks (CRC), which are well suited to detect burst errors (contiguous sequences of erroneous data) [14.29, 30].

To allow also the correction of erroneously transmitted symbols, so-called *forward error correction* (FEC) schemes are employed.

Typically in GNSS a FEC 1/2 with a constraint length of 7 is used. The broadcast navigation data bits are convoluted with two different bit sequences (often called polynomials in this context) of length 7. The output of those two convolutions is timely multiplexed resulting in the symbol stream. The symbol stream has twice the data rate of the bit stream. The encoding can be performed in a continuous way over the whole navigation message (e.g., GPS CNAV, SBAS) or over selected block of the message (e.g., for Galileo messages). The receiver employs a so-called Viterbi decoder to decode the symbols and to retrieve the data bits from it. The decoder is not only able to identify bit errors but is also able to correct them to some extent. The Viterbi decoder causes a delay in the data stream, which has to be accounted for when the time of week is retrieved from the message.

As the Viterbi algorithm has generally a better performance if symbol errors are equally distributed in the data stream but burst errors are more likely to occur during the transmission, so-called interleaving is

employed. The symbols within one block of data are reshuffled in a defined way, such that burst errors are spread out. The receiver has to rearrange the symbols before passing them to the Viterbi decoder.

The Galileo INAV messages transmits identical data on E1 and E5b but in a timely different order. So-called even and odd pages alternate on the two signals. This allows a dual-frequency receiver to decode the navigation message in a shorter time frame and also increases the robustness against burst errors.

A GNSS navigation message changes its content typically only every few hours, when new ephemeris data is uploaded from the ground segment. It is therefore possible to increase the decoding sensitivity of a receiver by stacking multiple instances of the received data stream. Furthermore, the message can be relatively well predicted ($\approx 99\%$) once it has been received completely. This generally increases the robustness for carrier-phase tracking as four-quadrant phase discriminators can be employed instead of Costas discriminators.

### 14.5.5 Data Extraction

Once the message has been received and all parity checks have passed successfully the data content can be read. It consists of a sequence of bit-fields and each field typically represents a signed or unsigned integer number. Those integers are converted to floating point numbers using scale factors and offsets. The precise algorithms can be found in the interface control documents (ICDs).

## 14.6 GNSS Measurements

The primary measurements of a tracking channel are:

- The estimated code pseudorange between satellite and receiver
- The estimated Doppler of the received signal
- The estimated carrier phase (or carrier pseudorange) of the received signal
- The estimated amplitude (or power) of the received signal.

These four values are generated for each tracked GNSS signal by the receiver. If the receiver tracks multiple signals or services of one satellite, then independent values are generated for each signal. The output rate is application dependent and usually ranges from 1–20 Hz. The measurements are taken at exactly the same epoch for all tracking channels. If a navigation signal consists of a data and pilot component, then it is common practice to output one single measurement set incorporating contributions from both components, as most of the important error sources (multipath, transient errors or hardware delays) are highly correlated between these components anyway. Only the carrier pseudorange might be based on the pilot component only, as this is free of the 180° ambiguity.

Usually the measurement epoch is aligned to GNSS time (most commonly to the GPS time). This ensures that data from different receivers can be properly aligned to each other, which could otherwise become tricky if each receiver would rely on its own clock. The measurements of two different receivers would tend to shift with respect to each other.

The measurements reflect the true receiver position, velocity and the receiver clock behavior. Furthermore, several atmospheric effects, receiver-satellite hardware components and signal processing artifacts influence the measurements. The relation between those unknowns and the measurements are called *observation equations*. They will be discussed in the following sections from the signal processing point of view. A more generic discussion can be found in Chap. 19.

### 14.6.1 Code Pseudorange

Loosely speaking, the *code delay* of the replica signal $\hat{\tau}$ follows the true but unknown delay $\tau$ of the received signal. Looking in more detail into the correlation process defined in (14.18) one realizes that the actual argument of the spreading sequence is the *code phase* of the replica signal given by $\hat{\nu}(k) = T_s k - \hat{\tau}$. The code delay multiplied with the speed of light is the *code pseudorange*. It is also referred to as *code* or *pseudorange* for simplicity.

It is common practice that the receiver uses the code phase $\hat{\nu}(k)$ as defined in Sect. 14.5 as a working variable for PRN code generation and not the code delay. This is mostly related to the fact that the code phase is directly related to the generated spreading code, which saves gates in an ASIC and/or CPU power. Working with separate variables for $T_s k$ and $\hat{\tau}$ would also require a high number of bits to represent the covered time spans with the required resolution of less than 1 mm. Overall the receiver maintains the code phase $\hat{\nu}(k)$ of (14.58) in one register of the NCO. This code phase is split into a fractional part being smaller than one code period, and the number of code periods as described in Sect. 14.5. This combined

code phase equals the nominal sent time of the signal.

If the considered GNSS signal has a data and a pilot component of a different primary PRN code length, it might be reasonable to maintain separate code phase entries in the NCO. If combined data and pilot processing is considered as described in Sect. 14.7.3 then the code and pilot NCO values are kept synchronously. That is, the data/pilot code phases modulo the shorter PRN period are identical.

With these considerations the code pseudorange $p(k)$ expressed in meters can be obtained via

$$p(k) = c\hat{\tau}(k) = c\,[t_{\mathrm{rec}} - \hat{\nu}(k)] \tag{14.64}$$

and it is the difference of the nominal receiver time $t_{\mathrm{rec}}$ minus the estimated sent time $\hat{\nu}(k)$ multiplied with the speed of light $c$.

The nominal receiver time is the raw receiver time. It is realized by simply counting the samples produced by the ADC, thus $t_{\mathrm{rec}} = T_{\mathrm{s}}k$. The ADC sampling rate (as well as the local oscillators for downconversion) is derived from the receiver oscillator. The oscillator may be of different quality ranging from a simple quartz to an atomic frequency standard. The nominal receiver time has an arbitrary offset to the true time, called receiver clock error, and this offset changes with time according to the oscillator drift.

If the measurement epoch (being aligned to e.g., a full GPS second) falls between two sampling epochs, then linear interpolation is sufficient to obtain both time values. This interpolation is easily done in the receiver firmware based on the code phase and code rate values of an adjacent sampling epoch.

The pseudorange definition (14.64) is sometimes called *absolute pseudorange* as it can be done for each tracking channel individually. Sometimes it is more convenient to introduce another definition – *relative pseudoranges* – which are based on choosing a reference channel denoted with an subscript 0. Then the relative pseudorange is defined as

$$p_{\mathrm{r}}(k) = c\,(\hat{\tau}(k) - \hat{\tau}_0(k)) = c\,[\hat{\nu}_0(k) - \hat{\nu}(k)]\ . \tag{14.65}$$

It can be computed without decoding the navigation message and resolving the code ambiguity, as the code phase difference between two tracking channels is readily available inside the receiver. The relative pseudorange of the reference channel is zero. The relative pseudorange does not contain any receiver clock error, thus timing information cannot be extracted from it. The relative pseudorange is rarely used and only if utmost simplicity is sought for receiver design.

The absolute pseudorange is usually modeled as

$$\begin{aligned} p = {} & \rho - c(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + I + T \\ & + c(d_{\mathrm{r}} + d^{\mathrm{s}}) + p_{\mathrm{T}} + \epsilon_{\mathrm{mp}} + \epsilon_{\mathrm{n}}\ . \end{aligned} \tag{14.66}$$

Here $\rho$ denotes the geometric distance between the receive antenna at the reception epoch and the transmit antenna at the transmission epoch. $dt^{\mathrm{s}}$ and $dt_{\mathrm{r}}$ are the satellite and receiver clock offsets with respect to a common system timescale, $I$ and $T$ represent ionospheric and tropospheric path delays, $d_{\mathrm{r}}$ and $d^{\mathrm{s}}$ denote satellite- and receiver-specific group delays, and the remaining terms describe various forms of measurement errors. These include loop transient errors ($p_{\mathrm{T}}$), multipath errors ($\epsilon_{\mathrm{mp}}$) and tracking noise ($\epsilon_{\mathrm{n}}$). All terms generally depend on the time or epoch $k$.

The observation equation introduced in Chap. 19, namely (19.6), describes the same model as (14.66) but from the positioning point of view. In particular (19.6) uses the indices $r$, $s$ and $j$ to denote different receivers, satellites or signals, whereas (14.66) omits indices as it is for one tracking channel and thus for one receiver, one satellite and one signal. The measurement error $e$ in (19.6) equals the sum of $p_{\mathrm{T}} + \epsilon_{\mathrm{mp}} + \epsilon_{\mathrm{n}}$ in (14.66). Furthermore, the relativistic correction $\delta t^{\mathrm{rel}}$ of (19.6) is merged with $dt^{\mathrm{s}}$ in (14.66) and phase center variations $\xi$ of (19.6) are neglected here.

The receiver clock error $dt_{\mathrm{r}}(k)$ is the deviation of the nominal receiver time $t_{\mathrm{rec}} = T_{\mathrm{s}}k$ from the true GNSS timescale $t_{\mathrm{t}}(k)$,

$$dt_{\mathrm{r}}(k) = T_{\mathrm{s}}k - t_{\mathrm{t}}(k)\ . \tag{14.67}$$

The receiver clock may assume numerically very large values, because the nominal receiver time does in general not reflect the absolute start time of the measurement. Instead, the start of the measurement expressed in the nominal receiver time is zero, since $k = 0$. To avoid numerical problems when producing the code pseudorange, the GNSS receiver introduces an artificial and additional clock error $dt_{\mathrm{r,a}}$, which is applied before outputting the code (and also the carrier) pseudorange according to

$$p(k) \rightarrow p(k) - c dt_{\mathrm{r,a}}(k)\ . \tag{14.68}$$

The artificial clock $dt_{\mathrm{r,a}}$ error usually assumes integer multiplies of 1 ms and may change over time to keep the combined receiver clock error $dt_{\mathrm{r,a}}(k) + dt_{\mathrm{r}}(k)$ close to zero (and the pseudoranges near 25 000 km). Every time the artificial clock error changes its value one speaks of a *receiver clock jump* or 1 ms jump. The artificial clock error might also be adjusted continuously and steered towards zero, but discrete jumps are easier to detect

in the navigation software and also allows real physical modeling of the receiver clock error. Both cases can be seen as some kind of *software* clock steering. Many receivers are equipped with oscillators that can be tuned via a configurable input voltage. If this approach is used, one speaks of *hardware* clock steering. Hardware clock steering needs also to be modeled in the navigation process.

The satellite clock error $dt^s$ in (14.66) measures the deviation of the transmission time $\nu(k)$ in the nominal satellite timescale to the true GNSS timescale,

$$dt^s(k) = \nu(k) - t_t(k) \,. \tag{14.69}$$

It is broadcast by the navigation message and kept low (usually much below 1 ms) by the control segment.

The ionospheric delay is denoted as $I(k)$ and the tropospheric delay by $T(k)$. Both are positive and more details can be found in Chap. 19.

The symbol $d_r$ in (14.66) denotes the receiver hardware delay. It is composed of contributions from the antenna, cables, amplifiers, mixers and filters. The receiver hardware delay is temperature dependent and thus generally time dependent. For signals with an identical modulation scheme, for example for GPS L1 C/A code signals from all satellites, it is usually considered to be identical. There are small differences depending on the modulation scheme (e.g., between BOC and BPSK signals) if the same center frequency is used. Larger differences occur for different center frequencies (e.g., for the GLONASS G1 signals), because group delay variations of the RF filters cannot be neglected for surface acoustic waves (SAWs) or ceramic filters, which are commonly used in GNSS receivers.

The satellite hardware delay is denoted as $d^s$ and similar considerations as for the receiver hardware delay apply.

The symbol $\epsilon_{mp}$ is used to denote the ranging error caused by the fact that in general not only the line-of-sight signal is received but also reflections from nearby objects. This so-called *multipath* is for many applications the most difficult error to get control of and is discussed also in Chap. 15. Every single object in the surroundings of the receiving antenna reradiates reflections from the satellite signal. Although the single contributions might be small, their accumulation can cause a generally increased noise budget, which can easily achieve a few meters standard deviation. There might also be cases of a large surface acting as a specular reflector causing a single dominant multipath reflection. This case can be handled in a relatively simple theoretical way by means of so-called *multipath envelopes*. Assuming a single multipath reflection of a relative amplitude $\alpha$ and an increased path length $\tau_m$ (both with respect to the line-of-sight signal), the corresponding ranging error can be bounded by writing

$$t_{mp;-}(\alpha, \tau_m) \le \epsilon_{mp} \le t_{mp;+}(\alpha, \tau_m) \,. \tag{14.70}$$

The bounds $t_{mp;+-}(\alpha, \tau_m)$ are obtained by solving the following equation for $t$

$$\text{real}\,[D_c(t) \pm \alpha D_c(t + \tau_m)] = 0 \,. \tag{14.71}$$

Here $D_c(t)$ is the coherent part of the used code discriminator. The coherent part is the complex valued discriminator computed for example by subtracting the complex valued late correlator from the early correlator. The ranging error bounds $t_{mp;+,-}$ equal the resulting value of $t$ and depend on $\tau_m$ and $\alpha$. For $\tau_m = 0$, the multipath error vanishes. The two signs considered are either for constructive or destructive interference of the line-of-sight signal with the multipath reflection and represent the maximum magnitudes of the multipath error. The two solutions are denoted as $t_{mp;+,-}(\alpha, \tau_m)$ and are chosen so that $t_{mp;+} \ge t_{mp;-}$ (which can always be achieved).

An example for a CBOC signal with a narrow correlator is shown in Fig. 14.17. By choosing a narrow correlator spacing $d$, the maximum multipath error can be reduced. By combining two early/late pairs into one code discriminator, the medium and far range multipath can be virtually eliminated (at least for BPSK signals). There are many other ways to optimally select the code discriminator, which clearly goes beyond the scope of this chapter. For further reading see for example [14.31]. Near-range multipath with delays of maximally several meters still remains a big hurdle in navigation signal processing.

The symbol $\epsilon_n$ in (14.66) denotes the noise in the measurement. The noise comprises thermal noise

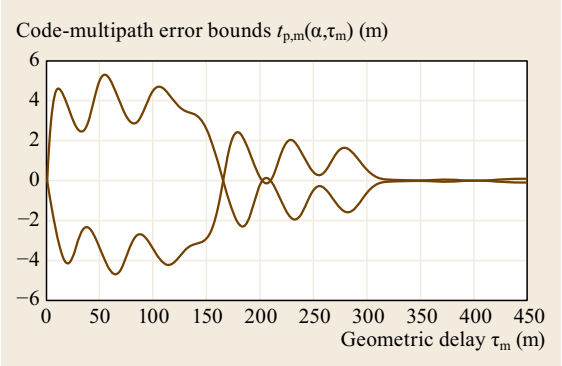

**Fig. 14.17** Code multipath error envelope for a 12 MHz Galileo E1B signal, an early/late correlator spacing of $d = 0.05$ chip and a $\alpha = -6$ dB multipath signal

contributions mostly from the first low-noise amplifier (LNA) after the passive antenna element and quantization noise of the ADC. If the RF noise can be considered as white noise, which is described by a noise density $N_0$, then $\epsilon_n$ is a zero mean Gaussian random variable whose variance depends on signal type, discriminator type and loop parameters. For the example of an idealized infinite bandwidth BPSK signal, and an early-power minus late-power code discriminator (14.55) with an early-late spacing of $d$ chips, the variance $\sigma_n^2$ of $\epsilon_n$ expressed in squared meters is according to [14.16]

$$\sigma_n^2 = T_C^2 \frac{B_{DLL} d}{2C/N_0} \left[ 1 + \frac{2}{(2-d)TC/N_0} \right] . \qquad (14.72)$$

The symbol $T_C$ denotes the chip duration in meters.

A lower DLL bandwidth $B_{DLL}$ and a high signal power $C$ reduce the noise. The term in the brackets is called squaring loss and is relevant for low received signal power, which typically occurs if the receiver is not operated in open sky conditions. By increasing the coherent integration time $T$, the squaring loss can be reduced. This comes at the cost of increased receiver complexity, especially if $T$ is larger than the data bit/symbol duration. Commercial receivers often employ integration times of a few milliseconds.

Though a reduction of the correlator spacing $d$ also diminishes the noise, this reduction levels off for finite bandwidth signals and small values of $d$. In fact (14.72) is only an approximation and for finite bandwidth signals a rather complex theory exists to compute the variance. It relates the power spectral density of the signal to the power spectral density of the received noise in dependence on the used code discriminator [14.7, 32]. This theory is then also able to give closed expressions for BOC signals or other modulation schemes.

The spectral characteristics of the measurement noise $\epsilon_n$ relates to the DLL bandwidth $B_{DLL}$ and the measurement rate. In case the product of both is much larger than 1, then $\epsilon_n$ can be assumed to be white. If near or lower than 1, $\epsilon_n$ is *colored noise* and $\epsilon_n$ reflects the filter characteristics of the DLL. In that case, the noise power is contained between 0 Hz and $B_{DLL}$ but (14.72) is still valid. As a consequence, receivers with a high measurement rate need to employ high tracking loop bandwidths, as they would otherwise (i. e., with low loop bandwidths) generate timely correlated measurements.

For the already considered Galileo signal E1B, the code noise is shown in Fig. 14.18. At a typical signal power value of 45 dB-Hz it is two decimeters and for many applications negligible compared to the multipath error.

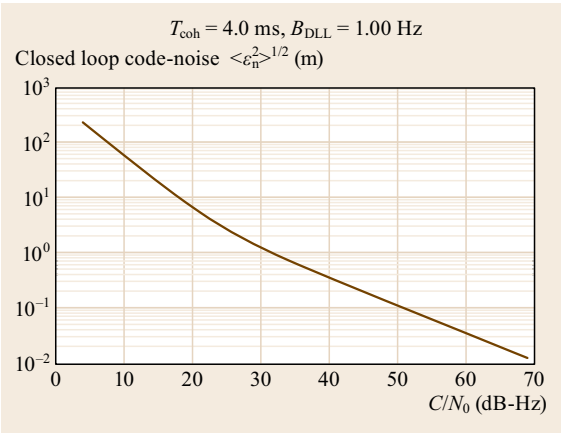

**Fig. 14.18** Code noise for a 12 MHz Galileo E1B signal and an early/late correlator spacing of 0.05 chip

The *transient* error $p_T$ is the opponent of the thermal noise error $\epsilon_n$ as both cannot be minimized at the same time. The transient error reflects the inability of the tracking loop to perfectly follow the signal dynamics (user motion) and the tracking loop lags behind the true signal dynamics. Transient errors are, due to the nature of the user motion in general, timely correlated but shall not be mistaken for colored measurement noise, as they are independent of the measurement rate.

For a first-order DLL, the response of the tracking loop to a user range jump of 1 m is

$$p_T = e^{-4B_{DLL}t} \qquad (14.73)$$

and shown in Fig. 14.14. A lower loop bandwidth $B_{DLL}$ causes transient errors to persist for a longer time. Transient errors exist also for higher-order loop filters and receiver design is always a trade-off between thermal noise and transient errors. $B_{DLL}$ is chosen to be application dependent. For example, a second-order DLL with a bandwidth of 0.2 Hz may be used in a high-sensitivity mass market receiver and is able to track signals as low as $\approx$ 15 dB-Hz. In that case transient errors are experienced by the user, even for typical vehicular accelerations.

### 14.6.2 Carrier Phase

The locally generated replica signal as defined in (14.5) has an instantaneous carrier phase $\phi_{NCO}(k)$ defined as the argument of the complex exponential. It is one variable of the NCO and related to the definitions of (14.5) by

$$\hat{\phi}_{NCO}(k) = 2\pi \left( f_{IF} + \hat{f}_d \right) T_s k + \hat{\phi}(k) . \qquad (14.74)$$

Similar to the code pseudorange, the NCO does not work with $\hat{\phi}(k)$, but rather with $\hat{\phi}_{\mathrm{NCO}}(k)$, which is the direct argument of the sin/cos functions. Otherwise the multiplication of $(f_{\mathrm{IF}}+\hat{f}_{\mathrm{d}})T_{\mathrm{s}}k$ may cause numerical errors or may consume unnecessary area on the GNSS chip (or unnecessary instructions in the processor) to realize the multiplication, especially if large time spans are considered.

If phase tracking is employed and phase lock is achieved, this instantaneous carrier phase follows the received carrier phase, as the PLL steers

$$\hat{\phi}_{\mathrm{NCO}}(k) - 2\pi(f_{\mathrm{IF}}+f_{\mathrm{d}})T_{\mathrm{s}}k + \phi(k)$$

towards zero.

Referring back to the discussion of the code pseudorange in the previous section, the absolute *carrier pseudorange* $\varphi(k)$ expressed in meters is defined as

$$\varphi(k) = -\lambda\left(\frac{\hat{\phi}_{\mathrm{NCO}}(k)}{2\pi} - f_{\mathrm{IF}}T_{\mathrm{s}}k\right) . \tag{14.75}$$

The carrier pseudorange, which is most commonly called *carrier phase* for simplicity, is the difference between the NCO carrier phase minus the nominal increase (provided that $f_{\mathrm{IF}} \neq 0$). The latter term can also be seen as the nominal receiver time scaled with $f_{\mathrm{IF}}$ and the first term is the transmitted carrier phase from the satellite. Carrier-phase measurements are taken simultaneously with code measurements eventually employing interpolation techniques if the measurement epoch is between two samples.

If the GNSS signal has a data and pilot component two options exist to generate the carrier pseudorange: carrier-phase measurements can be taken separately for data and pilot or a combined measurement can be generated, as further detailed in Sect. 14.7.3. As the nominal phase difference between data and pilot signal is known (usually it is 0° or 90°), and both components are affected by the same propagation delays, there is no information loss if only a combined measurement is generated. An important exception from this rule can occur, when utmost accuracy is sought in determining receiver-satellite hardware delays (as it is done in the control segment and networks of reference GNSS receivers). If the satellite payload combines data and pilot component using analog circuits then, a residual phase bias between data and pilot may exist due to inevitable tolerances in the circuits of a few degrees. This bias needs then to be estimated, for carrier-phase-based applications.

A possibly applied artificial receiver clock error (14.68) must also be accounted for in the carrier-phase measurements and we write

$$\varphi(k) \rightarrow \varphi(k) - cdt_{\mathrm{r,a}}(k) . \tag{14.76}$$

To keep the numerical range of the carrier-phase measurements limited, one may start counting the carrier phase from a reference epoch $t_{0,\mathrm{c}}$ on. This results in

$$\varphi(k) = -\lambda\left(\frac{\hat{\phi}_{\mathrm{NCO}}(k)}{2\pi} - f_{\mathrm{IF}}(T_{\mathrm{s}}k - t_{0,\mathrm{c}})\right) . \tag{14.77}$$

The epoch $t_{0,\mathrm{c}}$ can be chosen quite freely, and shall be kept constant as long as the carrier phase is within the valid numerical range. Usually one tries to keep the carrier-phase values near to the pseudorange values. When choosing $t_{0,\mathrm{c}}$, one should make sure that

$$\mathrm{e}^{2\pi \mathrm{j} f_{\mathrm{IF}} t_{0,\mathrm{c}}} = 1 \tag{14.78}$$

to ensure that the integer character of the carrier-phase ambiguities is not changed, when readjusting $t_{0,\mathrm{c}}$.

The carrier phase is modeled as

$$\begin{aligned}\varphi = {} & \lambda N + \rho - c(dt_{\mathrm{r}} - dt^{\mathrm{s}}) - I + T \\ & + c(\delta_{\mathrm{r}} + \delta^{\mathrm{s}}) + p_{\mathrm{T}'} + \epsilon_{\mathrm{mp}'} + \epsilon_{\mathrm{n}'} .\end{aligned} \tag{14.79}$$

This model is similar to (14.66), with the exception that the ionospheric delay $I$ changes sign and the carrier-phase ambiguity $N$ has been added.

Comparing the model (14.79) to (19.9) of Chap. 19, we realize slight differences, which are due to the different focus of the respective chapters. Similar to the code pseudorange model (19.6), also (19.9) includes relativistic effects $\delta t^{\mathrm{rel}}$ and phase center corrections $\zeta$. Both have been neglected in (14.79) as well as the phase wind-up correction $\omega$. The measurement error $\epsilon$ of (19.9) equals the sum of $p_{\mathrm{T}'} + \epsilon_{\mathrm{mp}'} + \epsilon_{\mathrm{n}'}$ in (14.79).

The ambiguity term $N$ can be seen as an integer (remember, satellite and receiver hardware delays $\delta_{\mathrm{r}}$, $\delta^{\mathrm{s}}$ are modeled separately) and reflects the fact that $\hat{\phi}_{\mathrm{NCO}}$ is initialized with an arbitrary integer part, when the tracking process starts. Furthermore the choice of $t_{0,\mathrm{c}}$ is also in some sense arbitrary. Thus a 360°, or integer-cycle, ambiguity exists.

In the case where a data-only signal is tracked with a Costas PLL, the phase discriminator is insensitive to 180° jumps and the resulting half-cylce (180°) ambiguity can only be resolved by analyzing the preamble (Sect. 14.5.3) or other parts of the broadcast navigation message. Its correct resolution is essential for many navigation algorithms and receiver manufacturers put large efforts into this issue.

Unfortunately rather small effects like unexpected high user dynamics, short signal blocking, high multipath or high noise may disturb the PLL and phase lock can ultimately be lost. Even if this occurs only for a fraction of a second and phase lock is established again, the integer value of $N$ may have changed, as the PLL only readjusts the fractional part but not the integer part. A *cycle slip* occurred. Its detection, and its eventual correction, is difficult, especially in a dynamic scenario. Cycle slips still are the main hurdle to be taken to fully exploit the otherwise very precise carrier-phase measurements.

The geometric range $\rho$ and the receiver $dt_\mathrm{r}$ and satellite clock errors $dt^\mathrm{s}$ are the same as for the code pseudorange.

The receiver hardware delays $\delta_\mathrm{r}$ and the satellite $\delta^\mathrm{s}$ are similar to the code counterparts but may differ slightly depending on hardware components.

The transient error $p_{\mathrm{T}'}$ reflects the inability of the PLL to instantaneously follow the user dynamics or receiver oscillator jitter and can be modeled similar to (14.73). Transient errors should be kept smaller than a fraction of a cycle by choosing a sufficiently high loop bandwidth to avoid cycle slips. Due to the short carrier wavelength, this limits PLL bandwidths to be greater than 5–10Hz, which is much larger than for the DLL.

Multipath errors $\epsilon_{\mathrm{mp}'}$ are omnipresent and typically much larger than thermal noise $\epsilon_{\mathrm{n}'}$ errors. They are limited by a quarter of a wavelength $|\epsilon_{\mathrm{mp}'}| \leq \lambda/4$ as detailed in Chap. 15. The maximum multipath error occurs if the multipath signal is of equal power to the line-of-sight signal and the multipath delay $\tau_\mathrm{m} = 0$. This is a rather unlikely case for normal propagation conditions like free view to the sky, under canopy or in a rural environment. Even more unlikely is the case of the multipath signal being stronger than the line-of-sight signal, in which case the receiver may lock onto the multipath signal and all the information it gathers is unrelated to the line-of-sight signal.

If $\alpha$ is the ratio of the multipath signal amplitude to the line-of-sight amplitude, then

$$|\epsilon_{\mathrm{mp}'}| < \frac{\sin^{-1}(\alpha|R(\tau_\mathrm{m})|)}{2\pi}\lambda \tag{14.80}$$

and carrier-phase multipath is often irrelevant for many applications, apart from real-time kinematic (RTK) positioning.

The carrier-phase noise is modeled as a zero mean Gaussian random variable, whose variance $\sigma^2_{\mathrm{n}'}$ is to a large extent independent on the used modulation scheme, and given by

$$\sigma^2_{\mathrm{n}'} = \frac{\lambda^2}{4\pi^2}\frac{B_\mathrm{PLL}}{C/N_0}\left(1+\frac{1}{TC/N_0}\right). \tag{14.81}$$

The noise is usually at the order of 1 mm or below and virtually irrelevant for many applications.

### 14.6.3 Doppler

Between tracking loop updates, the carrier phase (14.74) increases linearly. The carrier-phase increase between two samples equals $2\pi(f_\mathrm{IF}+\hat{f}_\mathrm{d})T_\mathrm{s}$. Usually this increase is stored in one NCO variable (including $f_\mathrm{IF}$). Within a simple receiver implementation, the Doppler frequency $\hat{f}_\mathrm{d}$ can be extracted straightforwardly from this rate. Doppler measurements can be done regardless of whether phase lock is achieved or not (provided that code and frequency lock has been achieved, i. e., the channel is actually tracking the signal).

The model for the Doppler frequency derives from the carrier-phase model (14.79) via a time derivative. By denoting time derivatives with a dot over the symbol, for example $\mathrm{d}x/\mathrm{d}t = \dot{x}$, then the Doppler observation equation is given by

$$\hat{f}_\mathrm{d} = -\frac{1}{\lambda}\left[\dot{\rho} - c(\dot{dt}_\mathrm{r} - \dot{dt}^\mathrm{s}) + p_{\mathrm{T}''} + \epsilon_{\mathrm{mp}''} + \epsilon_{\mathrm{n}''}\right], \tag{14.82}$$

with $\lambda = c/f_\mathrm{L}$ being the carrier wavelength.

For most GNSS applications, atmospheric delays and receiver/hardware delays do not contribute to the Doppler, as they vary only slowly with time. However, if highly accurate velocity estimates are required, then atmospheric delay variations on the order of maximal few millimeters per second need to be accounted for [14.33].

The most significant contributors to the Doppler are the line-of-sight velocity $\dot{\rho}$ and the receiver clock drift $\dot{dt}_\mathrm{r}$. The satellite clock drift $\dot{dt}^\mathrm{s}$ is very small.

The transient error is denoted as $p_{\mathrm{T}''}$ and is caused by the inability of the FLL or PLL to instantaneously follow the variations in the line-of-sight velocity.

Additionally, Doppler measurements are affected by multipath errors $\epsilon_{\mathrm{mp}''}$, but they are considered to be rather small (similar as for carrier-phase multipath).

The Doppler noise is bias free and its variance $\sigma^2_{\mathrm{n}''}$ is independent of the modulation scheme and carrier frequency,

$$\sigma^2_{\mathrm{n}''} = \frac{1}{4\pi^2 T^2}\frac{4B_\mathrm{FLL}}{C/N_0}\left(1+\frac{1}{TC/N_0}\right). \tag{14.83}$$

Using longer coherent integration times $T$, precise Doppler measurements are possible.

Generally speaking, timely integrated Doppler measurements represent the relative line-of-sight variation

with a higher accuracy than code pseudoranges (of course code pseudoranges give an absolute measurement and not only a variation). The terminology of integrated Doppler is also used by some receiver manufacturers for their method to derive the Doppler as time differenced carrier-phase measurements.

Even more sophisticated receivers use correlator values themselves and interpolation to provide more precise Doppler measurements. More specifically, the Doppler can be derived by fitting a polynomial to the correlator values

$$\hat{\alpha}_1 = \arg \min_{\alpha_0,\alpha_1,\alpha_2,\ldots} \sum_k \left( \frac{2\pi\varphi(k)}{\lambda} + \arctan \frac{Q_{\mathrm{P},k}}{I_{\mathrm{P},k}} - \alpha_0 - 2\pi\alpha_1 Tk - \alpha_2 k^2 T^2 + \ldots \right)^2 . \tag{14.84}$$

The linear term $\alpha_1 = \hat{f}_\mathrm{d}$ of the fitted polynomial is the Doppler frequency at the $k = 0$ point of the considered interval. For pilot signals, a four-quadrant arctan can be used. The Doppler values obtained in this way are free from any transient PLL or FLL errors and solely depend on the prompt correlation values in the considered interval. The higher the considered polynomial order, the noisier the Doppler measurements; the polynomial order can be seen as a replacement for the loop bandwidth.

### 14.6.4 Signal Power

The fourth observable that is generated by the receiver for each tracked signal is the estimated received signal power. In contrast to the other three observables, the signal power is not based on NCO variables, but can readily be derived from (14.21)

$$\widehat{C/N_0} = \frac{I^2 + Q^2 - 2}{2T} . \tag{14.85}$$

The signal power estimates can be averaged over all prompt $I/Q$ correlator values that are available during a measurement interval. For an integration time $T$ of 20 ms, these are 50 values assuming a measurement rate of 1 Hz. Averaging power estimates increases the precision of the estimates, which is important for low signal power values. High sensitivity receivers often average over 5–10 s to detect the presence of low power 10–15 dB-Hz signals.

The signal power estimate $\widehat{C/N_0}$ is affected by thermal noise but is otherwise an unbiased estimate. The variance of the estimate is independent of the true $C/N_0$ if expressed in natural units and not if expressed in decibels.

Multipath signals influence $\widehat{C/N_0}$: constructive interference increases the value, destructive interference reduces the value. For static receivers, multipath can usually be well identified by a look at a $C/N_0$ time series as the fluctuations have a similar spectral character as the carrier-phase multipath. If the $C/N_0$ time series shows a variation with a period of for example 300 s, then the carrier-phase multipath error will have the same periodicity of 300 s. Even the amplitude of the $C/N_0$ fluctuations and the carrier-phase multipath are correlated but it is quite difficult to establish a precise quantitative relationship.

Transient errors in the code tracking loop decrease the signal power estimate as $R(\delta\tau)$ will then be smaller than 1. Similarly, Doppler frequency transient errors cause $\mathrm{sinc}(\delta f_\mathrm{d} T)$ to be smaller than 1 and also reduce the $C/N_0$ estimate.

## 14.7 Advanced Topics

The code correlation technique based on the full knowledge of the PRN code provides all components of signal parameters of interest to be used in navigation but cannot be available to the P(Y)-code tracking in dual-frequency receivers. Without knowledge of the Y-code, dual-frequency high-precision civilian purpose receivers employ codeless or quasicodeless techniques for the reconstruction of the unmodulated carrier wave in order to obtain precise carrier phase (and partly code) measurements on L2.

In addition, the recent success of digital signal processing technologies provides a powerful tool to implement a software-based GNSS receiver that has extremely easy configurable properties, thus leading to many new processing schemes. It is ideally suited to many interesting applications, in order to improve signal tracking methods in modern digital GNSS receivers [14.34].

In this section we discuss advanced topics of signal processing technique focusing on a special case of signal processing in dual-frequency high-precision civilian receivers as well as recent progress in digital signal processing techniques of GNSS receivers.

### 14.7.1 Tracking of GPS P(Y)

Since the signal processing of the legacy GPS L1 and L2 signals requires both L1 CA- and L1/L2 P(Y)-codes

until now and the P(Y)-code is very long and officially unknown, only the L1 CA-code can be processed by the normal correlation technique. If the use of the P(Y)-code is guaranteed and officially available, both carriers on L1 and L2 can be easily reconstructed by the code correlation technique, enhancing the navigational performance. Without knowledge of the P(Y)-code, we can process it by applying codeless or quasicodeless techniques for the reconstruction of the unmodulated carrier wave. Currently, these techniques are widely used in dual-frequency GPS receivers for civilian survey purposes [14.35–38].

The first method is a squaring technique of the L2 P(Y)-code, which is based on autocorrelation of the received signal with itself to remove all modulations on L2. A 180° phase shift during modulation is equivalent to a change in the sign of the resultant signal, so the modulations will be removed by a squaring operation. However, the main drawback of this technique is that the satellite clock and orbit information, if the navigation data bits are modulated on the signal component, are lost in the process, and the signal-to-noise ratio is substantially degraded by 30 dB due to the squaring process. Also, the squaring operation results in the unmodulated carrier with the twice the original frequency, that is half the wavelength, in which the ambiguity resolution becomes more difficult [14.35, 36].

The second method is to use the cross correlation of L1 and L2. This technique is based on the fact that the unknown Y-code is identical on both carriers so that the cross correlation of the L1 and L2 signals is possible. The small delay due to the frequency-dependent propagation of an electromagnetic wave through the ionosphere is measurable as a variable. Therefore, the L2 P(Y)-code pseudorange and its carrier-phase measurements can be derived based on the cross-correlation output and the L1 CA-code pseudorange measurement. Full cycles of the L2 carrier can be retrieved. Due to the fact that the L1 P(Y)-code signal has twice the power of the corresponding L2 P(Y)-code signal, the cross correlation of the L1 and the L2 signal has an improvement of 3 dB in terms of the tracking threshold compared to the squaring of the L2 signal. However, compared to the code correlation technique, this method has a 27 dB degradation in the signal-to-noise ratio [14.35, 37].

The third method is so-called Z-tracking, which is an improved quasicodeless technique. This technique requires the P-code at a receiver to correlate separately with L1 and L2 signals with enough integration interval by a low-pass filter. The encryption signal bit (W-bit) is estimated separately in each frequency, which is then fed to the other frequency to remove the encryption code from the signal. In this way, the code ranges and full wavelength L1 and L2 carrier phases are obtained. However, in comparison to the code correlation technique, this method results in a 14 dB of the signal-to-noise ratio degradation [14.35, 37].

Besides these, several other techniques were reported in the society but it is supposed that such P(Y)-code tracking methods will not be commonly used in the long-term future due to the arrival of new open GNSS signals.

### 14.7.2 Generic Data/Pilot Multiplexing Approach

The presence of data bits in a navigational signal significantly degrades the performance of signal tracking because it limits the coherent integration time, which should be long enough for a high sensitivity. The introduction of a pilot signal in addition to the data signal with a signal power split by multiplexing techniques is one of the major developments in modern GNSS signals. For example, GPS L1C and L5, and Galileo E1-OS and E5 use this technique [14.28–30, 39, 40].

After a lot of research works on the optimal power split between the data and pilot signals considering different GNSS applications, the equivalent split of total power between the data and pilot signals optimized for the 50 bit/s navigation data was finally proposed for GPS L5 [14.29, 41, 42]. An optimal power split at a much higher data rate was later discussed for SBAS L5 signals [14.43, 44], and the trade-off analysis between data rate and signal power split in GNSS signal design was well performed in [14.40]. Improvements from having a pilot channel and sharing the signal power comprise the following:

- The use of coherent tracking for a pilot channel may improve a somewhat poor tracking accuracy by eliminating the squaring loss of Costas tracking for a data channel.
- The use of pilot-only (50%) tracking may provide a $C/N_0$ gain of 6 dB by doubling the PLL threshold while only moderately increasing the PLL thermal noise jitter as compared with that of data-only (50%) tracking.
- The use of combined tracking may provide a $C/N_0$ gain of 3 dB over pilot-only tracking and with fewer tracking errors.
- The use of pilot channels may allow direct measurement of the carrier phase without the need to decode the navigation message preamble (see Sect. 14.7.3 for more details).

### 14.7.3 Combined Processing of Data and Pilot Signals

Two signal channels (data/pilot) multiplexed at a single satellite signal allow several combinations of signal tracking for the performance improvement. The followings are three examples of the available combination of data/pilot tracking:

- Independent data and pilot tracking
- Pilot-only tracking and aiding of data demodulation
- Combined data/pilot tracking.

Basically, the pilot channel provides benefits such as a high sensitivity in terms of a PLL thermal noise jitter and a wider available region of $C/N_0$. The use of a pure PLL for the pilot channel, instead of the Costas loop used for the data channel, improves sensitivity as well as reliability, thereby gaining 4–9 dB in the carrier tracking [14.45, 46]. Here, an important question arises: Is a pilot channel alone sufficient for signal tracking? Or, is a data channel required in combination? The combined data/pilot tracking in an optimal manner will be beneficial in terms of high sensitivity compared to data-only tracking in Costas loop or pilot-only tracking in pure PLL [14.40]. However, due to the limited linearity of the pull-in-range of the Costas loop discriminator compared to that of the pure PLL discriminator, a proper combining method should be chosen depending on $C/N_0$.

Figure 14.19 shows the block diagram of the signal tracking loop with a data/pilot combining algorithm. In order to effectively use all the signal power originally transmitted by a satellite for tracking, while the data-only or pilot-only tracking merely use half, the data and pilot signal components should be processed in combination. For this, a linear combination of a pure PLL discriminator and a Costas loop can provide an optimal combining algorithm when based on the appropriate weighting coefficient for each channel. An unbiased estimate of the carrier-phase error (combined discriminator output) is given by [14.45]

$$\delta\phi_c = \alpha_D \delta\phi_D + \alpha_P \delta\phi_P \,. \tag{14.86}$$

Here, $\delta\phi_C$, $\delta\phi_D$, and $\delta\phi_P$ are the carrier-phase discriminator outputs from the combined, data, and pilot channels respectively. The weighting coefficients

$$\alpha_D = \frac{\sigma_P^2}{\sigma_D^2 + \sigma_P^2} \quad \alpha_P = \frac{\sigma_D^2}{\sigma_D^2 + \sigma_P^2} \,, \tag{14.87}$$

of the data and the pilot channels obey the relation $\alpha_D + \alpha_P = 1$ and can be obtained from the 1-$\sigma$ PLL thermal noise jitter of the data and pilot channels respectively.

In the case of a 50-50 power split between data/pilot channels, the combined tracking may have a $C/N_0$ gain of 3 dB over the pilot-only tracking when $C/N_0$ is high enough. However, the pilot-only tracking is beneficial in low $C/N_0$ region due to its threshold efficiency. Therefore, a logic to select combined tracking or pilot-only tracking based on the $C/N_0$ estimate should be applied [14.40].

### 14.7.4 Combined Processing of Code and Carrier

In order to estimate signal parameters in (14.4), a classical tracking method widely uses single-input-single-output (SISO) DLL/PLL/FLL separately for code and carrier tracking as described in Sect. 14.4.1. The well-known DLL/PLL is equivalent to the special case of the linear quadratic Gaussian (LQG) optimal controller that is the combination of the Kalman filter (KF) and the output state feedback controller. Based on this, the

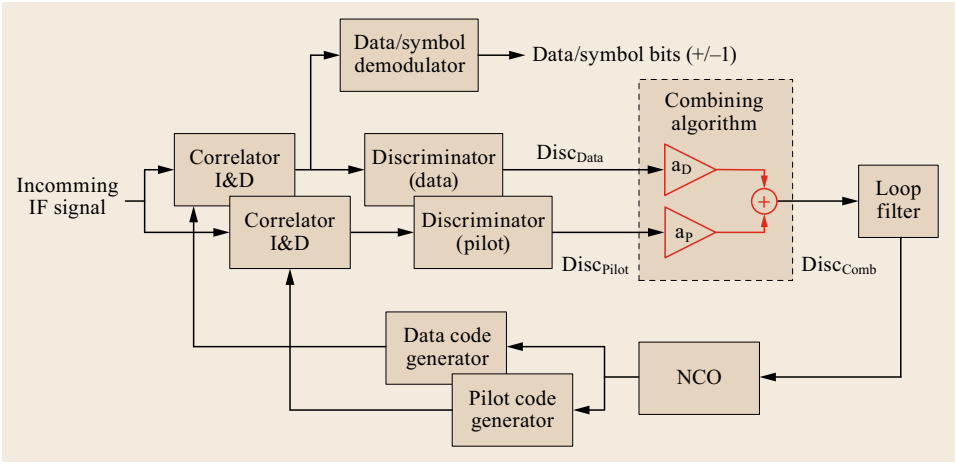

**Fig. 14.19** Block diagram of signal tracking loop with a data/pilot combining algorithm

code and carrier tracking problem can be considered as a multiple-input-multiple-output (MIMO) control problem, which combines the code and carrier tracking altogether by means of the state feedback [14.47].

For a single satellite signal, a filter equation for a combined DLL/PLL/FLL including code and carrier NCOs based on concurrent code/carrier tracking is given in a state space form [14.1, 48] by the expression

$$\boldsymbol{x}_{k+1} = \mathbf{F}\boldsymbol{x}_k + \mathbf{L}\boldsymbol{e}_k \,. \tag{14.88}$$

The statevector

$$\boldsymbol{x} = \left[A, \tau, \phi, f_\mathrm{d}, \dot{f}_\mathrm{d}\right]^\top ,$$

comprises the amplitude $A$, the code delay $\tau$, the carrier phase $\phi$, the Doppler shift $f_\mathrm{d}$, and the Doppler rate $\dot{f}_\mathrm{d}$. The transition matrix

$$\mathbf{F} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & sT & 0 \\ 0 & 0 & 1 & T & 0 \\ 0 & 0 & 0 & 1 & T \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

is used to propagate the state across the update interval $T$, and the gain

$$\mathbf{L} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \omega_\tau T & 0 & 0 \\ 0 & 0 & 2.4w\omega_\phi T & 0 \\ 0 & 0 & 1.1w\omega_\phi^2 T & \sqrt{2}(1-w)\omega_{f_\mathrm{d}} T \\ 0 & 0 & w\omega_\phi^3 T & (1-w)\omega_{f_\mathrm{d}}^2 T \end{bmatrix}$$

determines the state correction for a given vector

$$\boldsymbol{e} = [\delta A, e_\tau, e_\phi, e_{f_\mathrm{d}}]^\top$$

of DLL, PLL, and FLL discriminator outputs, additionally including the signal amplitude difference.

In the above equations, $\omega_\tau, \omega_\phi, \omega_{f_\mathrm{d}}$ are the natural frequencies of the DLL/PLL/FLL and $w \leq 1$ is the weighting factor of the PLL relative to the FLL. Finally, $s = R_\mathrm{c}/f_\mathrm{L}$ denotes a scale factor used in the carrier-aided DLL for converting the carrier Doppler in Hertz to the code Doppler in chips per second. It is given by the ratio of the code chipping rate $R_\mathrm{c}$ (in chips per second) and the carrier frequency $f_\mathrm{L}$ (in Hz), since the Doppler effect on the signal is inversely proportional to the wavelength of the signal.

It is noted that if the phase error input of the PLL becomes zero or $w$ is set to zero, the filter operates as a pure FLL and vice versa. If both phase and frequency error inputs do not sufficiently converge to zero, the use of $w$ makes it possible that the FLL assists the PLL to handle the phase error of $\pm 90°$ and the PLL helps the FLL to provide a correct frequency error at $180°$ phase reversals.

It is also noted that in (14.88) a first-order carrier-aided DLL with narrow bandwidth for code tracking, and a combination of a second-order FLL and a third-order PLL for the carrier phase and Doppler tracking are specially adopted.

### 14.7.5 Carrier Tracking Kalman Filter

The traditional signal tracking architecture can be substituted by a Kalman filter (KF). A KF is equivalent to a digital phase-locked-loop (DPLL) with a time-invariant proportional integrator (PI) controller, which includes an integrator in the closed-loop feedback, whereas the KF has time-varying coefficients recursively computed by the KF equations in a form of a Kalman gain matrix [14.49]. The constant gain matrix in the DPLL is equivalent to the Kalman gain in the steady state, which can be obtained by numerical computation of the Kalman equations until convergence [14.50], or by the closed-form expressions [14.51].

Several different forms of KFs for signal tracking have been proposed especially for deep coupling architectures of a GNSS receiver. They can be grouped into several different approaches depending on how the measurement equations are constructed, or how the combination of state variables is made. For example, baseband $I$ and $Q$ components can be directly used as measurements [14.47, 52]. Also, nonlinear discriminator outputs are able to be used as measurements for a loop filter excluding NCO (i. e., error state KF) [14.53, 54] or measurement residual for an overall tracking loop including NCO (i. e., direct state KF) [14.1]. Both are equivalent to each other in terms of the loop filter transfer function [14.55].

In the following we consider the case of a carrier tracking KF, but the discussion is similar for code tracking and can also be extended to combined code/carrier tracking.

Based on the practical assumption that the carrier measurement residuals can be directly obtained from nonlinear discriminator outputs (i. e., $\tilde{\boldsymbol{z}} = [\delta\phi, \delta f_\mathrm{d}]^\top$), the signal dynamics and measurement models for a signal tracking KF to substitute the carrier tracking loop described in the previous section are given in similar way as for conventional KF design [14.55]

$$\boldsymbol{x}_{k+1} = \mathbf{F}\boldsymbol{x}_{k-1} + \boldsymbol{w}_k \,, \tag{14.89}$$

$$\boldsymbol{z}_k = \mathbf{H}\boldsymbol{x}_k + \boldsymbol{v}_k \,, \tag{14.90}$$

where $\boldsymbol{x}_k = [\phi, f_\mathrm{d}, \dot{f}_\mathrm{d}]_k^\top$ is the state vector at time $k$, $\boldsymbol{z}_k$ is the measurement vector, $\boldsymbol{w}_k$ is the process noise vector, and $\boldsymbol{v}_k$ is the measurement noise vector. The noise vector $\boldsymbol{w}_k$ and $\boldsymbol{v}_k$ should satisfy the well-known additive white Gaussian noise assumption [14.56]. The state transition matrix $\mathbf{F}$ and the design matrix $\mathbf{H}$ are given by

$$\mathbf{F} = \begin{bmatrix} 1 & T & \frac{T^2}{2} \\ 0 & 1 & T \\ 0 & 0 & 1 \end{bmatrix}$$

and

$$\mathbf{H} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}.$$

The measurement update equation of the signal tracking KF can be written in a state-space form as

$$\hat{\boldsymbol{x}}_k = \mathbf{F}\hat{\boldsymbol{x}}_{k-1} + \mathbf{K}\tilde{\boldsymbol{z}}_k \,, \tag{14.91}$$

where $\mathbf{K} = \left[k_{ij}\right]$ is a $3\times 2$ Kalman gain matrix, which can be computed by the well-known Kalman filter equations

$$\mathbf{K} = \mathbf{P}_k^- \mathbf{H}^\top (\mathbf{H}\mathbf{P}_k^- \mathbf{H}^\top + \mathbf{R}_k)^{-1} \tag{14.92}$$

with the propagation and update equations for the covariance matrices

$$\mathbf{P}_{k+1}^- = \mathbf{F}\mathbf{P}_k\mathbf{F}^\top + \mathbf{Q}_k \,, \tag{14.93}$$

$$\mathbf{P}_k = (\mathbf{I} - \mathbf{K}\mathbf{H})\mathbf{P}_k^- \,, \tag{14.94}$$

where $\hat{}$ and $^-$ denote the notations of a posterior estimate and of a priori estimate respectively, $\mathbf{P}$ is a $3\times 3$ state covariance matrix, $\mathbf{R}$ is a $2\times 2$ measurement noise covariance matrix, and $\mathbf{Q}$ is a $3\times 3$ process noise covariance matrix.

In fact, KFs require exact knowledge of the noise statistics in its initialization and tuning processes, which are to set the initial state vector ($\boldsymbol{x}_0$) and its error covariances ($\mathbf{P}_0$, $\mathbf{Q}$, $\mathbf{R}$). This should be done empirically by fully employing a priori information of the system and the circumstances in which the KF operates. For example, in the signal tracking KF in a GNSS receiver, the coarse Doppler estimates $\hat{f}_{\mathrm{d},0}$ and its error range from the acquisition can be used for the initialization of $\hat{\boldsymbol{x}}_0$ and $\mathbf{P}_0$. Also, an empirical knowledge on the noise statistics of discriminator outputs can be used for tuning $\mathbf{R}$. Therefore, tuning of $\mathbf{Q}$ effectively determines the overall behavior of the signal tracking KF. Note that the uncertainty of the system dynamics model is dependent on the user dynamics, whereas that of the measurement model is governed by $C/N_0$. Therefore, an adaptive scheme can be employed to adjust the equivalent noise bandwidth by regularly testing the process and measurement noise statistics in response to changes in the signal dynamics as well as $C/N_0$ [14.57, 58].

Note that the signal tracking KF example described here is for the carrier-phase tracking loop, which uses both the PLL and FLL discriminator output for its measurement residuals, but can be also used for the PLL-only, the FLL-only, the DLL or their combined tracking with the relevant modifications of the architecture.

### 14.7.6 Vector Tracking

The concept of vector-based tracking technology, which is known as one of the most advanced signal processing architectures of modern digital GNSS receivers, was originally proposed in the early 1980s [14.59–63]. The most commonly cited reference for this appeared in the mid-1990s [14.64, 65]. Figure 14.20 shows an internal block diagram of a vector-tracking architecture.

The vector-tracking combines the signal tracking and navigation processing into one algorithm by a global optimum feedback through a line-of-sight projector, whereas a conventional scalar-tracking tracks each satellite's signal independently followed by a separate navigation solution processing [14.64, 65]. This means that in the vector-tracking mode individual tracking loops are eliminated and effectively replaced by a global feedback path from a navigation filter to each local channel to make a loop closure. Therefore, it enables efficient channel interactions, which represents the use of the redundant number of available satellites and their geometry in tracking a single satellite. It provides many benefits over the conventional scalar tracking, such as increased antijamming robustness, a higher signal tracking sensitivity, a better robustness to receiver dynamics, the ability to bridge signal outages and immediately reacquiring blocked signals [14.66]. Its primary drawbacks, however, are increased processing load and complexity, and instability of tracking channel by presence of a fault in one channel [14.1, 67, 68].

In fact, the vector tracking is originally based on the fact that the navigational solution parameters (i. e., position and time) of a GNSS receiver are not directly observable from the received signals. They are obtained through a two-layered nonlinear process: the first layer extracts the signal parameters of interest such as code delay, carrier phase, and Doppler from the received signals that are easily converted to range and range-rate measurements, and then the second layer calculates the navigational solution parameters by using these measurements. In other words, the received signal is a nonlinear function of the user's navigational solution parameters. Therefore, the vector-tracking architecture is implemented by closing the loop all the

way back to the signal correlators instead of having two separate shorter loops as in the conventional scalar-tracking architecture.

Theoretically the vector-tracking architecture has only one position estimator to calculate the navigational solution parameters directly from the received signals [14.53, 54, 69]. However, this approach has a serious drawback in a real implementation due to the physical limits of processing power; the signal processing channel should operate at a relatively higher rate than the navigation processing part and CPU limitations can mean that the navigation processing part cannot catch up with such a high operation speed. Moreover, the asynchronous property of each local signal tracking channel can be problematic [14.1, 70].

For this reason, a two-step filtering approach that has high-rate internal tracking loops and a low-rate navigation process (Fig. 14.20) is widely used [14.70–74]. Fundamentally, this approach is equivalent to the determination of efficient optimal parallel processing structures for channels that provide optimal estimates of the global system states for the navigational solution parameters. An appropriate error covariance at each layer should also be provided to the next layer for system optimality. A first look at this type of systems seems to turn back to the conventional scalar-tracking system, but it is noted that the main advantages of vector-tracking stated before are obtained from the efficient channel interaction performed by the global feedback, not from the construction of nonlinear measurement equations of received signals in terms of navigational solution parameters [14.1].

Therefore, in the vector tracking, two techniques, that is the efficient use of signal tracking KF and the channel interaction by the global loop closure, play an important role in achieving the performance improvement compared to the conventional scalar tracking [14.1, 70].

Another efficient method that links the high-rate internal tracking to the navigational solution is to first compute high-rate code pseudoranges and Doppler measurements and then model them during the measurement interval (e.g., every 1 s) by a polynomial as described in Sect. 14.6.3. The polynomial is then evaluated at the navigation update epoch for PVT computation. Practical results of this *polyfit* vector tracking method can be found in [14.75].

The outputs of signal tracking KFs in a local channel bank are then inputted into the navigation processor to solve the navigational equation as well as to produce feedback values for the NCO command in the individual local channels through a line-of-sight projector. The line-of-sight projector for the $i$th local channel, which is to project the navigational solution vector onto the line-of-sight domain of each channel, is implemented via a design matrix of the navigation solution and the predicted state variables. Without loss of generality it is expressed by the error state vector expression [14.70]

$$\begin{bmatrix} \delta\hat{\rho}_i \\ \delta\hat{\dot{\rho}}_i \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{H}}_{\rho_i} \\ \hat{\mathbf{H}}_{\dot{\rho}_i} \end{bmatrix} \delta\hat{\boldsymbol{x}}_{\mathrm{N}} \,, \tag{14.95}$$

where $\delta\hat{\rho}_i$ and $\delta\hat{\dot{\rho}}_i$ are the residual of predicted pseudorange and range rate respectively, $\hat{\mathbf{H}}_{\rho_i}$ and $\hat{\mathbf{H}}_{\dot{\rho}_i}$ are the partials of the modeled pseudorange and range rate with respect to the navigation solution, and $\delta\hat{\mathbf{x}}_{\mathrm{N}}$ is the residual of the navigation solution vector (i. e., global solution). The residual of predicted pseudorange and range rate, that is the projected residual of the navigation solution vector is converted to NCO commands, and then fed into the code/carrier generators to control replica signals in the next step.

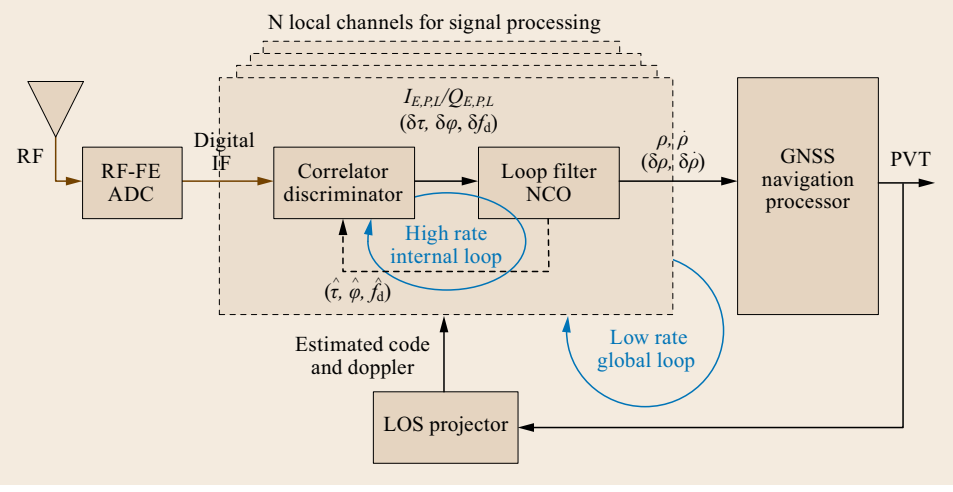

**Fig. 14.20** Internal block diagram of a vector-tracking architecture

Since the predicted pseudorange is less accurate than the corresponding carrier phase, it is critical when integrating the PLL into the vector-tracking architecture. If carrier-phase measurements are not required for positioning, the carrier phase should not be calculated from the projected pseudoranges. Instead, the carrier phase is freely running and determined by integrating the feedback Doppler [14.70].

It is necessary that all the channel measurements in a navigation processor should be synchronous, in order to achieve meaningful observables with a common clock bias, but that the start and stop boundaries of integration and dump process in a bank of channels are asynchronous. The meaningful observables having a common clock bias in a bank of channels can be obtained by propagating the pseudorange and range rate at a channel dump time to the receiver's fundamental time frame that is common to all the channels. This is performed in a NCO by using a state transition matrix for the corresponding time offset in the individual channel [14.70].

The benefit of this channel interaction effect was well reported analytically [14.68] and numerically [14.76] under the assumption of constant pseudorange residuals. Also, the benefits of various signal tracking KFs were analyzed by means of numerical simulations [14.1]. Overall, it is known from previously performed field tests and analyses that the vector tracking can provide about 7 dB gain in terms of $C/N_0$ compared to the conventional scalar tracking, where around 3 dB gain can be obtained from the efficient use of signal tracking KF and the other 4 dB gain from the channel interaction [14.1, 77]. This gain makes it possible to bridge a certain level of faded signals that very often occurs in urban canyons [14.70, 78].

# 15. Multipath

Michael S. Braasch

Multipath is the phenomenon whereby the signal from a satellite arrives at the receiver via multiple paths due to reflection and diffraction. These nondirect-path signals distort the received signal and cause errors in code and phase measurements. Differential techniques do not eliminate multipath and thus multipath is an important error source in high precision applications. The physical surroundings around the receiver's antenna dictate the multipath environment and thus cause significant differences for land, marine, airborne, and spaceborne users.

This chapter describes the multipath environment and presents models describing the impact of multipath on code and phase measurements. The influence of the type and rate of the broadcast code as well as the receiver architecture will be highlighted. Mitigation techniques based on receiver design will also be described along with the impact of receiver dynamics. Finally, a technique to measure multipath is described and its usage in evaluating static environments is discussed.

The goal of this chapter is to provide the reader with the tools to assess the impact of multipath on both the code and phase and to understand the performance improvements and limitations associated with various multipath mitigation techniques.

The signals broadcast by a given global navigation satellite system (GNSS) satellite at a particular moment in time will be received over a large fraction of the Earth's surface (specifically, the portion of the Earth that is *visible* to the satellite). The broadcast signal thus illuminates all objects in the vicinity of a given GNSS receiver in addition to the GNSS receiver–antenna itself. The composite signal received is therefore a combination of the direct line-of-sight (LOS) signal and signals that are reflected and/or diffracted from nearby objects. The *undesired* non-LOS signals cause distortion of the desired LOS signal. This, in turn, leads to tracking errors in the receiver and subsequently code and phase measurement errors.

The term *multipath* is derived from the phrase *multiple paths* but is conventionally used to describe the non-LOS signal (paths) that degrade the desired direct (path) signal. The first step in mitigating the multipath problem is to characterize the multipath environment. Following this, the impact of the multipath on the receiver processing and measurement generation can be determined. Mitigation strategies may then be effec-

tively implemented. Finally, techniques are needed to measure multipath error on GNSS measurements so that assessments can be made of the magnitude of the multipath problem for a given environment as well as to determine the efficacy of any mitigation strategies that are employed.

In order to avoid possible confusion, it should be noted that a phenomenon other than multipath can occur in dense urban canyon environments. In such places it is not uncommon for the LOS signal to be completely blocked (a situation that is also referred to as *shadowing*). It is then possible, in some cases, for a GNSS receiver to track and form measurements on non-LOS signals. Resulting errors can be very large since the measurements are not tied in any way to the direct path signal. This non-LOS signal tracking problem is separate from, and should not be confused with, the multipath problem that is the subject of this chapter.

## 15.1 The Impact of Multipath

Multipath is just one of many error sources that affect GNSS accuracy and thus its impact must be characterized in the context of a given environment and application. Besides multipath, typical GNSS error sources include satellite clock and ephemeris error (that induce ranging errors on the order of 1–2 m), ionospheric delay (with ranging errors varying from 5 to 30 m if uncompensated), tropospheric delay (ranging errors varying from 2 to 20 m if uncompensated), and receiver noise (pseudorange errors on the decimeter to meter level and carrier-phase errors on the order of millimeters to centimeters). Pseudorange multipath errors can range as high as 100 m in the most severe conditions whereas carrier-phase multipath errors range from millimeters to centimeters.

The severity of the multipath impact is strongly dependent upon the GNSS application. For example, aircraft utilizing GNSS for enroute navigation can tolerate several hundred meters of position error and thus multipath is not a significant error source. Ships traversing open water are in a very similar situation as are satellites utilizing GNSS for orbit determination and station keeping. In general, any application that does not require the use of differential corrections (either ground based or space based) will typically not be significantly affected by multipath.

However, any application that does require the use of code differential corrections will find multipath to be problematic. This is due to the fundamental principle of differential GNSS: Differential corrections only remove those error sources that are common both to the remote unit and the reference station (Chap. 12 and Chap. 31). Even for closely spaced receivers, multipath error will not, in general, be removed by differential corrections. The distinct difference in multipath error at physically separated receivers is due mainly to the short carrier wavelength of GNSS signals. Even small receiver separations are relatively large in terms of GNSS wavelengths.

For differential carrier-phase applications, multipath has two primary effects. Since initial ambiguity estimates are typically derived from pseudorange measurements, pseudorange multipath will force a large search space and thus cause ambiguity resolution to take longer than would be the case in a cleaner environment. Once ambiguities have been resolved, carrier-phase multipath will limit the accuracy of the determined baseline.

## 15.2 Characterizing the Multipath Environment

The general multipath environment is illustrated in Fig. 15.1. In addition to the desired direct path signal, there are three non-LOS signals impinging upon the antenna of the GNSS receiver. There are two reflected signals (one from the building on the right and one from the ground) and one diffracted signal. The reflected signals obey Snell's law wherein the angle of incidence equals the angle of reflection. Diffracted signals emanate from the edges of objects, such as the roof corner of the building on the left, and scatter in a wide range of angles.

An important principle can be drawn from Fig. 15.1. All multipath signals travel a longer path than the direct signal. A given point on the direct path signal will therefore arrive at the antenna earlier in time than the same point on any of the multipath signals. In general there are five parameters that characterize a given multipath signal:

1. Relative delay
2. Relative amplitude
3. Relative phase
4. Relative phase rate
5. Relative polarization.

*Relative* refers to the direct path signal. Thus multipath with a relative amplitude of, say, −10 dB, means the am-

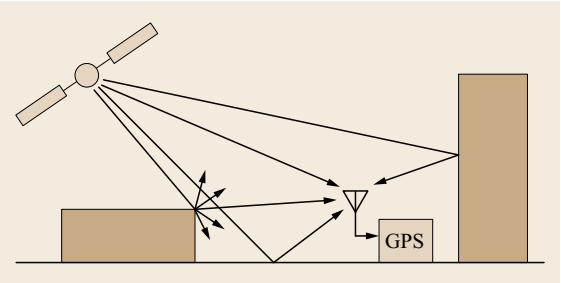

**Fig. 15.1** General multipath environment

plitude of the multipath is 10 dB below the amplitude of the direct path signal. In some contexts, the *relative* is understood and thus is not stated explicitly.

For the case of simple reflections from flat surfaces, determination of relative delay can be aided through the use of *image theory* from electromagnetic theory. First consider the simple reflection case illustrated in Fig. 15.2. Note that since the distance from the antenna to the satellite is much, much larger than the distance between the antenna and the reflecting surface, the signal paths from the satellite are approximated as being parallel. Determining the relative delay of the multipath requires determining the extra path length traveled by the multipath. Although certainly a tractable problem, it is greatly simplified through the use of image theory as depicted in Fig. 15.3. An imaginary *image* antenna is placed at a distance $h$ below the reflecting plane whereas the actual antenna is located at a height $h$ above the plane. The path length from the satellite to the image antenna in Fig. 15.3 is the same path length as for the multipath depicted in Fig. 15.2. With image theory, however, determination of the additional multipath path length is a simple application of trigonometry.

The amplitude of the multipath is affected by the size, shape, and reflection coefficient of the multipath inducing surface. The primary factor affecting the amplitude of the reflected or diffracted signal is the reflection coefficient of the multipath-inducing surface. Detailed treatment of reflection coefficients will not be provided here but it must be noted that reflection coefficients are a function of the angle of incidence of the signal and typically approach unity for near parallel incidence (e.g., very small elevation angles in the case of ground reflection). Thus, although dry soil will attenuate a reflected GNSS signal by approximately 10 dB for normal incidence (e.g., 90° elevation angle in the case of ground reflection), the amount of attenuation decreases as the elevation angle decreases. Table 15.1 lists approximate attenuation values for typical surface types for the L1 frequency with normal incidence. The table indicates that strong reflections are possible from wet soil, bodies of water, and tinted glass. As will be described later, surface roughness can effectively provide some attenuation to the reflected signal.

Following the theory of optics, significant signal reflection only occurs for objects large enough in size that they span a significant fraction of a cross-section of the

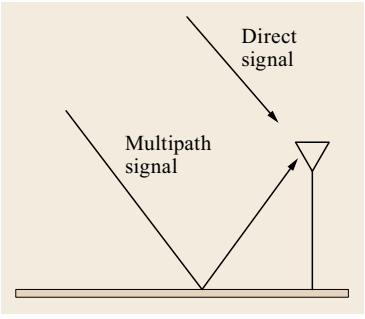

**Fig. 15.2** Simple reflection case

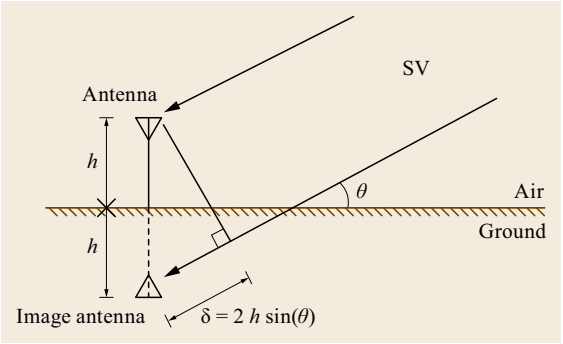

**Fig. 15.3** The image antenna is located at a distance below the reflecting plane equal to the distance of the real antenna above the reflecting plane. The multipath relative delay is given by the extra distance that the signal has to travel to the image antenna versus the path to the real antenna. This may easily be obtained from the figure through simple trigonometry

**Table 15.1** Reflection coefficients and attenuation factors for common surfaces at normal incidence (elevation angle of 90°) at the L1 frequency (after [15.1–3])

| Surface type | Reflection coefficient | Attenuation factor (dB) |
|---|---|---|
| Dry soil | 0.268 | −11.4 |
| Moderate soil | 0.566 | −4.94 |
| Wet soil | 0.691 | −3.21 |
| Grassy field | 0.334 | −9.53 |
| Asphalt | 0.121 | −18.3 |
| Fresh water | 0.800 | −1.95 |
| Sea water | 0.811 | −1.83 |
| Glass | 0.421 | −7.51 |
| Tinted glass | 0.950 | −0.446 |
| Brick | 0.345 | −9.24 |
| Concrete | 0.404 | −7.87 |

first Fresnel zone [15.4]. The first Fresnel zone is an ellipsoid about the LOS between a transmitting antenna and a receiving antenna consisting of all points each with a combined path length to the receiving and transmitting antennas that is one-half wavelength longer than the LOS distance. In the case of GNSS reflected signals, however, the receiving antenna is not the actual antenna but, rather, the image antenna. This is depicted in Fig. 15.4 for the same ground reflection scenario discussed earlier. The cross-section of the first Fresnel zone is observed to be an ellipse. It follows that if the satellites were directly overhead (i. e., normal incidence), the cross-sectional area would be a circle. The first-order approximation of the radius of this circle (known as the first Fresnel zone radius) is given by [15.5]

$$r = \sqrt{\frac{\lambda d_t d_r}{d_t + d_r}}\,, \tag{15.1}$$

where $\lambda$ is the carrier frequency of the transmitted signal, $d_t$ is the distance from the cross-section to the transmitter and $d_r$ is the distance from the cross-section to the receiver. Note it is assumed that $d_t$ and $d_r$ are both much, much larger than $\lambda$.

For cases where $d_t$ is much, much larger than $d_r$ (such as GNSS), the denominator in (15.1) is approximated by $d_t + d_r \approx d_t$ and then (15.1) reduces to

$$r = \sqrt{\lambda d_r}\,. \tag{15.2}$$

For oblique incidence, the cross-section is an ellipse, not a circle. The length of the semimajor axis of this ellipse can be approximated by $a = r/\sin(\theta)$ where $\theta$ is the angle between the reflecting plane and the LOS to the satellite (Fig. 15.3). The Fresnel zone radius may be computed using (15.2) but note that in the oblique incidence case, the distance from the image antenna to the point of reflection is given by the orthogonal distance of the antenna from the reflecting plane divided by the sine of $\theta$.

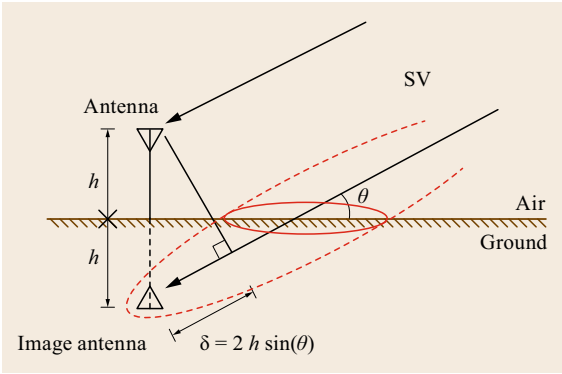

**Fig. 15.4** Depiction of the ellipsoidal Fresnel zone along the path from the satellite to the image antenna

As an example, if an antenna is 1 m above a reflecting surface and a satellite is directly overhead, the radius of the Fresnel zone cross-section (at the L1 frequency) is 0.436 m. For the same antenna height, the length of the semimajor axis of the cross-section for a satellite at 5° elevation angle is approximately 17 m. At a height of 10 m, the radius of the circular cross-section is 1.4 m and for a 5° elevation angle satellite, the semimajor axis length is approximately 54 m. For reflecting surfaces that are not horizontal, the same concepts apply but the actual calculations are somewhat more complex. In any case, it is clear that objects less than a wavelength in size are not significant sources of reflected energy. For oblique incidence, the reflecting surface needs to be dozens or even hundreds of wavelengths in size depending upon the orthogonal distance of the antenna from the reflecting plane.

Regarding reflecting obstacle shape, planar surfaces are the most problematic since they produce reflections that are focused in a particular region. Besides the surface of the earth itself (either the ground or bodies of water), planar surfaces abound particularly in urban canyon environments in the form of industrial and office buildings. A concept related to obstacle shape is surface roughness. A flat piece of metal is obviously an ideal reflector. However, what if one considers a field of tall grass (i. e., one that has not been mowed)? Although entire books have been written on the subject of electromagnetic scattering from rough surfaces [15.4], suffice it to say that rough surfaces do not produce pure specular reflection in a particular direction. Instead, each small locally flat surface produces a weak reflection in a direction consistent with Snell's law. This yields a broadly scattered field. In this context, the electromagnetic *roughness* of a surface is a function of the wavelength of the transmitted signal and the angle of incidence. A surface can be considered eletromagnetically rough if it has variations in height that are on the order of a wavelength or more and in which peak to trough variations occur laterally with spacing also on the order of a wavelength. However, this characterization only holds for normal incidence (i. e., an elevation angle of 90° in the case of ground reflection). Even rough surfaces appear smooth for very small *grazing* angles (e.g., *elevation* angles in the case of ground reflection).

Reflections from electromagnetically smooth surfaces are referred to as *specular* reflections whereas reflections from rough surfaces are referred to as *diffuse* reflections. As an example, diffuse reflections of GNSS signals from a grassy field will be attenuated by approximately 2–4 dB (for elevation angles ranging from

5–90°). Similarly, for dense brush/weeds, the attenuation ranges from 5 to 10 dB and for trees the attenuation ranges from 10 to 20 dB [15.6].

The relative phase of the multipath dictates whether it will constructively or destructively interfere with the direct signal. As will be described later, this results in a range of pseudorange and carrier-phase measurement errors that can occur for a multipath signal with a given delay and amplitude. The relative phase of the multipath is a function of the relative path delay and the reflection coefficient of the multipath-inducing surface. Since the reflection coefficient is, in general, a complex quantity, the reflected signal can experience an effectively instantaneous change of phase upon reflection.

The relative phase of the multipath can experience a nonzero time rate of change due to the relative motion of the transmitter, receiver, and multipath-inducing obstacle. As will be discussed later, GNSS receiver tracking loops will, to varying degrees, attenuate the multipath component of the received signal if its relative phase-rate is large compared to the tracking loop bandwidth. Thus, a GNSS-equipped automobile driving by a large building will not be affected as severely as when it is parked near the building.

The multipath phase-rate may be obtained by calculating the derivative of the multipath relative delay. As an example, consider the simple ground reflection scenario depicted in Fig. 15.3. The multipath relative delay is given by

$$\delta(t) = 2h(t)\sin[\theta(t)] \,. \tag{15.3}$$

It is instructive to consider two special cases: static and dynamic receivers. In the case of a static receiver (e.g., a ground reference station), the height is a constant and only the satellite elevation angle is changing. Conversely, in the case of a dynamic receiver (e.g., an aircraft descending to land), the satellite elevation angle can be considered constant (over short time intervals) whereas the receiver height is changing. Note the principle is the same if, say, a car is driving toward a large building; however the geometry is slightly more complex to analyze. For the static receiver case, the derivative of the relative delay is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\delta(t) = 2h\cos[\theta(t)]\frac{\mathrm{d}\theta}{\mathrm{d}t} \,. \tag{15.4}$$

Although precise rates-of-change of satellite elevation angle can be obtained using the broadcast ephemeris parameters for specific receiver locations, a rough rule-of-thumb can be obtained simply by recognizing that, at mid-latitudes, the main satellite pass of the day (i. e., satellite rise to satellite set) takes approximately 8 h. Thus roughly 180° of elevation are traversed in 8 h which corresponds approximately to $10^{-4}$ rad/s. For a nominal satellite elevation angle of 30° and an elevation angle rate of $10^{-4}$ rad/s, (15.4) yields a multipath relative delay rate of $h \cdot 1.73 \cdot 10^{-4}$ m/s. This can be converted to a phase rate by dividing by the carrier wavelength. For the example considered, at L1 this yields $h \cdot 9.1 \cdot 10^{-4}$ Hz or, roughly, 1 mHz/m of antenna height. For typical ground reference station antennas, then, the error oscillations due to ground reflection are very low frequency. These frequencies are referred to in the literature as multipath phase rates or as *fading frequencies*.

Conversely, for dynamic receivers, significantly higher fading frequencies are possible. Over short time intervals (e.g., less than a minute), the satellite elevation angle can be considered a constant and the derivative of (15.3) yields

$$\frac{\mathrm{d}}{\mathrm{d}t}\delta(t) = 2\sin(\theta)\frac{\mathrm{d}}{\mathrm{d}t}h(t) \,. \tag{15.5}$$

Again, this can be converted to a phase rate by dividing by the carrier wavelength. At L1, for example, a descent rate of 1 m/s results in a phase rate of approximately 0–10 Hz for satellite elevation angles ranging from 0 to 90°. For a specific application, consider an aircraft performing an approach to landing. For a typical 3° glide path angle and an approach speed of 100 knots, the vertical descent rate is approximately 2.7 m/s. For a nominal satellite elevation angle of 30°, (15.5) yields a relative delay rate of approximately 1.3 m/s and, at L1, a fading frequency of approximately 7 Hz. Note this is 3 orders of magnitude larger than the ground reflection fading frequencies generated for a static receiver. As will be discussed later, certain receiver architectures can significantly attenuate the so-called fast fading multipath.

The last parameter is the relative polarization of the multipath signal. GNSS signals are circularly polarized. A circularly polarized signal reflected from a perfect conductor (e.g., metal) will experience a polarization reversal. Thus if the incident wave is right-hand circularly polarized, the reflected signal will be left-handed. This is important since GNSS antennas are designed to receive the desired polarization and will attenuate the opposite polarization (typically on the order of 10 dB). For nonmetallic surfaces, however, the polarization of the reflected signal will be a mixture of both right- and left-handed yielding what is known as elliptical polarization. In this case the antenna will attenuate only that portion of the signal that is reverse polarized. Typically this is half the reflected field and thus approximately 3 dB of attenuation is achieved.

## 15.3 Multipath Signal Models

A received GNSS signal consisting of the LOS signal plus $N$ reflected signals can be modeled as [15.7]

$$s(t) = \sum_{i=0}^{N} a_i(t)p[t-\tau_i(t)]\cos[\omega_o t + \theta_i(t)] + \epsilon(t)\,, \tag{15.6}$$

where $a_i(t)$ is the amplitude of the $i$-th component, $p(t)$ is the GNSS code modulation, $\tau_i(t)$ is the relative time delay of the $i$-th component, $\omega_o$ is the nominal frequency of the LOS signal, $\theta_i(t)$ is the relative phase of the $i$-th component and $\epsilon(t)$ represents the noise. In this model, all other error sources are ignored. The LOS signal component corresponds to $i = 0$ and, without loss of generality, the LOS signal parameters are defined as: $a_0(t) = 1$, $\tau_0(t) = 0$, and $\theta_0(t) = 0$.

As described in Chap. 14, tracking of the code of most GNSS signals utilizes some form of delay-lock loop (DLL) also known as early-minus-late tracking. Tracking of the carrier involves processing a *prompt* channel that lies between the early and late channels. To understand the influence of multipath on both the code and carrier, we must first consider its impact on the correlation function. This is illustrated in Fig 15.5 for the simplified case of a binary phase shift keying (BPSK) signal with infinite bandwidth and a single multipath signal. The left illustration in the figure depicts the absence of multipath in which the main correlation peak is symmetrical about a lag of zero. In the center, the correlation peak associated with a single multipath signal is illustrated along with the direct path peak. These separate peaks are not observable in reality but are useful to consider separately for analysis purposes. On the right, the combination of the two is illustrated with the assumption that the multipath is *in phase* with the direct signal (e.g., the relative phase of the multipath is zero). This composite, distorted, correlation function is what the receiver must process for tracking. As will described next, the asymmetry of the distorted correlation function results in tracking error that yields pseudorange measurement error. The multipath also distorts the phase of the received signal and this leads to carrier-phase measurement error.

Figure 15.6 illustrates the formation of the DLL discriminator function (sometimes referred to as the S-function or S-curve) for the case of 1 chip early-to-late spacing. In the absence of multipath, the zero-crossing of the discriminator function provides a tracking point that corresponds to the peak of the unshifted (referred to as *prompt*) correlation function. In the presence of multipath, however, the asymmetrical distortion of the correlation function induces a shift in the zero-crossing point. The amount of shift, when converted from chips to units of distance, is equal to the pseudorange error due to multipath.

There are two broad categories of DLLs. Coherent DLLs assume the carrier-tracking loop is locked in phase to the received signal. Noncoherent DLLs do not make this assumption and must, as a result, square the correlator outputs prior to forming the discriminator function. For the aforedescribed general signal model, the coherent DLL discriminator function is given by [15.7]

$$S_{\text{coh}}(\tau) = \int_{t}^{t+T_{\text{avg}}} \sum_{i=0}^{N} a_i(t)\cos(\theta_i - \theta_c) \times \left[R\left(\tau - \tau_i + \frac{d}{2}\right) - R\left(\tau - \tau_i - \frac{d}{2}\right)\right] \mathrm{d}t\,, \tag{15.7}$$

where $\theta_c$ is the phase of the composite received signal, $R(\tau)$ is the correlation function of the GNSS code for a lag value of $\tau$, $d$ is the early-to-late correlator spacing

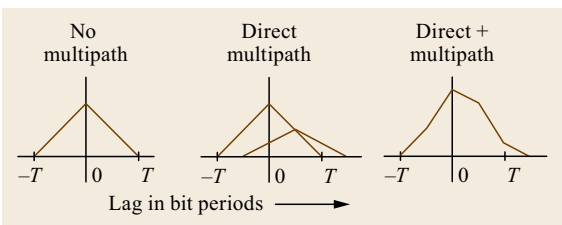

**Fig. 15.5** Correlation function for combination of direct and reflected signal

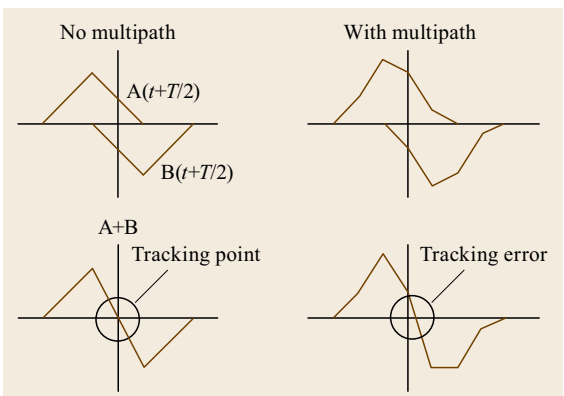

**Fig. 15.6** Discriminator function for combination of direct and reflected signal

and $T_{\text{avg}}$ is the time over which the correlator outputs are averaged before forming the discriminator function. Note the code tracking loop bandwidth is given by the one-sided noise bandwidth of the averaging [15.7]: $B_{\text{L}} = 1/(2T_{\text{avg}})$.

Although a variety of noncoherent discriminators exist, the simplest is the early-power-minus-late-power detector (Chap. 14). For this noncoherent DLL, the early and late correlator components are squared before they are differenced [15.7]

$$S_{\text{ncoh}}(\tau) = \int_{t}^{t+T_{\text{avg}}} \left| \sum_{i=0}^{N} a_i(t) R\left(\tau - \tau_i + \frac{d}{2}\right) \mathrm{e}^{\mathrm{j}\theta_i} \right|^2 - \left| \sum_{i=0}^{N} a_i(t) R\left(\tau - \tau_i - \frac{d}{2}\right) \mathrm{e}^{\mathrm{j}\theta_i} \right|^2 \mathrm{d}t \,. \tag{15.8}$$

As described in Chap. 14, the DLL tracks the received signal by shifting its locally generated code so as to drive the discriminator function to zero. As shown in Fig. 15.6, in the presence of multipath the discriminator function zero-crossing point is erroneous. This zero-crossing point (or DLL tracking point of the composite signal) will be denoted by $\tau_{\text{c}}$ in this chapter.

The carrier-tracking loop tracks the phase of the composite received signal. This composite phase is given by the phase angle of the prompt correlator output. The prompt correlator output is given by the vector sum of the prompt correlation of each component given in (15.6) [15.7]

$$\theta_{\text{c}} = \arg\left[ \int_{t}^{t+T_{\text{avg}}} \sum_{i=0}^{N} a_i \mathrm{e}^{\mathrm{j}\theta_i} R(\tau_{\text{c}} - \tau_i) \mathrm{d}t \right], \tag{15.9}$$

where, as noted above, $\tau_{\text{c}}$ is the DLL code tracking error due to the multipath. Since the phase of the LOS signal is zero by definition, $\theta_{\text{c}}$ is the carrier-phase measurement error as well as the phase of the composite received signal.

A first-order model of the correlation function is given by

$$R(\tau) = \begin{cases} 1 - \frac{|\tau|}{T_{\text{c}}} \,, & |\tau| \le T_{\text{c}} \\ 0 \,, & |\tau| > T_{\text{c}} \,, \end{cases} \tag{15.10}$$

where $T_{\text{c}}$ is the period of the GNSS code chip. This model ignores the influence of noise, assumes an infinite bandwidth signal and assumes the correlation function has no sidelobes (i. e., nonzero values outside of the main peak). If noise is ignored in this manner, then the integration/averaging operations in (15.7)–(15.9) can be dropped.

An alternate form of (15.9) can be obtained by first considering the phasor diagram of Fig. 15.7 depicting the direct signal and a single multipath signal [15.8]. The relative phase of the multipath is $\theta_{\text{m}}$ whereas the phase of the composite received signal is $\theta_{\text{c}}$. The phasors are given by

$$\begin{aligned} D &= a_0 R(\tau_{\text{c}}) \,, \\ M &= a_1 R(\tau_{\text{c}} - \tau_1) \mathrm{e}^{\mathrm{j}\theta_{\text{m}}} \,, \end{aligned} \tag{15.11}$$

where, as before, $\tau_{\text{c}}$ is DLL code tracking error (depicted, for example, in the *lower right* of Fig. 15.6). To aid in the determination of $\theta_{\text{c}}$, the multipath phasor is decomposed into in-phase ($M_{\text{I}}$) and quadrature ($M_{\text{Q}}$) components depicted in Fig. 15.8 [15.8]

$$\begin{aligned} M_{\text{I}} &= a_1 R(\tau_{\text{c}} - \tau_1) \cos(\theta_{\text{m}}) \,, \\ M_{\text{Q}} &= a_1 R(\tau_{\text{c}} - \tau_1) \sin(\theta_{\text{m}}) \,. \end{aligned} \tag{15.12}$$

Determination of $\theta_{\text{c}}$ is then a simple application of trigonometry

$$\begin{aligned} \theta_{\text{c}} &= \arctan\left( \frac{M_{\text{Q}}}{D + M_{\text{I}}} \right) \\ &= \arctan\left[ \frac{\alpha_1 R(\tau_{\text{c}} - \tau_1) \sin(\theta_{\text{m}})}{R(\tau_{\text{c}}) + \alpha_1 R(\tau_{\text{c}} - \tau_1) \cos(\theta_{\text{m}})} \right], \end{aligned} \tag{15.13}$$

where $\alpha_1 = a_1/a_0$ is the relative amplitude of the multipath (also known as the multipath-to-direct ratio or M/D). For the general case of N multipath signals, the composite phase is given by [15.9]

$$\theta_{\text{c}} = \arctan\left( \frac{\sum_{i=1}^{N} \alpha_i R(\tau_{\text{c}} - \tau_i) \sin(\theta_{\text{m},i})}{R(\tau_{\text{c}}) + \sum_{i=1}^{N} \alpha_i R(\tau_{\text{c}} - \tau_i) \cos(\theta_{\text{m},i})} \right). \tag{15.14}$$

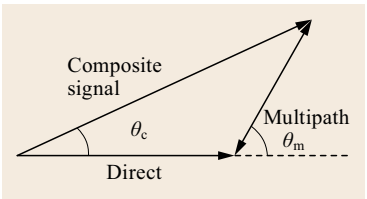

**Fig. 15.7** Phasor diagram depicting the composite phasor as the vector sum of the direct and multipath phasors

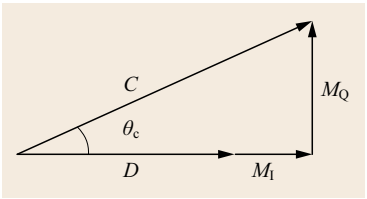

**Fig. 15.8** Phasor diagram with the multipath phasor resolved into in-phase and quadrature components

Note that since $\theta_c$ spans 0 to $2\pi$, a four-quadrant arctangent function must be utilized when performing computer simulations.

For simple reflections from planar surfaces, the relative delay can be calculated as discussed earlier. The relative amplitude is determined as a combination of the reflection coefficient and any attenuation provided by surface roughness. For reflecting surfaces that do not fully span the first Fresnel zone, an additional attenuation factor applies as well.

## 15.4 Pseudorange and Carrier-Phase Error

Calculation of pseudorange and carrier-phase multipath error for the case of coherent DLLs is somewhat complicated due to the coupling of the equations. For example, (15.7) provides the equation for the discriminator function that is distorted due to multipath. The $\tau$ for which this function is zero corresponds to the pseudorange error due to the multipath (noted herein by $\tau_c$). However, in addition to the parameters that specify the receiver's correlator spacing ($d$) and the multipath ($a_i$, $\theta_i$, $\tau_i$), the composite phase ($\theta_c$) must also be specified. The composite phase is given in (15.14) but note this equation requires the pseudorange tracking error ($\tau_c$) which, as just stated, is the solution of (15.7) when it is set equal to zero. The simultaneous solution of these equations must thus be performed iteratively. Initial guesses for $\tau_c$ are used to calculate the discriminator value and slope and the initial guesses are also used in the calculation of the composite phase. Specifically, for a given value of $\tau$ used to evaluate the discriminator, that same value is first used to determine the composite phase. As the iteration continues in the search for the zero of the discriminator function, both $\tau_c$ and $\theta_c$ converge to the correct solution simultaneously. Of course, the situation is simpler in the case of noncoherent DLLs since the discriminator function (15.8) is not a function of the composite phase.

## 15.5 Multipath Error Envelopes

The pseudorange multipath error concept just illustrated can be quantified analytically and through simulation. Figure 15.9 provides an example of a BPSK pseudorange multipath error *envelope* for the case of a single multipath signal that is half the amplitude of the direct signal (the relative amplitude is also referred to as the multipath-to-direct or M/D ratio).

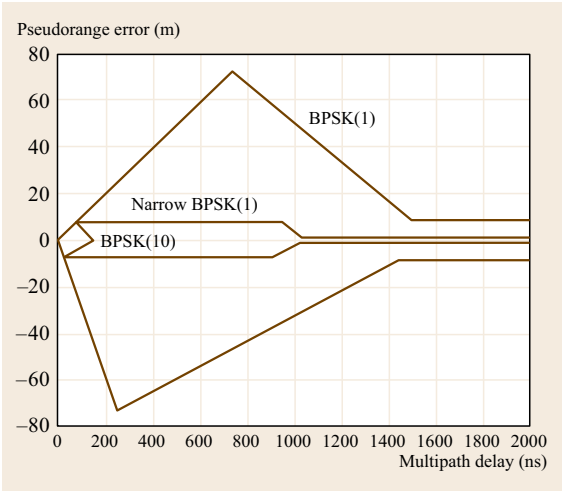

**Fig. 15.9** Pseudorange multipath error envelopes for BPSK(1) wide correlator, BPSK(1) narrow correlator, and BPSK(10) wide correlator (infinite bandwidth assumed)

Three cases are illustrated (all with the simplifying assumption of infinite signal bandwidth):

1. BPSK(1) tracking with 1 chip early-to-late spacing
2. BPSK(1) tracking with 0.1 chip spacing
3. BPSK(10) tracking with 1 chip spacing.

In each case, the upper curve represents the maximum error due to multipath and the lower curve represents the minimum error. For pseudorange measurements, the maximum error occurs when the relative phase of the multipath is zero (also referred to as *in-phase* multipath) and the minimum error occurs when the relative phase is 180° (also known as *out-of-phase*). The pseudorange error for all other multipath relative phases will lie somewhere between the upper and lower curves, hence the use of the term *envelope*. A general form of the infinite-bandwidth multipath error envelope (for BPSK signals) was derived in [15.10] and is illustrated in Fig. 15.10.

Several important points may be noted from this figure. First, the maximum pseudorange error is $\alpha d/2$ where $\alpha$ is the M/D ratio and $d$ is the early-to-late correlator spacing. This provides an easily calculated upper bound on pseudorange multipath error for a sin-

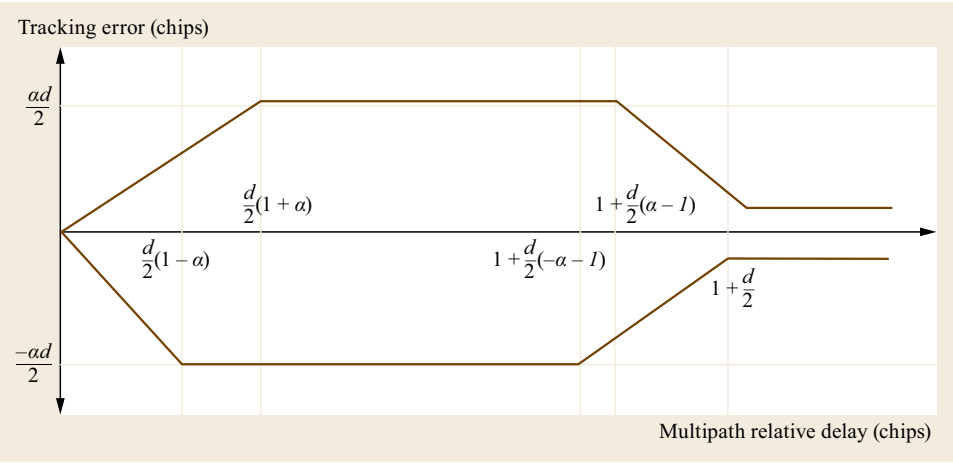

**Fig. 15.10** Generalized infinite-bandwidth multipath error envelope for BPSK tracking

gle specular reflection. Second, the maximum negative error occurs at a shorter relative delay than the maximum positive error and this is related to the fact that the error has a nonzero mean, especially when the M/D ratio is large. Third, the envelope does not decrease to zero at large relative delays. This is due to the presence of sidelobes in the autocorrelation function of the GNSS signal [15.10]. It should also be noted that the pseudorange multipath error envelopes are the same for both coherent and noncoherent DLLs. Behavior within the envelopes, however, are different and this manifests in differing average error characteristics as will be shown in a later section.

As described in Chaps. 7 and 9, newer signal structures have been developed based on binary offset carrier (BOC)/multiplexed binary offset carrier (MBOC)/composite binary offset carrier (CBOC) techniques. As shown in Chap. 4, the correlation functions of these signals have the same envelope as those of BPSK signals (with the same chipping rate) but differ via the sawtooth shape within the envelope. As a result, the general BPSK multipath error envelope (Fig. 15.10) bounds the corresponding envelopes of the BOC/MBOC/CBOC signals. An example is shown in Fig. 15.11 for $\alpha = 0.5$ and $d = 0.1$ (except for the BPSK(10) signal in which $d = 1$).

Calculation of the pseudorange multipath error envelope is simplified somewhat due to the decoupling of the pseudorange and carrier-phase errors. Specifically, maximum pseudorange error occurs when there is maximum distortion of the modulation of the received signal. As described above, this occurs under conditions of total constructive interference (i. e., the multipath is in-phase with the direct) or total destructive interference (i. e., out-of-phase multipath). Thus, the multipath relative phase is simply 0 or π. Such a simple relationship is not the case, however, when one attempts to calculate

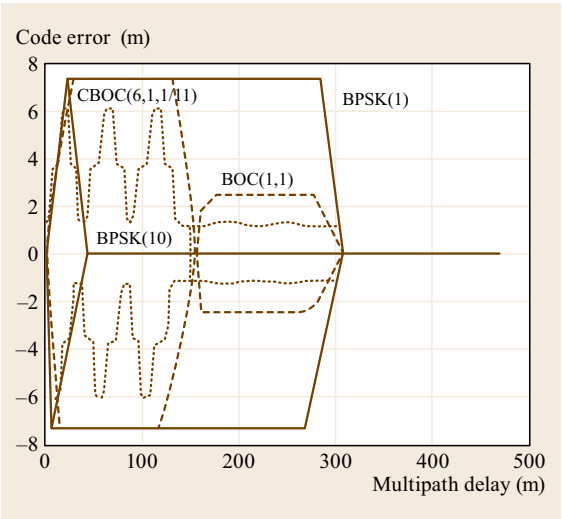

**Fig. 15.11** Infinite-bandwidth multipath error envelopes for narrow correlator ($d = 0.1$ chip) for BPSK(1), BOC(1,1), CBOC(6,1,1/11) and standard correlator ($d = 1$ chip) for BPSK(10). The relative multipath amplitude is 0.5

the carrier-phase multipath error envelope. The theoretically exact result must be obtained through a search process. Specifically, for a given multipath relative delay ($\tau_m$), the carrier-phase error equation (e.g., (15.13) and either (15.7) or (15.8)) must be solved for a range of relative phases between 0 and π. The envelope value is then given by the maximum value of $\theta_c$ obtained over all relative phases. This procedure was utilized in [15.8] and the results were validated with a real receiver and a hardware simulator.

The aforementioned procedure is cumbersome and simplified models have been described [15.7, 11]. As can be readily deduced from Fig. 15.7, the maximum carrier-phase error occurs when the multipath phasor is

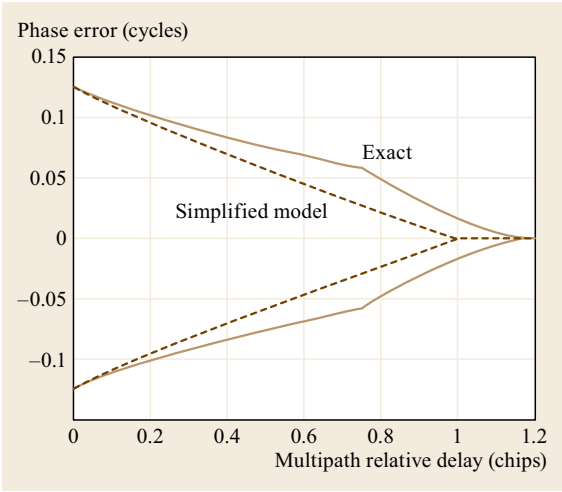

**Fig. 15.12** Carrier-phase multipath error envelope (strong multipath, wide correlator)

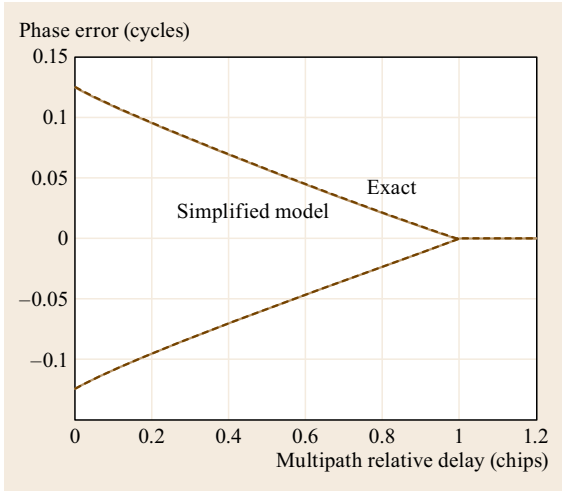

**Fig. 15.13** Carrier-phase multipath error envelope (strong multipath, narrow correlator)

orthogonal to the composite phasor. In this special case, the composite carrier-phase is given by [15.12]

$$\begin{aligned}\max(\theta_c) &= \arcsin(M/D) \\ &= \arcsin\left(\frac{\alpha_1 R(\tau_c - \tau_1)}{R(\tau_c) + \alpha_1 R(\tau_c - \tau_1)}\right) . \end{aligned} \quad (15.15)$$

However, this equation is difficult to evaluate for coherent DLLs since, as discussed above, $\tau_c$ can only be determined after $\theta_m$ has been specified. *Van Nee* has noted [15.7] that a simplification can be achieved if the pseudorange tracking error ($\tau_c$) is negligibly small. Specifically, if $\tau_c \approx 0$, then the first-order model of the correlation function (15.10) yields: $R(0) = 1$. Substituting these values into (15.15) yields the approximate formula [15.7, 8, 11]

$$\max(\theta_c) \approx \arcsin(\alpha_1 R(\tau_1)) . \quad (15.16)$$

Figure 15.12 depicts the carrier-phase multipath error envelope for a coherent DLL with an early-to-late correlator spacing of 1 chip and an M/D of −3 dB. Both the theoretically exact result and the result with the approximate formula are shown. In this somewhat extreme case, there is a noticeable discrepancy between the two. However, even with such a strong multipath signal, if a narrow-correlator architecture (0.1 chip early-to-late spacing) is utilized, the approximation is quite good as shown in Fig. 15.13. Furthermore, for the case of weak multipath signals, the approximate formula is quite accurate even for wide correlator spacing (Fig. 15.14). Observe that, unlike the pseudorange, the carrier-phase multipath error envelope has its maximum value at a relative delay of zero. Thus carrier-phase multipath error increases as the receiver–antenna gets closer to a reflecting object.

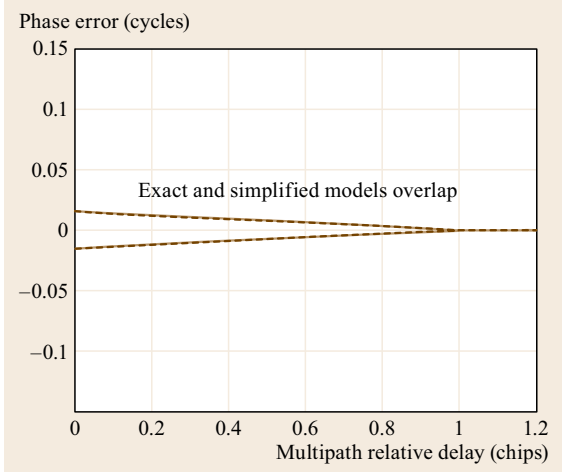

**Fig. 15.14** Carrier-phase multipath error envelope (weak multipath, wide correlator)

## 15.6 Temporal Error Variation, Bias Characteristics and Fast Fading Considerations

Typically the multipath relative delay will vary with satellite/receiver/reflecting-obstacle motion. For example, in the case of a stationary receiver experiencing ground multipath (Fig. 15.3), the relative delay will start near zero as the satellite rises above the horizon, will increase to a maximum value of $2h$ when the satellite is directly overhead, and then will decrease back to zero as the satellite sets (the maximum value will be less if the satellite does not pass directly overhead).

To understand the temporal variation of the pseudorange and carrier-phase multipath error as relative path delay varies, Figs. 15.15 and 15.16 plot, for BPSK(1) and $d = 1$, the errors for a short range of relative delay with the relative multipath phase computed only as a function of the path delay. In these plots, the relative phase of the multipath is computed from path delay by converting the path delay to units of wavelengths, subtracting off the whole number of wavelengths, and then converting the remaining residual to radians (note this computation ignores any phase shifts that occur at the surface of the reflecting obstacle). From these figures, one can observe that the errors are largely sinusoidal for weak multipath relative amplitudes but are nonsinusoidal for strong multipath relative amplitudes. The errors also appear to be orthogonal. That is, the pseudorange errors appear to peak when the carrier-phase error is zero and vice versa. This is not precisely correct. As discussed earlier, the multipath phasor must be orthogonal to the composite phasor to achieve maximum carrier-phase error. For strong multipath this will occur for relative phase values significantly greater than 90°. For weak multipath scenarios and/or multipath-mitigating receiver architectures such as narrow-correlator, the pseudorange, and carrier-phase errors are approximately orthogonal.

Furthermore, pseudorange multipath errors have nonzero mean values. This can be shown by averaging the pseudorange multipath errors, at a given value of relative delay, for relative phase values over the range of 0 to $2\pi$. Figure 15.17 depicts the BPSK bias error for a coherent wide correlator spacing (1.0 chip) receiver with multipath relative amplitudes ranging from −20 to −3 dB. The bias error is most pronounced for strong multipath and relative delays in the range of one-half to one chip. As Fig. 15.18 shows, there is approximately a factor of 5 reduction in peak bias error with narrow correlator spacing (0.1 chip). However, for short delay multipath, the performance advantage disappears as shown in Fig. 15.19.

Similar characteristics may be observed with noncoherent receivers. Figure 15.20 depicts bias error for a noncoherent wide correlator spacing (1.0 chip) receiver with multipath relative amplitudes ranging from −20 to −3 dB. Although the peak error is nearly dou-

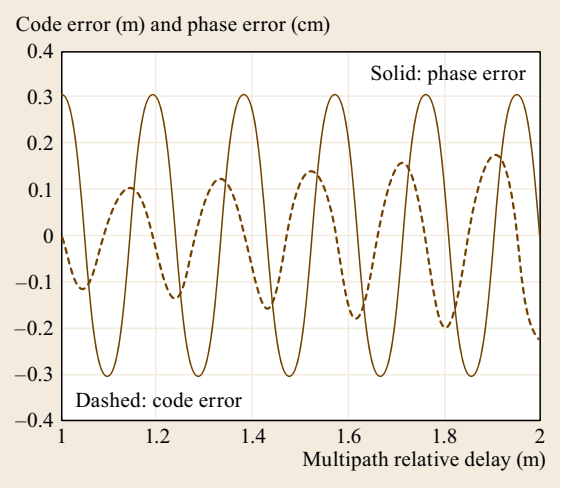

**Fig. 15.15** Code and carrier-phase multipath error variation with multipath relative phase computed as a direct function of relative delay. The signal is BPSK(1) and the early-to-late correlator spacing is 1 chip (weak multipath case: $M/D = -20$ dB)

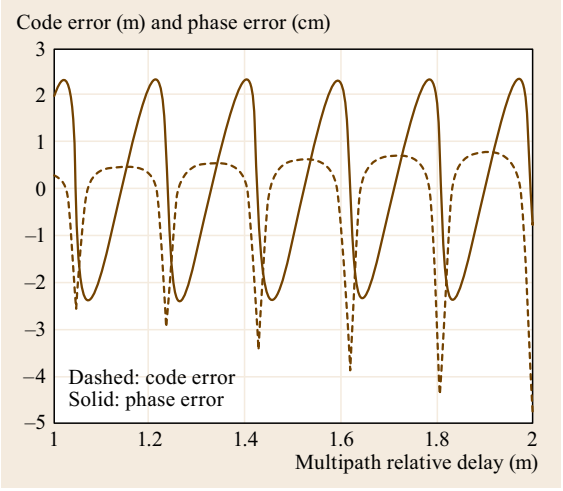

**Fig. 15.16** Code and carrier-phase multipath error variation with multipath relative phase computed as a direct function of relative delay. The signal is BPSK(1) and the early-to-late correlator spacing is 1 chip (strong multipath case: $M/D = -3$ dB)

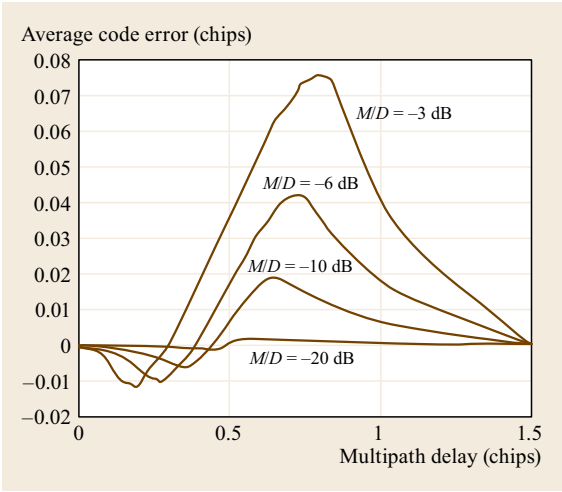

**Fig. 15.17** Average pseudorange multipath error for a coherent BPSK receiver with 1 chip correlator spacing

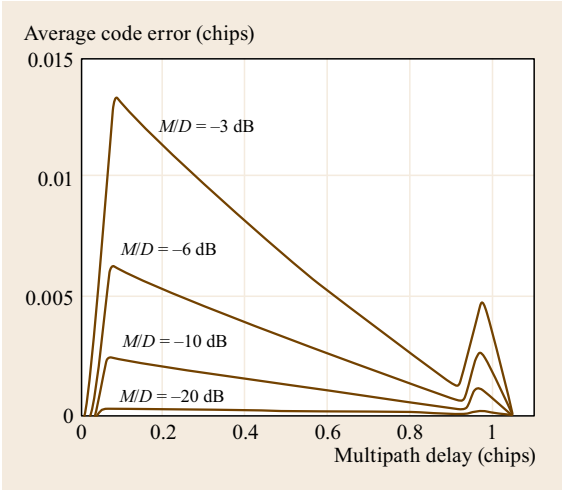

**Fig. 15.18** Average pseudorange multipath error for a coherent BPSK receiver with 0.1 chip correlator spacing

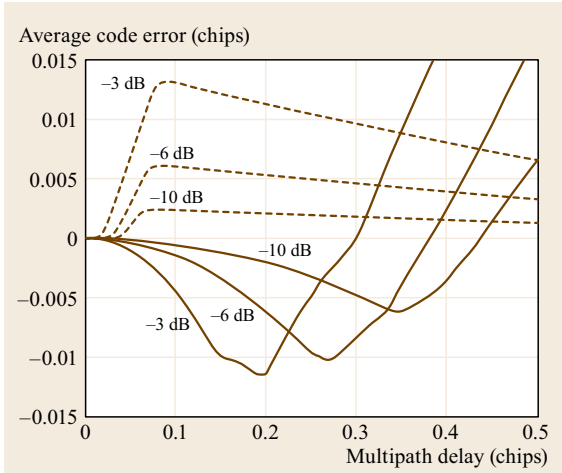

**Fig. 15.19** Comparison of average pseudorange multipath error for wide correlator (*solid lines*) and narrow correlator (*dashed lines*) coherent BPSK receivers for short multipath relative delay

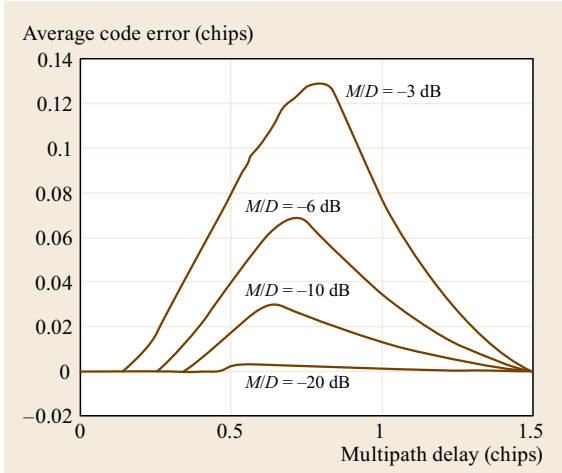

**Fig. 15.20** Average pseudorange multipath error for a noncoherent BPSK receiver with 1 chip correlator spacing

ble the corresponding value for the coherent receiver, it may also be noted that the error is effectively zero for very short relative delays. The average error for noncoherent narrow-correlator receivers is depicted in Fig. 15.21. Although it is not immediately apparent, the average error for the noncoherent narrow correlator is slightly larger than the corresponding average error for the coherent narrow correlator receiver shown earlier. Again, the distinct difference in behavior of the wide and narrow-correlator receivers for short delay multipath may be observed in Fig. 15.22.

Thus, it is important to understand that simple averaging of measurements from a static receiver is not guaranteed to eliminate the effects of pseudorange multipath. However, the same is not true for the carrier-phase. Carrier-phase multipath error is in fact zero-mean and thus the error can effectively be reduced through averaging for static receivers.

As described earlier, dynamic receivers can induce relatively high phase rates in the received multipath signal. Detailed simulation and laboratory experiments have shown that typical GNSS receiver tracking loops are relatively insensitive to multipath signals with fading frequencies that exceed the loop bandwidth. Since carrier tracking loops are typically quite wide (e.g., 10–25 Hz), this phenomemon is not of much practi-

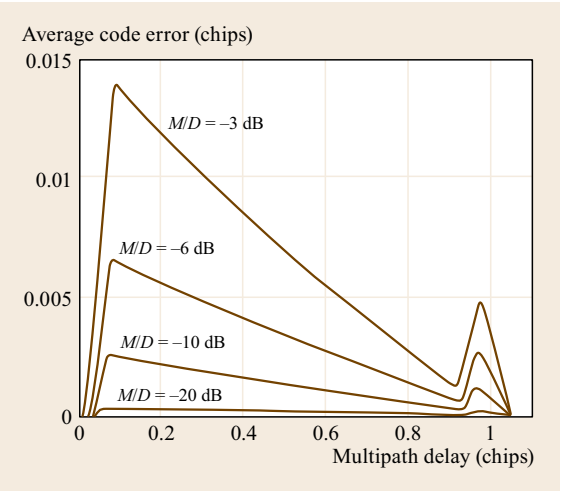

**Fig. 15.21** Average pseudorange multipath error for a noncoherent BPSK receiver with 0.1 chip correlator spacing

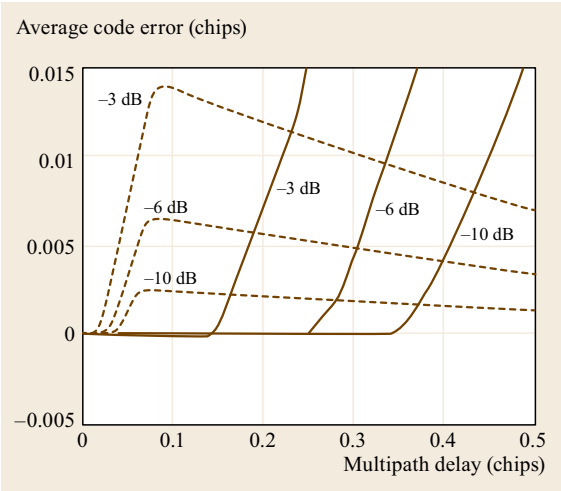

**Fig. 15.22** Comparison of average pseudorange multipath error for wide correlator (*solid lines*) and narrow correlator (*dashed lines*) noncoherent BPSK receivers for short multipath relative delay

cal use for carrier-phase multipath reduction. However, many receivers are constructed with carrier-aided code tracking loops and, in such receivers, the code tracking loop can be quite narrow (e.g., 0.05 Hz). Significant pseudorange multipath error reduction can be achieved for situations in which receiver dynamics induce multipath fading frequencies well above 0.1 Hz [15.8, 13].

One must be careful, however, not to assume that the error is attenuated linearly with multipath fading frequency. It has been shown that a bias can remain that is a function both of the fading frequency and the multipath relative delay [15.13].

## 15.7 Multipath Mitigation

There are four broad categories of multipath mitigation techniques:

- Antenna placement
- Antenna type
- Receiver type
- Measurement post-processing.

### 15.7.1 Multipath Mitigation via Antenna Placement

Although it is a statement of the obvious, the best way to mitigate multipath is to place the antenna in a low or ideally multipath-free environment. The location for a permanent differential ground reference station, for example, should be chosen only after careful consideration of the multipath environment. Frequently, in such cases, there are conflicting requirements. For example, the most ideal, low-multipath environment is a flat, open field. The sole source of multipath, ground reflection, could be eliminated by placing the antenna flush on the ground itself. However, this is not typically practical since the antenna could be inadvertently covered by snow, ice or leaves and could be damaged by ground-keeping equipment. Thus, even in open fields, differential ground reference station antennas are typically mounted on pedestals and some ground reflection is accepted.

In practice, it is more common to encounter a nonideal environment and still need to minimize the impact of multipath. Small changes in antenna location can still have a significant impact. This may be highlighted with a specific situation encountered by the author of this chapter. A differential ground reference station had been installed on top of the elevator tower of a multistory parking garage (Fig. 15.23). After many weeks of operation, it was determined that multipath was affecting the performance but was doing so inconsistently. Specifically, there were long periods of time in which the multipath contamination was negligible and yet there were also long periods of time in which the multipath was highly problematic.

Using multipath measurement techniques (that will be described later in this chapter), it was eventually determined that when the top level of the garage was empty, the antenna was subject to specular reflection

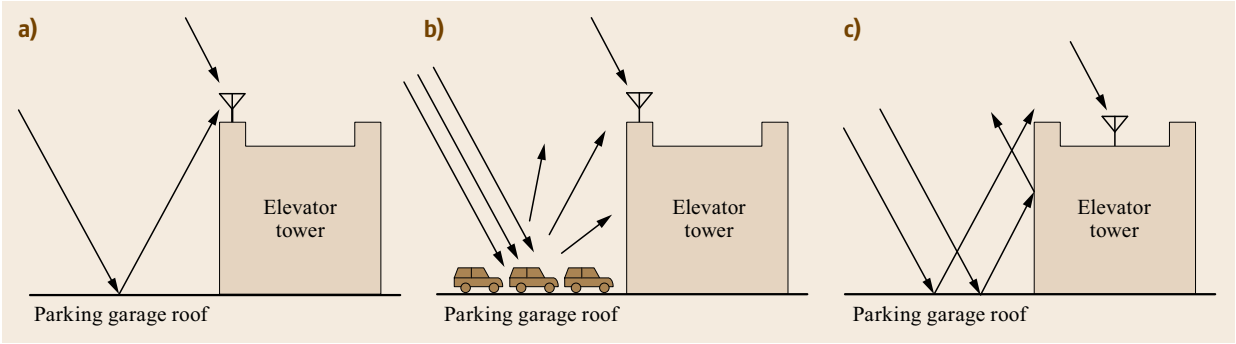

**Fig. 15.23a–c** Ground reference antenna siting case study: When there were no cars on the top level of the parking garage, there were strong specular reflections in the direction of the differential ground reference station antenna **(a)**. The presence of cars on the top level of the parking garage induced diffuse multipath with relatively little energy directed toward the differential ground reference station antenna **(b)**. By placing the antenna in the center of the elevator tower roof and at the level of the surrounding wall, the reflections from the top level of the garage were blocked by the elevator tower itself **(c)**

as shown in Fig. 15.23a. However, when the top level was full of cars, the reflections became diffuse thus reducing the strength of the multipath impinging on the antenna. The solution was to move the antenna to the middle of the elevator tower roof and let the tower block the reflections. The elevator tower roof was surrounded by a 1 m high wall and the antenna was installed at a height that was even with the top of this wall. The height of the antenna above the roof itself prevented the antenna from being covered with snow during the winter months. This installation worked extremely well by reducing the multipath to negligible levels.

### 15.7.2 Antenna Type

With a given environment, the next line of defense against multipath is to choose an antenna that attenuates the multipath while preserving the strength of the (desired) direct signal. In differential ground reference stations, for example, the primary source of multipath is the ground itself. The multipath is thus incident from negative elevation angles whereas the desired direct signal is incident from positive elevation angles. An ideal ground reference station antenna would have uniform gain above a given mask angle and zero gain below it. Two broad categories of antennas have been developed in an attempt to approximate this ideal: (a) single-element antennas mounted on specialized groundplanes; (b) fixed-beam phased-array antennas.

In the mid 1980s, research was conducted on the use of radio frequency (RF) absorber material to reduce the effect of multipath. A single-element global positioning system (GPS) antenna was mounted on a planar slab of RF absorber. Test results indicated at least a 30% reduction in pseudorange error due ground reflections could be achieved by using the absorber material [15.14]. Despite the promising results, however, the technique was not widely adopted by the GNSS community. This was due in part to the expense of the material and challenges associated with maintaining its integrity under various weather conditions. Furthermore, the development of the choke ring antenna proved to be superior.

The choke ring design was originally developed by the Jet Propulsion Laboratory and the University of New Brunswick [15.15] shortly after the aforementioned RF absorber studies. The design consists of a single-element antenna mounted inside a set of concentric conductive rings. The rings effectively present a capacitive series reactance to the incident electric field and thus *choke out* electromagnetic waves arriving at low and negative elevation angles [15.15]. The antenna system thus has low gain at low and negative elevation angles. Given the relative ease of manufacture, rugged design and relative compactness, the choke ring antenna became the standard multipath-reducing antenna of choice for ground reference stations, particularly for surveying applications.

Although the choke ring design was, and continues to be, very popular, it is not considered portable since the outer diameter of the ring system is approximately 36 cm and the overall antenna system typically weighs over 4 kg. In 2000, NovAtel introduced a proprietary design to provide choke ring performance with significantly reduced size and weight [15.16, 17]. The design, known as a *pinwheel* antenna, consists of an array of 12, aperture coupled, spiral slots surrounded by 11 concentric slot rings. The antenna yields nearly identical performance to a choke ring design but is half the diameter and one-eighth the weight.

Although the choke ring and pinwheel antennas work well for surveying applications, both are ham-

pered by low gain between 5 and 15° elevation. Both types of antennas have gain patterns that peak at zenith (90° elevation) and gradually roll-off as the elevation angle decreases (with the lowest gain occuring for an elevation angle of −90°). The benefit is very low gain at negative elevation angles and thus ground reflections are suppressed. The penalty, however, is that the direct LOS signal is severely attenuated for elevation angles less than about 15° and thus both pseudorange and carrier-phase measurements will be very noisy. This gradual roll off in the antenna pattern is an unavoidable result of the antennas being electrically *small*. That is, both antenna types are small in terms of L1 wavelengths. The choke ring has a diameter of approximately 2 wavelengths and the pinwheel is approximately 1 wavelength in diameter. For most surveying applications, mask angles are typically 15° (primarily to avoid tropospheric spatial decorrelation) and thus the poor performance of these antennas below that angle is not of concern.

There are applications, however, in which mask angles must be set at 5° or even slightly lower in order to provide sufficient system availability. A prime example of this is the ground-based augmentation system (GBAS). GBAS is a form of differential GNSS that provides guidance information for aircraft landing in low visibility conditions (Chap. 31). Without the use of satellites between 5 and 15° elevation (as well as those that are higher), the availability of the system (i. e., the percentage of the day in which the system is operational) would not be high enough to be of practical use.

For an antenna to provide sufficient gain at the 5° mask angle and simultaneously attenuate signals at negative elevation angles, an electrically large phased array is needed. This basic concept was first described in 1994 [15.18, 19] and two basic design variations were contemplated. The first to be developed and field-tested [15.20] consisted of a vertically stacked linearly polarized dipole array along with a single circularly polarized antenna element mounted in a concave reflector [15.21]. The 16-element dipole array provided coverage from 5 up to 35° elevation. The mini dish antenna provided coverage from 30° up to zenith. Separate GPS receivers, tied to a common clock, were fed by the two antenna subsystems and a downstream central processing unit (CPU) ran software that dealt with the hand-off of satellites between antennas for rising or setting satellites.

The second of the two design variants consisted exclusively of a vertical stacked array of circularly polarized elements [15.22]. The primary advantage of such an antenna is the need for only a single receiver and no complex downstream software to accommodate satellite hand-off between antenna subsystems. Significant design challenges extended the development period [15.23] but it eventually became the standard ground reference station antenna for the United States version of GBAS.

Before closing this section it should be noted that promising techniques in novel ground plane design were introduced in 2010. The performance of one of these designs is highlighted in the carrier-phase multipath measurement section later in this chapter.

### 15.7.3 Receiver Type

As shown in Fig. 15.9, there is a distinct difference in pseudorange multipath error for wide and narrow correlator receiver architectures. Further, the size of the multipath error envelope scales inversely with chipping rate (e.g., BPSK(1) versus BPSK(10)). The narrow correlator principle can be applied to higher rate codes but the performance improvement is not as significant due to bandwidth limitations on the broadcast signal.

Starting in the mid-1990s, however, receiver designs were developed to exploit the full bandwidth of the slower chipping rate signals. In the case of GPS, these designs processed the coarse/acquisition (C/A)-code signal yet achieved nearly P(Y)-code multipath performance. Some examples include the Strobe correlator [15.24], enhanced Strobe correlator [15.25], designs by Leica [15.26], and so-called *superresolution* [15.27, 28]. The general concepts were described along with a theoretical noise analysis in [15.29]. One of two primary techniques were utilized. Gating or windowing of the received signal around the chip edges yielded effectively narrower chips and thus commensurately scaled down multipath error envelopes [15.25, 29].

The second technique combines two early and two late correlators in order to create a very narrow discriminator function. Improved multipath performance is thus achieved since the size and shape of the pseudorange multipath error envelope is proportional to the size and shape of the discriminator function. The four correlators associated with this technique are depicted in Fig. 15.24 for the case of a BPSK correlation function. Note the first pair $(E_1, L_1)$ are separated by $d$ chips and the second pair $(E_2, L_2)$ are separated by $2d$. The discriminator function is constructed as the difference of two narrow-correlator discriminator functions [15.29, 30]

$$\begin{aligned} D_{\Delta\Delta} &= (E_1 - L_1) - \frac{1}{2}(E_2 - L_2) \\ &= D_{\text{narrow}}(d) - \frac{1}{2} D_{\text{narrow}}(2d) \,. \end{aligned} \tag{15.17}$$

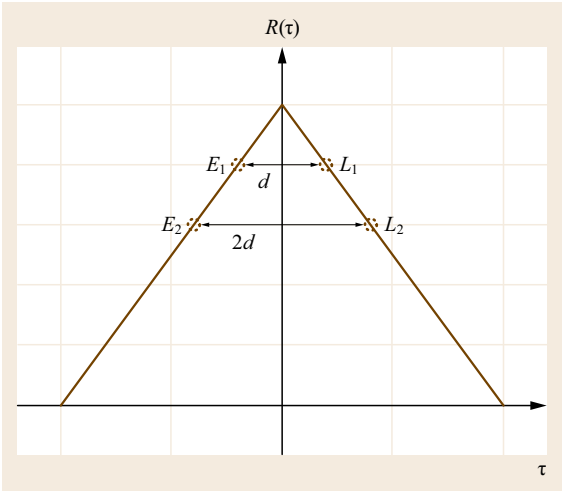

**Fig. 15.24** There are two sets of early/late correlators in the double delta. One set has a separation of $d$ chips and the other has a separation of $2d$ chips

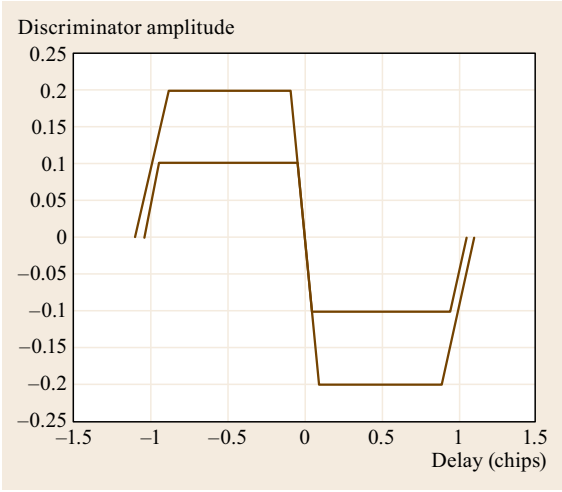

**Fig. 15.25** The double delta can be viewed as a combination of two narrow correlator discriminator functions. This figure illustrates the two constituent functions for BPSK with $d = 0.1$ chip. The curve that peaks at $\pm 0.2$ is the discriminator function for $2d = 0.2$ chip, the curve that peaks at $\pm 0.1$ for $d = 0.1$ chip. These curves are combined using (15.17) to yield the double-delta discriminator shown in Fig. 15.26

Although this technique was implemented by manufacturers with names such as the *Strobe correlator* [15.25] and *pulse aperture correlator* [15.31], it was first generalized as the *high resolution correlator* [15.29]. However, the technique became most widely known as the *double-delta correlator* since it effectively consists of the difference of two differences [15.30]. The two constituent narrow correlator discriminator functions are depicted in Fig. 15.25 and the resulting double-delta discriminator is depicted in Fig. 15.26 for the case of $d = 0.1$ chip (both for BPSK). The multipath envelopes for the double-delta constructed from 0.1 chip to 0.2 chip narrow correlators are depicted in Fig. 15.27 for the case of BPSK(1) where the relative multipath amplitude is −6 dB. It should be noted that in many environments, multipath is predominately short and medium delay and thus the echoes in the double-delta multipath error envelope at a delay of approximately 1 chip are not of serious concern.

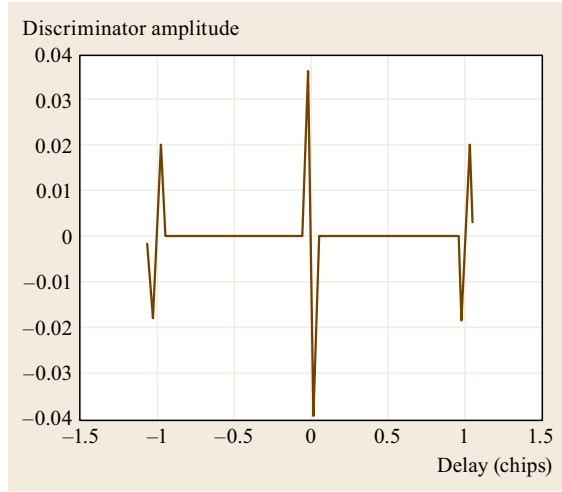

**Fig. 15.26** The double-delta discriminator consists of a narrow *s-curve* region along with parasitic responses at plus and minus one chip delay (BPSK with $d = 0.1$ is depicted)

Echoes not withstanding, the double-delta correlator thus achieves a narrow discriminator function and narrow multipath envelope with the use of four correlators as opposed to the conventional single early and single late correlators used in a traditional DLL. Subsequent research has shown that almost arbitrary shaping of the discriminator function (also known as the S-curve) can be achieved with the use of additional correlators. This technique has been referred to as *S-curve shaping* and researchers have investigated the development of optimum S-curves given the use of a large number of correlators [15.32, 33].

### 15.7.4 Measurement Processing

This final category of mitigation involves dealing with multipath-contaminated measurements. There are numerous applications in which multipath is unavoidable despite the best attempts at optimum choice of antenna placement, antenna design, and receiver architecture.

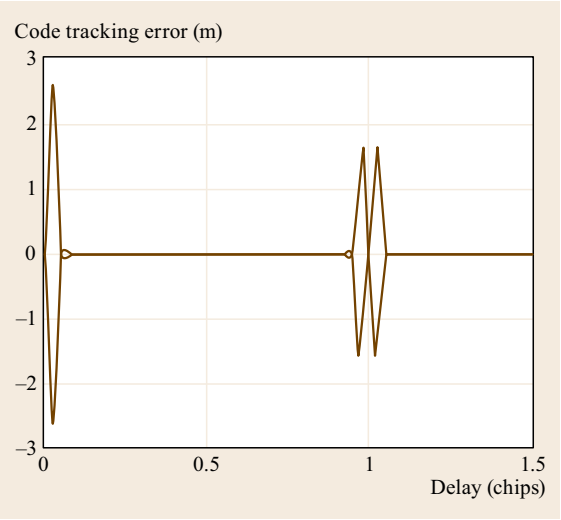

**Fig. 15.27** The double-delta pseudorange multipath error envelope for BPSK(1) and $d = 0.1$ for the case where the multipath is 6 dB below the direct signal

The choice of measurement-processing mitigation technique depends on whether real-time operation is needed or not and whether the receiver is stationary or not.

The most challenging scenario, of course, is the need to mitigate multipath at the measurement level for a dynamic receiver in real time. The simplest technique involves elevation-angle dependent measurement weighting in a generalized least-squares solution or in a Kalman filter. The key idea is that, in most applications, multipath contamination of the measurements is approximately inversely proportional to the elevation angle of the satellite (note that this principle is true of tropospheric and ionospheric errors as well). The variances of the ranging measurements can be divided by the sine of the elevation angle to provide a simple, but reasonable approximation.

Beyond simple weighting schemes, real-time multipath mitigation in a dynamic receiver requires some technique to monitor the presence of multipath in the measurements. As will be described in the next section, it is possible to observe, in post-processing, the presence of multipath on pseudorange measurements via a judicious combination of the pseudorange measurement with the carrier-phase measurement. In real time, the difference between the raw pseudorange measurement and the output of a Hatch filter (carrier-smoothed pseudorange) can be computed as a metric of the combination of noise and multipath. The measurement can then be deweighted in proportion to the magnitude of the metric.

For non real-time applications, two techniques may be utilized for mitigation depending on whether the receiver is static or dynamic. If the receiver is dynamic, then the pseudorange multipath measurement technique, described in the next section, may be used to determine the magnitude of multipath contamination and then used to weight the measurements accordingly. If the receiver and its surroundings are static, then the multipath error will repeat daily in conjunction with the repeat of the satellite ground track. This phenomenon of multipath repeatability will be explored more in the next section but it can be exploited to reduce the impact of multipath at fixed sites (such as crustal monitoring and structural deformation monitoring applications). The technique is known as *sidereal filtering* since the GPS satellite ground tracks repeat approximately once every sidereal day. Put simply, the position solution results over the course of a day are low-pass filtered to estimate the multipath error and this correction is then removed from the results on subsequent days in order to observe small changes. Detailed descriptions may be found in [15.34, 35].

Specialized hardware–software have also been developed to monitor for abnormal multipath error (along with other signal deformations). The advent of so-called software defined receiver architectures, or more generally, receivers with more than three correlators per channel (in some cases, thousands of software correlators per channel), have enabled the development of signal quality or signal deformation monitoring. The use of many correlators per channel allows the correlation peak to be analyzed for deviations from nominal. The use of these techniques to detect multipath has been described, for example, in [15.36–39].

## 15.8 Multipath Measurement

It is frequently necessary to evaluate the impact of multipath using actual measurements. Measuring multipath presents challenges since there are a variety of GNSS error sources. In addition to multipath, pseudorange and carrier-phase measurements are impacted by satellite and receiver clock offsets, ionospheric and tropospheric delays and receiver noise and tracking error. Thus a simple differencing of a measurement with the truth would yield the sum of all error sources and not any one in particular. What is needed is a technique to isolate the multipath error from the rest. The typical approach to assess multipath error on pseudorange

measurements is to exploit the commonality of a subset of the errors on both the pseudorange and carrier-phase. Isolation of carrier-phase multipath involves the use of carrier-phase double differencing of measurements obtained at a test site and at a reference site. Each of these two techniques will be described in turn.

### 15.8.1 Isolation of Pseudorange Multipath

Models of the pseudorange and carrier-phase measurements are given as follows

$$p = \rho + c\,dt_\mathrm{r} - c\,dt^\mathrm{s} + I + T + M_p + e + D_p\,, \tag{15.18}$$

$$\varphi = \rho + c\,dt_\mathrm{r} - c\,dt^\mathrm{s} - I + T + M_\varphi + \varepsilon + D_\varphi + N\lambda\,, \tag{15.19}$$

where all terms are in units of distance:

| | |
|---|---|
| $p$ | pseudorange measurement |
| $\varphi$ | carrier-phase measurement |
| $\rho$ | true satellite-to-receiver range |
| $c\,dt_\mathrm{r}$ | receiver clock offset |
| $c\,dt^\mathrm{s}$ | satellite clock offset |
| $I$ | ionospheric delay |
| $T$ | tropospheric delay |
| $M_p$ | pseudorange multipath error |
| $M_\varphi$ | carrier-phase multipath error |
| $e$ | pseudorange noise |
| $\varepsilon$ | carrier-phase noise |
| $D_p$ | dynamics-induced code-tracking loop delay |
| $D_\varphi$ | dynamics-induced carrier-tracking loop delay |
| $N\lambda$ | carrier-phase range integer ambiguity. |

The technique to isolate the pseudorange multipath error relies on the fact that the true range, satellite and receiver clock offsets, and the tropospheric delay are common both to the pseudorange and carrier-phase measurements [15.40–42]. By differencing the pseudorange and carrier-phase measurements for a given satellite, the true range, clock offsets and tropospheric delay all cancel

$$p - \varphi = 2I + (M_p - M_\varphi) + N\lambda + (D_p - D_\varphi) + (e - \varphi)\,. \tag{15.20}$$

This observable (sometimes referred to as *code-minus-carrier* or CMC) has twice the ionospheric error since the ionospheric delay is equal in magnitude, but opposite in sign, for the pseudorange and carrier-phase measurements (the opposite effect of the ionosphere on the pseudorange and carrier-phase is referred to as *ionospheric divergence*). In most cases, the carrier-phase noise and multipath errors can be considered negligible, compared to those of the pseudorange, since they are typically smaller by approximately 2 orders of magnitude. This simplifies the multipath observable to

$$p - \varphi \approx 2I + M_p + N\lambda + (D_p - D_\varphi) + e\,. \tag{15.21}$$

As would be expected, tracking loop delays due to dynamics are only a concern when a receiver is experiencing nontrivial acceleration. Obviously, this is not an issue for static receiver data collections. Furthermore, most receivers designed for vehicle applications have sufficiently wide tracking loop bandwidths to accommodate all normal vehicle maneuvers. In fact, even in receivers designed for static applications the carrier tracking loop bandwidth is wide enough to accommodate medium dynamics such as $2g$ turns in an aircraft. However, the code tracking loops in some receivers designed for static applications (e.g., surveying) are too narrow (and not carrier-aided) and exhibit lags during dynamics if the receiver is used in a vehicle. Sometimes this situation occurs when a survey-grade receiver is being used as a truth-reference system during a flight test. Vehicle dynamics result in nontrivial tracking error in the pseudorange but not in the carrier-phase. This difference shows up in the multipath observable and care must be taken not to confuse the effect with multipath error [15.42].

For static data collections, the dynamic terms are zero and the multipath observable reduces to

$$\rho - \varphi \approx 2I + M_p + N\lambda + e\,. \tag{15.22}$$

Assuming the carrier tracking loop has not experienced any cycle slips (a reasonable assumption if the carrier-to-noise ratio is strong and the receiver is static), the integer ambiguity is constant and thus shows up as a bias in the multipath observable. It can be removed simply by estimating and subtracting off the mean value of the multipath observable. This process also removes any bias in the multipath error component, however, so the result only depicts peak-to-peak behavior.

The ionospheric divergence can be handled in two ways. First, under normal conditions (e.g., in the absence of solar storms inducing ionospheric scintillation), ionospheric delay is strongly dependent upon the satellite elevation angle and thus exhibits itself as a long-term trend in the multipath observable. Roughly speaking, the ionospheric delay is inversely proportional to the satellite elevation angle. Since a satellite pass (across the sky for a static observer) has a duration of approximately 3–8 h, the ionospheric delay looks like a first- or second-order trend in a multipath observable that is less than a couple of hours in length. Thus the ionospheric term can be eliminated by fitting and removing a first- or second-order curve from

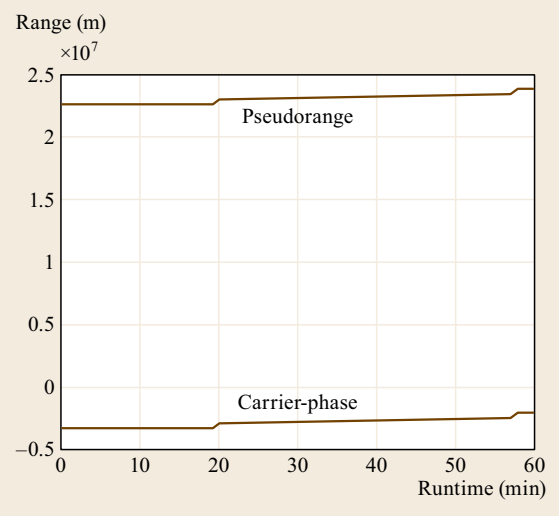

**Fig. 15.28** Pseudorange and carrier-phase for pseudo-random noise (PRN) 20 GPS C/A-code. The data was collected from 1300 to 1400 h, GPS time, on day 350 of 2012 at the STKR continuously operating reference station (CORS) site in Athens, Ohio, USA

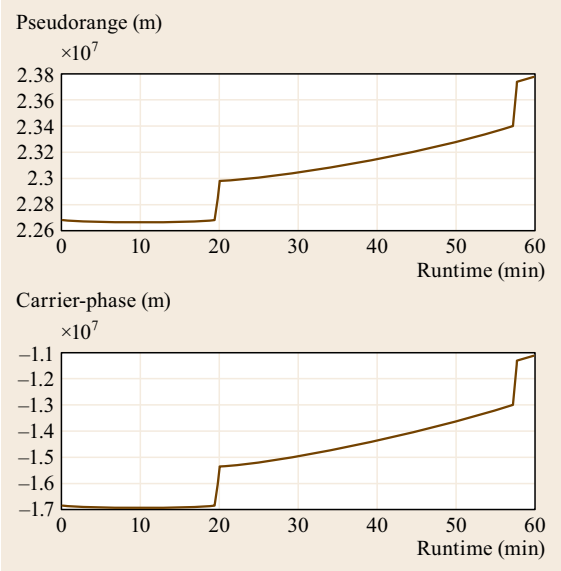

**Fig. 15.29** Zoomed view of the pseudorange and carrier-phase for PRN 20 GPS C/A-code. Two clock jumps are clearly visible in both measurements

the multipath observable. A visual inspection of the raw observable is used to determine whether a first- or second-order curve-fit is appropriate.

The second technique can be applied if dual-frequency measurements are available. The ionospheric delay is estimated by forming the usual dual-frequency correction but doing so with carrier-phase measurements instead of pseudorange measurements. Since the carrier-phase noise and multipath are negligible compared to the pseudorange, the use of this correction does not severely impact the resulting observable. Of course, an ionospheric delay estimated by carrier-phase measurements will have a bias error (due to the range ambiguities) but, as discussed earlier, the multipath observable already has an unknown bias that has to be removed anyway. A closed-form expression for the dual-frequency iono-corrected code-minus-carrier observable is given by [15.43]

$$\mathrm{CMC} = p_{\mathrm{L1}} - \frac{f_1^2+f_2^2}{f_1^2+f_2^2}\varphi_{\mathrm{L1}} - \frac{2f_2^2}{f_1^2+f_2^2}\varphi_{\mathrm{L2}}\,, \qquad (15.23)$$

where $f_1$ and $f_2$ are the L1 and L2 carrier frequencies. There is nothing unique about these two frequencies, however, and the observable could be formed with measurements, for example, from L1 and L5. It should be noted the observable still has a carrier-phase ambiguity and thus the mean needs to be removed.

To illustrate this procedure, the results of a multipath analysis are presented for a rooftop CORS station (STKR) located at Ohio University in Athens, Ohio, USA. The data was collected from 13:00 to 14:00 h (GPS time) on day 350 (December 15) of 2012. The pseudorange and carrier-phase measurements for GPS PRN 20 are shown in Fig. 15.28. Figure 15.29 shows a zoomed view that reveals two receiver clock jumps that occur simultaneously on both measurements and thus will cancel when the multipath observable is formed.

Figure 15.30 shows the results when the code-minus-carrier multipath observable is formed and the bias is removed. A long-term trend may be observed and is due to the ionospheric divergence. The medium frequency components are multipath and the high frequency components are noise.

Since the collected data included dual-frequency measurements, the ionospheric divergence can be removed by forming the dual-frequency ionospheric correction with the carrier-phase. The results are shown in Fig. 15.31. Note the long-term trend has been eliminated.

### 15.8.2 Short-Delay Multipath

The STKR CORS site consists of a roof-top mounted antenna. As a result, the dominant reflections originate from the roof itself and thus are *short* delay (i. e., less than 0.1 chip). As shown in the multipath error envelopes described earlier, both the BPSK(1) and BPSK(10) error envelopes overlap for short relative

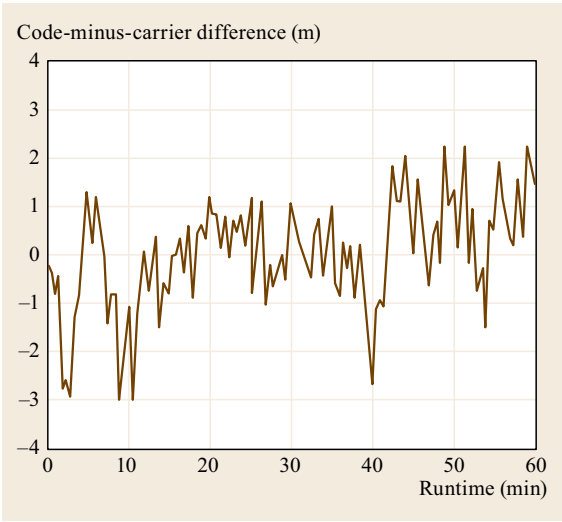

**Fig. 15.30** Code-minus-carrier multipath observable for PRN 20 GPS C/A-code. The bias in the observable has been estimated and removed. The long-term trend in the data is the ionospheric divergence. The medium frequency behavior is pseudorange multipath and the high-frequency components are noise

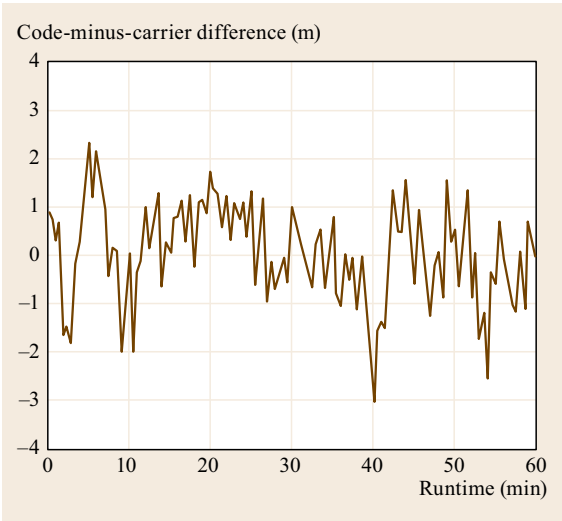

**Fig. 15.31** Code-minus-carrier multipath observable for PRN 20 GPS C/A-code. The long-term trend due to ionospheric divergence has been eliminated through the application of a dual-frequency ionospheric correction based on carrier-phase measurements

multipath delay. This is illustrated in Fig. 15.32. Although the GPS P-code observable has less noise (as expected), both the P and C/A-code show similar multipath error characteristics.

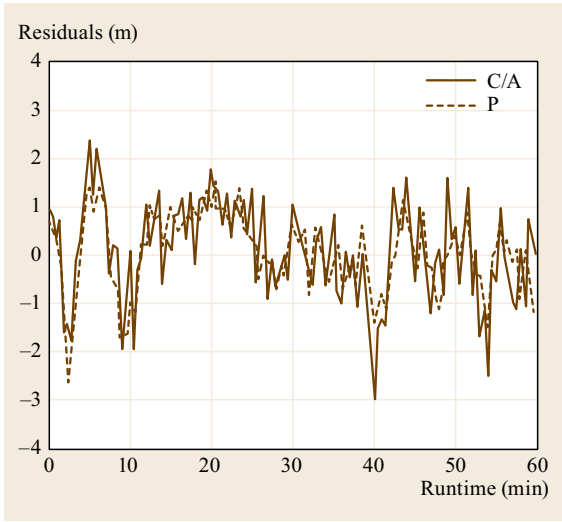

**Fig. 15.32** Ionosphere-corrected code-minus-carrier multipath observable for PRN 20 GPS C/A-code and P-code. The low/medium frequency components are due to multipath and are largely the same on both measurements. This is due to the short relative delay of the multipath

### 15.8.3 Multipath Repeatability

When a multipath environment is static (stationary receiver and multipath-producing objects), satellite ground-track repeatability can be exploited to help distinguish multipath from noise excursions. In GPS, for example, the satellite ground track repeats after approximately 23 h and 56 min. In a static multipath environment, the multipath error will thus also repeat along with the satellite ground-track. Thus, if a certain multipath error occurs, say, on a Tuesday at 4:00 pm, then that same error will occur again on Wednesday at approximately 3:56 pm. If a particular characteristic is observed in the ionosphere-corrected code-minus-carrier observable on separate days, it may be concluded that the characteristic is due to multipath and not noise.

To illustrate this technique, the results of a repeatability analysis are presented in the next series of plots. In addition to the data collected on day 350 of 2012 (discussed earlier), data was also analyzed from day 345 and day 349. Figure 15.33 depicts the PRN 20 C/A residuals for each of the 3 days (the residuals from the first and third days are intentionally biased by +4 and −4 m, respectively, to provide visual clarity and the 4 min/d shift has also be taken into account). When the code-minus-carrier observables for all 3 days are plotted together (Fig. 15.34), the multipath error oscillation during the first 10 min of the data collection period is clearly visible.

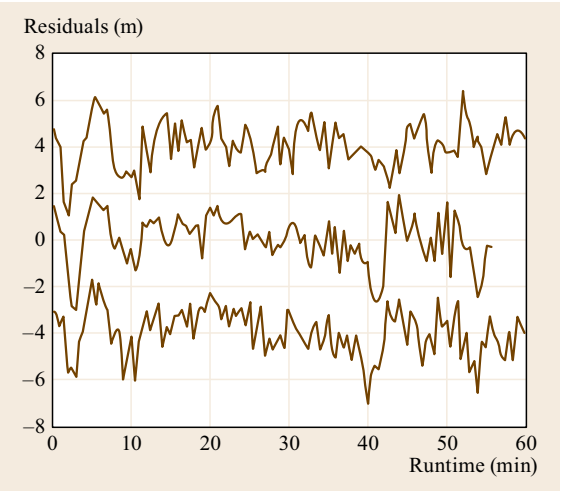

**Fig. 15.33** Multipath repeatability analysis for PRN 20 GPS C/A-code. The data was collected from 1300 to 1400 h, GPS time, on days 345, 349, and 350 of 2012 at the STKR CORS site in Athens, Ohio, USA. The code-minus-carrier observables for day 345 are intentionally biased by +4 m and those of day 350 are biased by −4 m for visual clarity

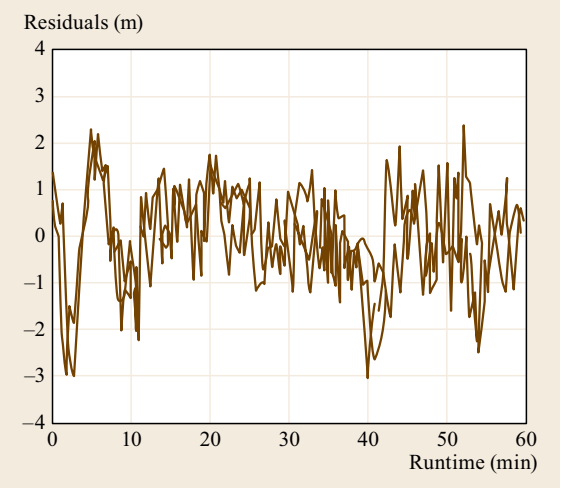

**Fig. 15.34** The code-minus-carrier observables of Fig. 15.33 for all 3 days are plotted on top of each other. The multipath oscillation during the first 10 min is clearly visible in all three

The results for PRN 04 are depicted in Fig. 15.35. In this case the multipath error appears to be about at the same level as the noise. The slightly lower noise P-code results (Fig. 15.36) do not, at first, clearly distinguish between noise and multipath. When the results from the 3 days are overlayed, (Fig. 15.37), however the multipath errors become much more apparent.

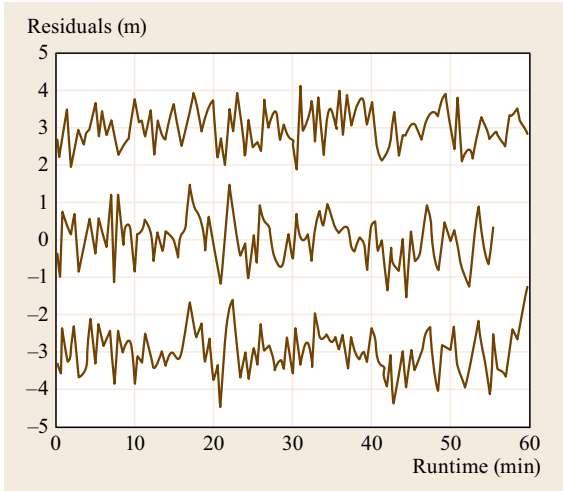

**Fig. 15.35** Same as Fig. 15.33 for PRN 04 GPS C/A-code

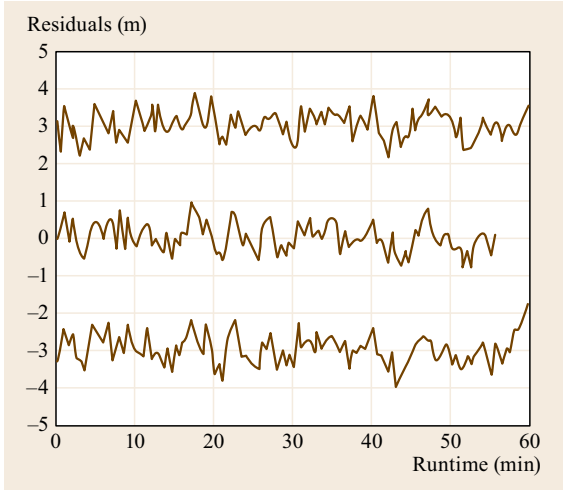

**Fig. 15.36** Same as Fig. 15.33 for PRN 04 GPS P-code

The lower impact of multipath on PRN 04 than on PRN 20 may be explained, at least in part, by examining the elevation angles of the satellites during the data collection (Fig. 15.38). Lower elevation angle satellites emit signals that have greater opportunity to interact with ground objects and produce multipath. That general principle is observed here with PRN 20 in the roughly 20–30° elevation angle range whereas PRN 04 rises from slightly over 50° at the beginning of the data to nearly 80° at the end.

### 15.8.4 Measurement of Carrier-Phase Multipath

One technique used to identify multipath contamination on the carrier-phase is through observation of the mea-

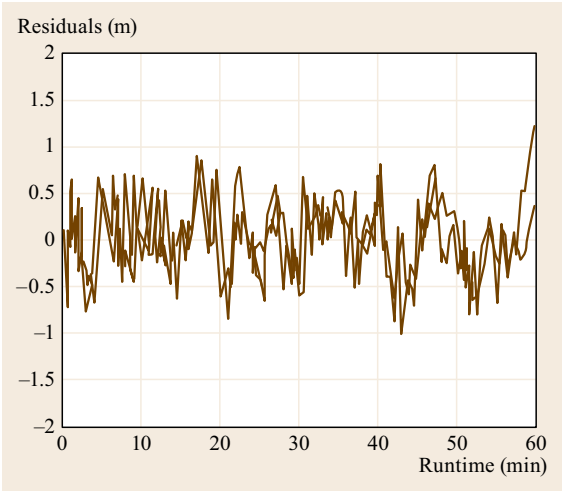

**Fig. 15.37** The code-minus-carrier observables of Fig. 15.36 for all 3 days are plotted on top of each other. Multipath error during the periods from 15 to 20 min and from 40 to 50 min (run time) is clearly visible

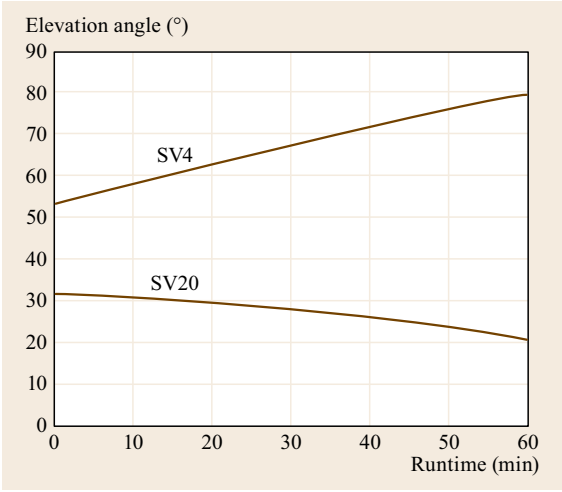

**Fig. 15.38** Elevation angle for the two satellites analyzed

sured signal-to-noise (SNR) or carrier-to-noise ratio. It has been shown [15.44] that there is a high degree of correlation between oscillations in the measured SNR and carrier-phase multipath. Specifically, the larger the amplitude fluctuations in the measured SNR, the greater the impact of multipath on the carrier-phase.

As just described, the synergy between the pseudorange and carrier-phase measurements enable a pseudorange multipath observation to be constructed. However, to observe multipath on the carrier-phase measurement itself, a different combination is needed. The commonly utilized technique involves the use of two separated, but stationary, receivers tracking at least two satellites. Furthermore, there should be negligible multipath contamination for both satellites at the reference receiver site and the test receiver site should only experience significant multipath on one of the two satellites. Under this specific scenario, it is possible to isolate the carrier-phase multipath error on the contaminated satellite measurement.

It can be shown (Chap. 20) that for closely spaced receivers the carrier-phase double-difference observation can be modeled by

$$\varphi_{km}^{pq} = \frac{1}{\lambda} R_{km}^{pq} + S_{km}^{pq} + N_{km}^{pq} , \qquad (15.24)$$

where receivers $k$ and $m$ are tracking satellites $p$ and $q$; $R$ is the true geometric range double difference; $S$ is the double difference of the noise and multipath errors and $N$ is the double-difference ambiguity. If the two receivers are in surveyed locations, the true geometric range double difference can be calculated either from broadcast ephemerides or from post-processed precise ephemerides. Obviously the precise ephemerides are preferred but if the baseline is short (i. e., less than a few kilometers), the typical errors in the broadcast ephemeris will cancel in the double differences. Assuming no cycle-slips, the double-difference ambiguity is a constant which can easily be estimated and subtracted.

After removal of the geometry and ambiguity, the result is the double difference combination of multipath and noise errors on the four constituent carrier-phase measurements. As mentioned earlier, ideally a reference receiver is established at a clean site where negligible multipath is experienced. For the second receiver, a first satellite is chosen that also has negligible multipath. The observable is then dominated by the multipath error on the second satellite [15.25]. For highly controlled laboratory experiments with carrier-phase multipath, this technique works especially well since hardware simulators can be set up to simulate zero multipath on the signals provided to the reference receiver and, similarly, multipath can be simulated on a single satellite at the second receiver. This technique was used in [15.8] to validate the carrier-phase multipath models described earlier in this chapter.

To illustrate this technique with actual field measurements, data were processed from two CORS receivers near Denver, Colorado in the United States. The data were collected between 5 am and 6 am, GPS time, on days 100 and 101 of 2014 at the ZDV1 and P041 CORS sites. The aforementioned observable was formed and the geometric range double difference was calculated and subtracted out. The results for GPS satellites PRN 4 and PRN 10 are shown in Fig. 15.39. These satellites were chosen according to the required criteria with both satellites exhibiting little multipath at

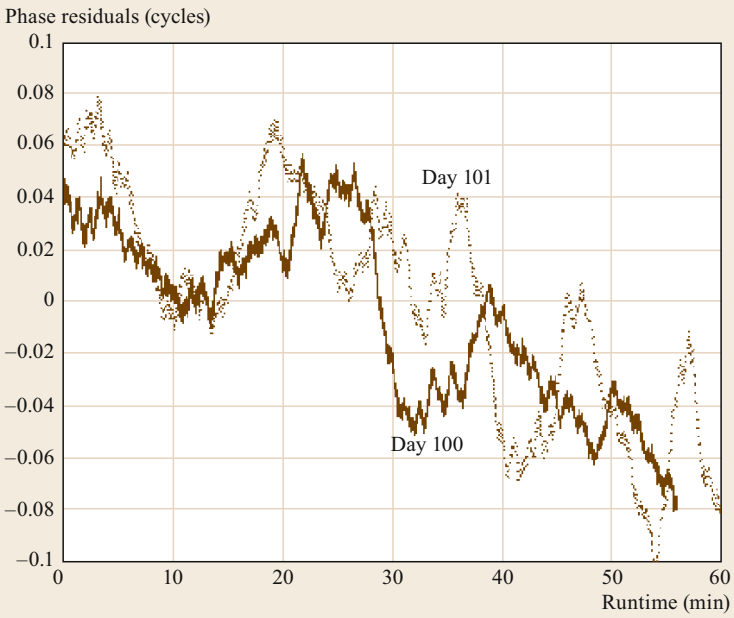

**Fig. 15.39** Carrier-phase double-difference multipath residuals. The data were collected from the ZDV1 and P041 CORS sites near Denver, Colorado from 5 am to 6 am (GPS time) on days 100 and 101 of 2014. Double differences were formed with GPS satellites PRN 4 and PRN 10. The geometric range double differences were calculated, based on the surveyed locations and broadcast satellite ephemerides, and were subtracted from the double-difference observations. The result is dominated by noise and multipath. The residuals for day 100 have been shifted by 4 min to account for the sidereal day shift

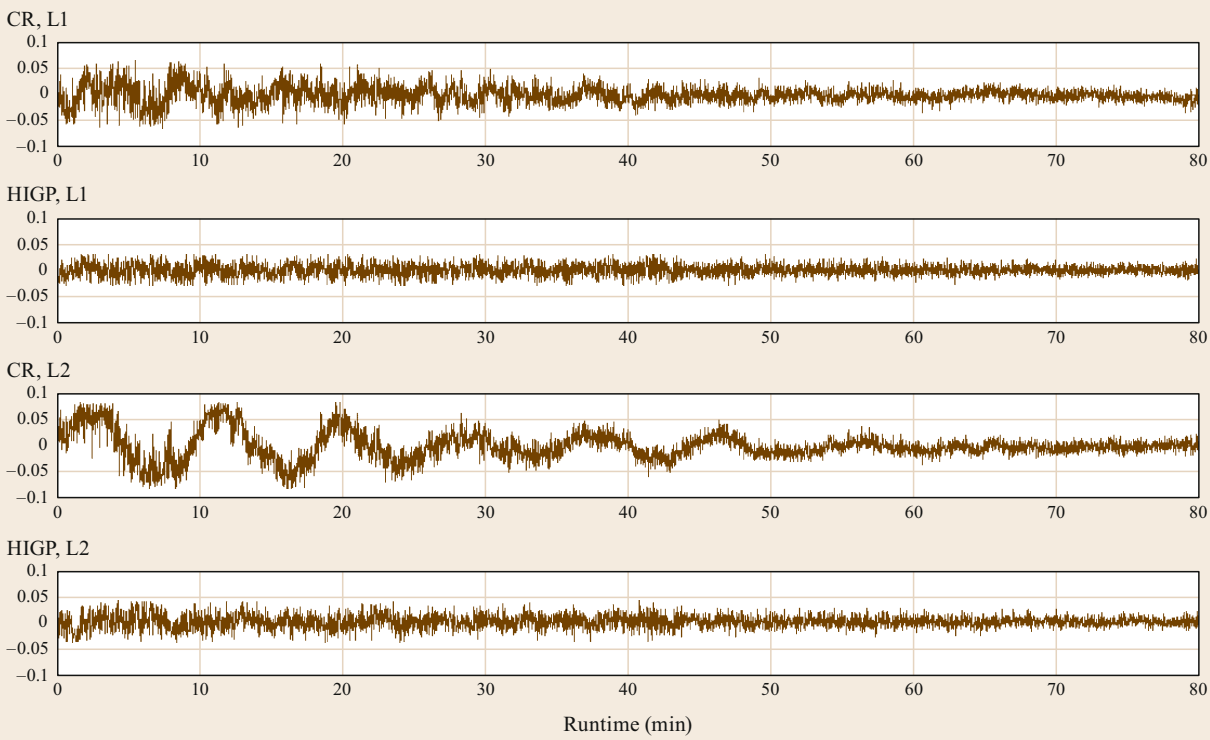

**Fig. 15.40** L1 and L2 carrier-phase double-difference multipath residuals illustrating the performance of a conventional choke-ring (CR) antenna versus a novel high impedance ground plane (HIGP) antenna. The *y*-axes are in units of carrier wavelengths. The error oscillations due to ground reflection are clearly shown in the choke-ring results as is the efficacy of the novel antenna ground plane (courtesy of Dmitry Tatarnikov of Topcon Positioning Systems)

the P041 site and only PRN 10 exibiting strong multipath at the ZDV1 site. The residuals from the 2 days match quite closely in the region from 5 to 15 min. This repeatability indicates that the residuals in this region are dominated by a stationary multipath source. Overall, the residuals from the two days share a common trend with a negative slope. This indicates the presence of a multipath source that is very close to the antenna and thus produces multipath with a very low frequency component. The inconsistency between the residuals of the 2 days is likely due to multipath sources that are not stationary and thus can vary from day to day (e.g., cars parked in the vicinity of one or both of the antennas).

Another example of the use of this technique is given in [15.45]. The paper describes a field data collection effort performed to determine how well a novel high-impedance ground plane would attenuate ground reflections. The double-difference technique was used to process data over a short baseline with a choke-ring antenna as a control and with the novel antenna under study. The key results are illustrated in Fig. 15.40. The efficacy of the novel antenna ground plane is clearly illustrated. The multipath error oscillations, shown particularly well in the L2/choke-ring residuals, are due to the change of the relative delay of the ground reflection as the satellite passed through the sky. Since the antennas were mounted approximately 2 m above the ground [15.45], a fading frequency of approximately 1.5 mHz would be expected at L2 for low elevation angles (as calculated from (15.4)). This corresponds to a period of approximately 11 min which matches closely with the periods observed in the plot.

## 15.9 A Note About Multipath Impact on Doppler Measurements

The most accurate Doppler (LOS velocity) measurements consist of scaled, temporal differences of carrier-phase measurements. The time differences are typically 1 s or less. Thus, the error in the Doppler measurement consists of the change of the error terms over the differencing interal. Recalling the carrier-phase observable (15.19), the error terms are the satellite and clock offsets, ionospheric and tropospheric delays, multipath, noise, dynamic tracking error, and the ambiguity. Thus the multipath component of Doppler measurement error consists of the change of carrier-phase multipath error over the time differencing interval. For cases in which the relative multipath phase-rate (fading frequency) is small (e.g., less than a hundredth of a Hertz) then the multipath component of the Doppler measurement error will be negligible.

## 15.10 Conclusions

In most differential GNSS (DGNSS) applications, multipath is a dominant error source. Measurement techniques can be used to assess the level of impact for a given situation. Antenna design/placement, choice of receiver architecture and measurement processing techniques all can be used to reduce multipath error. Higher rate codes for civilian use, made possible through so-called *GPS modernization* and the maturation of constellations such as Galileo will effectively eliminate the medium and long delay multipath error associated with lower rate codes.

*Acknowledgments.* The author would like to thank his current and former colleagues at Ohio University: Dr. Michael DiBenedetto, Dr. Sai Kalyanaraman (now with Rockwell Collins), and Mr. Joseph Kelly (now with mCube), along with Dr. Gary McGraw of Rockwell Collins, for their collaboration on various research projects that were drawn upon for material for this chapter. The author would also like to thank Dr. Dmitry Tatarnikov of Topcon Positioning Systems for the provision of the carrier-phase multipath data. Finally, the author would like to thank the US FAA, NASA, and DoD, along with Honeywell and Rockwell Collins for their support.

# 16. Interference

Todd Humphreys

Global navigation satellite system (GNSS) signals are so weak near the Earth's surface that they can be easily squelched by natural or man-made interference. Moreover, the most popular GNSS signals – those offered with unrestricted access – are unencrypted and unauthenticated, which means they can be counterfeited, or spoofed. Strict international laws protect the radio frequency bands allocated to GNSS, but mother nature does not respect these laws, and man-made interference – whether accidental or intentional – is a growing concern.

This chapter examines sources of GNSS signal interference and the interference effects on GNSS signal tracking. It offers a systematic treatment of natural, unintentional, and intentional interference, with emphasis on intentional jamming and spoofing. Theoretical performance bounds are developed for the simplest cases of narrowband and wideband interferences. The chapter finishes with a review of the state of the art in antenna-oriented and signal-processing-oriented interference detection and mitigation techniques.

All GNSS waveforms are spread-spectrum signals, which are uniquely resilient to interference. Indeed, robustness in the face of jamming was one of the primary features, along with low probability of intercept and good multiple access properties, which motivated the original development of spread-spectrum techniques for military systems. Nonetheless, GNSS signals are extremely vulnerable to jamming because, near the surface of Earth, they have no more flux density than light received from a 50 W bulb at a distance of 2000 km. To blandly remark that GNSS signals are weak is to understate their fragility: They are so weak that most modern electronics jam GNSS receivers at close range, requiring special precautions be taken to isolate receivers embedded in computers, mobile phones, vehicles, and other modern GNSS-dependent systems.

**Table 16.1** ITU space-to-Earth radio navigation satellite service (RNSS) frequency allocations (after [16.2, 3]). ARNS refers to the Aeronautical Radionavigation Service. Bands that are designated as both RNSS and ARNS enjoy, in principle, no greater International Telecommunication Union (ITU) protection from harmful interference than RNSS bands, but in practice they are granted more conservative safety margins (see, e.g., ITU-R M.1903) and they are likely to be monitored more assiduously by ITU member nations

| Frequency interval (MHz) | Bandwidth (MHz) | GNSS bands | Notes |
|---|---|---|---|
| 1164–1215 | 51 | L5/E5a/E5b/L3/B2 | ARNS band; pulsed DME/TACAN interference present [16.1] |
| 1215–1240 | 25 | L2 | Legacy GPS L2 band |
| 1240–1260 | 20 | L2 | Legacy GLONASS L2 band |
| 1260–1300 | 40 | E6/B3/LEX | |
| 1559–1610 | 51 | L1/E1/B1 | ARNS band; legacy GPS and GLONASS L1 band |
| 5010–5030 | 20 | C1 | |

Unintentional and intentional GNSS interferences are distinguished from each other more by motive than by effect. Both can be narrowband or wideband (relative to the bandwidth of the desired GNSS signal), structured or random. The user of a GNSS receiver suffering from interference may care little about the jammer's intent: What is important is a clean spectrum. Indeed, the recent emergence of so-called personal privacy devices (PPDs) – low-cost GNSS jammers used to ward off GNSS tracking – blurrs the lines between unintentional and intentional interference: The privacy device user only intends to jam GNSS receivers in an imaginary bubble around himself; he may never intend to disrupt the GNSS-dependent timing system at the bank down the street.

Interference that mimics GNSS signal structure and content is a special threat to GNSS receivers. Instead of simply degrading the accuracy of the position, velocity, and time (PVT) solution, transmission of such structured interference, referred to as spoofing, can fool a receiver into producing a precise but erroneous solution. Worse yet, the induced solution can be entirely dictated by the spoofer operator, who may have malevolent intentions. All GNSS signals are spoofable to one degree or another – at the very least, they can all be recorded and replayed into a target receiver, as is routinely done for receiver testing. But the most popular GNSS signals, the so-called open signals, are especially vulnerable because they are (so far) almost entirely predictable, lacking encryption or authentication of any form. For radionavigation as for communication, predictability is the enemy of security.

From the origins of GNSS, national and international policy has afforded special protection to the GNSS radio bands, and now that GNSS receivers have become pervasively embedded in the infrastructure that supports the global economy, such protection is of special importance. The International Telecommunication Union (ITU) forbids any interference *which endangers the functioning of a radionavigation service* [16.2] in the GNSS bands, which are designated as radionavigation satellite service (RNSS) bands by the ITU. Table 16.1 summarizes the ITU's current frequency allocations for GNSS signals.

In some regions, the penalty for emitting unauthorized signals in the GNSS bands is severe: In response to a rising number of so-called PPDs, the United States Federal Communications Commission (FCC) levies costly fines on intentional violators [16.4], and the penalty for intentional transmission in Australia can include a 2 yr prison term [16.5]. But despite government protections of the GNSS bands, they remain cluttered with interference, and there is every indication that such interference will worsen in the decades to come as more GNSS constellations begin broadcasting [16.6], as people respond to pervasive GNSS tracking by employing PPDs [16.7], and as communications signals ineluctably encroach on the enormously valuable GNSS spectral bands [16.8].

This chapter examines the effects of interference on GNSS receivers. The chapter begins with a presentation of the general analysis technique that will be used to evaluate the effect of interference that is statistically independent of the GNSS signals. The technique will then be applied to study the effects of canonical narrowband, wideband, and multiaccess interference. Following this, other specific interference waveforms such as pulsed interference will be discussed. Thereafter, GNSS spoofing, a particular type of interference that cannot be considered statistically independent of the GNSS signals, will be given a focused treatment. The chapter finishes with an examination of interference detection and mitigation strategies. Note that GNSS multipath, while a genuine type of interference, is treated separately in Chap. 15.

## 16.1 Analysis Technique for Statistically Independent Interference

Beyond the statement that GNSS interference always degrades PVT accuracy, one can say little in general about interference effects on late-stage signal processing products because these effects are highly receiver-dependent: A vector-tracking low-tracking-bandwidth receiver will, for example, produce a much more robust PVT solution than a scalar-tracking wide-bandwidth receiver. At earlier processing stages, however, interference effects are substantially common across receiver types and thus a general treatment becomes possible. Accordingly, this section presents an analysis of interference effects on the primitive correlation-and-accumulation products that form the basis of signal tracking in all GNSS receivers.

### 16.1.1 Received Signal Model

Consider the following generic representation of a received GNSS signal exiting a receiver's radio frequency (RF) front-end downconversion chain. For notational compactness, the signal is expressed by its complex baseband representation as

$$r_{\mathrm{S}}(t) = \sqrt{P_{\mathrm{S}}} D(t-\tau(t)) C(t-\tau(t)) \exp(\mathrm{j}\theta(t)), \quad (16.1)$$

where $P_{\mathrm{S}}$ is the received signal power in watts, $D(t)$ is the binary navigation data modulation, $C(t)$ is the binary spreading (ranging) code, $\tau(t)$ is the code phase, and $\exp(\mathrm{j}\theta(t))$ is the carrier with phase $\theta(t)$. The code phase $\tau(t)$ varies slowly and, for purposes of interference modeling and analysis, can be modeled as constant; thus, it will be denoted $\tau$ hereafter.

Let $r_{\mathrm{I}}(t)$ represent a complex-valued interference signal, and let $n(t) = n_{\mathrm{I}}(t) + \mathrm{j}n_{\mathrm{Q}}(t)$ be a zero-mean complex-valued Gaussian process that models thermal noise. Then, the full received signal-plus-interference-and-noise is given by

$$r(t) = r_{\mathrm{S}}(t) + r_{\mathrm{I}}(t) + n(t) .$$

The received components $r_{\mathrm{S}}(t)$, $r_{\mathrm{I}}(t)$, and $n(t)$ are assumed to be limited by a bandpass filter in the RF front end having a noise-equivalent bandwidth of $W_{\mathrm{FE}}$ Hz. The quadrature processes $n_{\mathrm{I}}(t)$ and $n_{\mathrm{Q}}(t)$ are modeled as spectrally flat on the range, $|f| < W_{\mathrm{FE}}/2$ with two-sided density $N_0/2$, where $N_0$ has units of W/Hz. Consequently, on this range the full complex thermal noise process $n(t)$ has a two-sided density of $N_0$. The data $D(t)$ and spreading code $C(t)$ are assumed to be normalized to unity power so that

$$P_{\mathrm{S}} = \lim_{T\to\infty} \frac{1}{T} \int_{-T/2}^{T/2} |r_{\mathrm{S}}(t)|^2 \mathrm{d}t .$$

If $r_{\mathrm{S}}(t)$, $r_{\mathrm{I}}(t)$, and $n(t)$ are statistically independent, then the total received power in the bandwidth $W_{\mathrm{FE}}$, denoted by $P_{\mathrm{T}}$, is

$$P_{\mathrm{T}} = P_{\mathrm{S}} + P_{\mathrm{I}} + P_n , \quad (16.2)$$

where $P_{\mathrm{I}}$ is the total power in $r_{\mathrm{I}}(t)$, and $P_n = W_{\mathrm{FE}} N_0$. The carrier power to thermal-noise density ratio is $C/N_0 = P_{\mathrm{S}}/N_0$, and the signal-to-thermal-noise ratio is $\mathrm{SNR}_{\mathrm{FE}} = P_{\mathrm{S}}/P_n$. Similarly, the signal-to-interference-and-thermal-noise ratio is $\mathrm{SINR}_{\mathrm{FE}} = P_{\mathrm{S}}/(P_n + P_{\mathrm{I}})$. Figure 16.1 offers an example illustration of the relationship between the power spectra of $r_{\mathrm{S}}(t)$, $r_{\mathrm{I}}(t)$, and $n(t)$.

### 16.1.2 Thermal-Noise-Equivalent Approximation

A key insight greatly simplifies GNSS interference analysis: The effect of interference on almost all GNSS receiver functions can be accurately modeled as if it were caused by spectrally flat thermal noise of a certain density. This subsection explains when this thermal-noise-equivalent approximation is valid and notes its limitations.

GNSS signal processing is founded on correlation of the received signal $r(t)$ with a local replica

$$l(t) = C_l(t-\hat{\tau}) \exp(\mathrm{j}\hat{\theta}(t)),$$

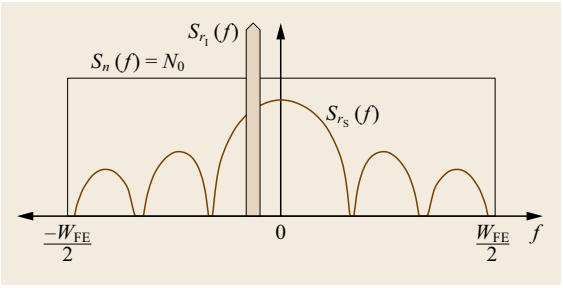

**Fig. 16.1** Stylized depiction of the power spectra $S_{r_{\mathrm{S}}}(f)$, $S_{r_{\mathrm{I}}}(f)$, and $S_n(f)$ that correspond, respectively, to the received components $r_{\mathrm{S}}(t)$, $r_{\mathrm{I}}(t)$, and $n(t)$. The spectra are assumed to be significant only within the interval $|f| \le W_{\mathrm{FE}}/2$, where $W_{\mathrm{FE}}$ is the bandwidth of the RF front end's narrowest bandpass filter. The total power in $S_{r_{\mathrm{S}}}(f)$, $S_{r_{\mathrm{I}}}(f)$, and $S_n(f)$ within this interval is, respectively, $P_{\mathrm{S}}$, $P_{\mathrm{I}}$, and $P_n$

where, ignoring the effects of band-limiting, $C_l(t)$ is often taken to be equal to $C(t)$, though it may differ from $C(t)$ when modeling early-minus-late correlation or when a specialized code replica is generated to reduce multipath. Suppose that a GNSS receiver is tracking the carrier phase of $r_S(t)$ so that $\hat{\theta}(t) \approx \theta(t)$. Then, the complex correlator output

$$Y(t) \equiv r^*(t)l(t) = S(t) + I(t) + N(t) \tag{16.3}$$

is composed of the desired component

$$S(t) \approx \sqrt{P_S} D(t-\tau)C(t-\tau)C_l(t-\hat{\tau}),$$

an interference component

$$I(t) = r_I^*(t)C_l(t-\hat{\tau})\exp(\mathrm{j}\hat{\theta}(t)),$$

and a random noise component $N(t) = n^*(t)l(t)$.

If the components $r_I^*(t)$, $C_l(t-\hat{\tau})$, and $\exp(\mathrm{j}\hat{\theta}(t))$ are wide-sense stationary and mutually statistically independent, as is a reasonable approximation for non-spoofing interference, then the autocorrelation function of $I(t)$ can be expressed as

$$\begin{aligned} R_I(\tilde{\tau}) &\equiv E[I^*(t)I(t-\tilde{\tau})] \\ &= E[r_I(t)r_I^*(t-\tilde{\tau})] \\ &\quad \times E[C_l(t-\hat{\tau})C_l(t-\tilde{\tau}-\hat{\tau})] \\ &\quad \times E(\exp(\mathrm{j}\hat{\theta}(t))\exp(\mathrm{j}\hat{\theta}(t-\tilde{\tau}))) . \end{aligned} \tag{16.4}$$

In other words, $R_I(\tilde{\tau})$ is the product of the autocorrelation functions corresponding to each of the three components of $I(t)$. Consequently, the power spectral density of $I(t)$, $S_I(f) = \mathcal{F}[R_I(\tilde{\tau})]$, where $\mathcal{F}$ denotes the Fourier transform, can be found by convolving the power spectra of the three components. Let $S_{C_l}(f)$, $S_{r_I}(f)$, and $\delta(f+\hat{f}_D)$ be the respective power spectra of $C_l(t)$, $r_I(t)$, and $\exp(\mathrm{j}\hat{\theta}(t))$, where

$$\hat{f}_D = -\frac{1}{2\pi}\frac{\mathrm{d}\hat{\theta}}{\mathrm{d}t}$$

is the receiver's estimate of the desired signal's apparent Doppler frequency, in Hz, and $\delta(f)$ is the Dirac delta function. It follows that

$$\begin{aligned} S_I(f) &= S_{C_l}(f) * S_{r_I}(f) * \delta(f+\hat{f}_D) \\ &= S_{C_l}(f) * S_{r_I}(f+\hat{f}_D) , \end{aligned}$$

where $*$ denotes convolution.

The values of $S_I(f)$ within a narrow neighborhood about $f = 0$ are a useful starting point for predicting GNSS interference effects. To understand why, consider the block diagram in Fig. 16.2, which illustrates correlation of the received signal $r(t)$ with the local signal replica $l(t)$ followed by an accumulate-and-dump operation that produces the discrete complex accumulation products $Y_k = I_k + \mathrm{j}Q_k, k = 1, 2, \ldots$. The accumulate-and-dump operation acts as a low-pass filter having a squared frequency response

$$|H_a(f)|^2 = \mathrm{sinc}^2(fT_a) ,$$

where $\mathrm{sinc}(x) \equiv \sin(\pi x)/\pi x$ and $T_a$ is the accumulation interval in seconds. The interference power that passes through the accumulate-and-dump filter into the complex accumulation products – and thereafter into the code and carrier tracking loops – is given by

$$P_{aI} = \int_{-\infty}^{\infty} |H_a(f)|^2 S_I(f)\mathrm{d}f .$$

Let the noise-equivalent bandwidth of the accumulate-and-dump filter be defined as

$$W_a \equiv \int_{-\infty}^{\infty} \mathrm{sinc}^2(fT_a)\mathrm{d}f = \frac{1}{T_a}$$

and let $I_0 \equiv S_I(0)$. Then, so long as $S_I(f)$ is nearly constant (flat) over a few multiples of $W_a$, $P_{aI}$ can be approximated as

$$P_{aI} \approx \tilde{P}_{aI} \equiv I_0 W_a .$$

For typical values of $T_a$, and for typical spreading code replicas $C_l(t)$, the quasi-constant condition on $S_I(f)$ is easily satisfied. To understand why, consider Fig. 16.3 in connection with the following argument. Assume that $S_{C_l}(f)$ and $S_I(f)$ are smooth (no spectral lines) with respective frequency derivatives $S'_{C_l}(f)$ and $S'_I(f)$. The error in the approximating $P_{aI}$ by $\tilde{P}_{aI}$ can be expressed in dB as

$$\Delta P_{aI} \equiv 10\log_{10}\left(\left|\frac{\tilde{P}_{aI}}{P_{aI}}\right|\right) ,$$

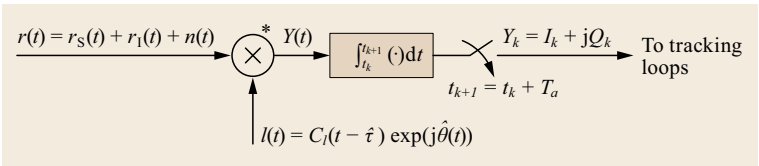

**Fig. 16.2** Block diagram of the standard correlation and accumulation process in a GNSS receiver. The complex product of the incoming signal $r(t)$ and the local replica $l(t)$ is accumulated over $T_a$ seconds to produce the discrete complex-valued accumulation product $Y_k$

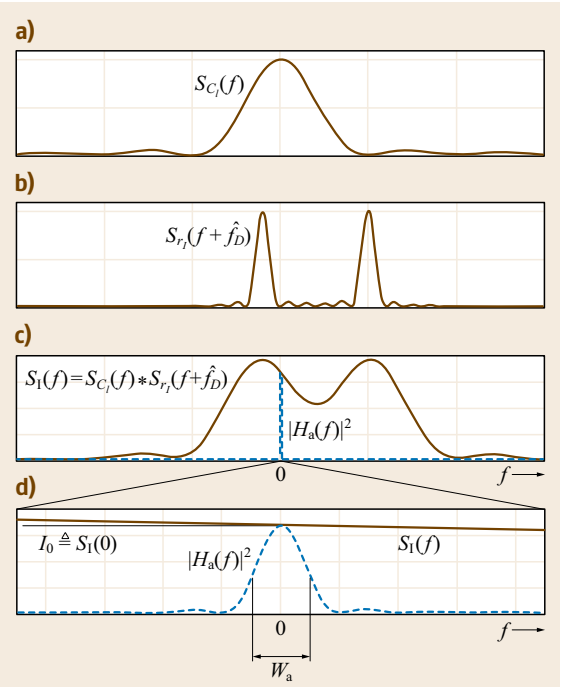

**Fig. 16.3a–d** Example power spectra and filtering involved in interference analysis: **(a)** $S_{C_l}(f)$, the spectrum of the GNSS replica code; **(b)** $S_{r_l}(f+\hat{f}_D)$, the spectrum of the received interference convolved with $\delta(f+\hat{f}_D)$; **(c)** $S_I(f)$, the spectrum of $I(t)$, together with $|H_a(f)|^2$, the squared frequency response of the accumulate-and-dump filter; **(d)** zoomed view of $S_I(f)$ and $|H_a(f)|^2$ near $f=0$ showing that, despite the interference being fairly narrowband, $S_I(f)$ is approximately flat over the noise-equivalent bandwidth $W_a$

which for practical $C_l(t)$ satisfies

$$\Delta P_{aI} < 10\log_{10}\left(1+\frac{|S'_I(0)|}{S_I(0)}W_a\right).$$

But, due to the properties of convolution,

$$\frac{|S'_I(0)|}{S_I(0)} \le \max_f \frac{|S'_{C_l}(f)|}{S_{C_l}(f)}.$$

And note that when performing the maximization, one need only consider $f$ values within

$$\mathcal{U}_\epsilon = \{f | \epsilon < S_{C_l}(f)\}$$

for some $\epsilon > 0$ because for $f \notin \mathcal{U}_\epsilon$ the possible contribution of $|S'_{C_l}(f)|/S_{C_l}(f)$ to $P_{aI}$ is small, making large values of $|S'_{C_l}(f)|/S_{C_l}(f)$ immaterial. Putting these pieces together, $\Delta P_{aI}$ can be upper bounded as

$$\Delta P_{aI} < \max_{f\in\mathcal{U}_\epsilon}\left[10\log_{10}\left(1+\frac{|S'_{C_l}(f)|}{S_{C_l}(f)}W_a\right)\right].$$

Consider an example designed for large $\Delta P_{aI}$. Let $C_l(t)$ be matched to the relatively narrowband GPS L1 C/A code (ignoring spectral lines), for which

$$S_{C_l}(f) = T_C \mathrm{sinc}^2(fT_C)$$
$$S'_{C_l}(f) = \frac{2T_C}{f}\left[\mathrm{sinc}\,(2fT_C) - \mathrm{sinc}^2(fT_C)\right],$$

where $T_C \approx 1\,\mu s$ is the spreading code chip interval. Choosing $\epsilon = S_{C_l}(0)/100$, it can be shown that $|S'_{C_l}(f)/S_{C_l}(f)|$ achieves a maximum of approximately $25T_C$ so that, even assuming $W_a = 1\,\mathrm{kHz}$ – the widest typical accumulate-and-dump bandwidth for the GPS L1 C/A signal – the ratio $\Delta P_{aI}$, and thus the error in approximating $P_{aI}$ by $\tilde{P}_{aI}$, remains less than 0.105 dB, which can be considered insignificant for most applications.

The thermal-noise-equivalent approximation to interference effects can be summarized as follows. At the input to the low-pass accumulate-and-dump filter that produces the complex accumulations $Y_k = I_k + jQ_k$, the carrier-power to thermal-noise density ratio is $C/N_0 = P_S/N_0$; at the output of the filter, the signal-to-thermal-noise ratio is $\mathrm{SNR} = P_S/N_0W_a$. When, in addition to thermal noise, interference is present, then at the filter input the carrier-power to interference-and-thermal-noise ratio (CINR) can be approximated as

$$\mathrm{CINR} = \frac{C}{N_{0,\mathrm{eff}}} = \frac{P_S}{N_0 + I_0},$$

where $N_{0,\mathrm{eff}} \equiv N_0 + I_0$ is the effective thermal noise density, which accounts for both thermal noise and interference. At the filter output, the signal-to-interference-and-thermal-noise ratio can be approximated as

$$\mathrm{SINR} = \frac{P_S}{N_{0,\mathrm{eff}}W_a}.$$

Thus, apart from the limitations described below, analysis of GNSS receiver behavior in the presence of interference can proceed just as analysis of receiver behavior in the presence of thermal noise, which is well understood [16.9–11], by substituting CINR (or $C/N_{0,\mathrm{eff}}$) for $C/N_0$, and SINR for SNR.

### 16.1.3 Limits of Applicability

Approximating interference that is statistically independent of the code and carrier replicas as if it were

thermal noise with spectral density $I_0$ at the input of the accumulate-and-dump filter yields excellent agreement with the full theoretical error statistics for acquisition, carrier tracking, and data demodulation [16.12]. The approximation is also accurate for predicting the statistics of any coherent correlation with code replica $C_l(t)$. For example, it accurately predicts the statistics of the coherent early-minus-late code phase error so long as data bits are estimated correctly, and $C_l(t)$ is taken to be the difference between early and late code replicas [16.12]. But the thermal-noise-equivalent approximation is known to produce biased code phase error statistics for noncoherent code phase discriminators [16.13, 14]. In this case, narrowband interference maximizes code tracking error not when the interference is centered at $f = 0$ Hz (i. e., when aligned with the desired signal's carrier frequency), as one would expect, but rather when it is centered at $f \approx 1/T_C$ Hz. However, if one properly accounts for squaring loss, then even the noncoherent phase error statistics can be reduced to an accurate thermal-noise-equivalent representation [16.12]. In short, the thermal-noise-equivalent approximation has wide applicability for analysis of interference effects.

It is worth noting that if the received interference $r_I(t)$ is not statistically independent of $C_l(t-\hat{\tau})$ and $\exp(j\hat{\theta}(t))$, then factorization of $R_I(\tilde{\tau})$ as in (16.4) is not possible and the thermal-noise-equivalent approximation is not valid. This case arises, for example, when the interference is structurally similar to the desired signal $r_S(t)$ and is approximately code-phase aligned with $r_S(t)$ – in other words, when the interference is a spoofing signal. For this reason, spoofing-type interference will be treated separately later in this chapter; meanwhile, all $r_I(t)$ will be assumed to be independent of $C_l(t-\hat{\tau})$ and $\exp(j\hat{\theta}(t))$. Furthermore, all code and carrier-phase measurements will be assumed to be produced by coherent phase discriminators. Under these conditions, the thermal-noise-equivalent approximation whereby CINR is substituted for $C/N_0$ can be expected to accurately predict receiver effects.

### 16.1.4 Overview of Interference Effects on Carrier Phase Tracking

Assuming the thermal-noise-equivalent approximation to be valid, this subsection gives an overview of interference effects on carrier-phase tracking. Attention is focused on phase tracking because the phase-tracking loop, or phase lock loop (PLL), is the weakest link in the signal tracking chain. Typically, if the PLL can maintain lock, then a frequency-tracking loop and a code-phase-tracking loop can as well.

#### Phase Error Variance

Consider a standard (nonsquaring) PLL with true phase input $\theta(t)$ and phase estimate $\hat{\theta}(t)$. When the phase error $\varphi(t) = \theta(t) - \hat{\theta}(t)$ is small enough that the PLL's phase detector can be regarded as linear, then, for zero-mean white driving noise, the PLL's phase error variance $\sigma_\varphi^2 = E[\varphi^2(t)]$ (in rad$^2$) is accurately approximated by [16.15]

$$\sigma_\varphi^2 = \frac{B_n N_0}{C} \equiv \frac{1}{\rho_L} , \tag{16.5}$$

where $B_n$ is the PLL's single-sided noise bandwidth and $\rho_L$ is the loop SNR. GNSS carrier-phase tracking of data-modulated signals requires a squaring (e.g., Costas) PLL, which is insensitive to the half-cycle phase changes induced by the data modulation. In a squaring PLL, the actual phase error tracked is $2\varphi$, with the corresponding variance denoted by $\sigma_{2\varphi}^2$. Furthermore, $\rho_L$ is reduced by a squaring loss factor approximately equal to [16.16]

$$S_L = \left(1 + \frac{N_0}{2T_a C}\right)^{-1} ,$$

where $1/T_a$ is the predetection bandwidth. Thus, for the squaring loop,

$$\sigma_\varphi^2 = \frac{\sigma_{2\varphi}^2}{4} = \frac{1}{\rho_L S_L}$$

is a useful approximation for $\sigma_\varphi^2$ in the linear regime. For analysis of the squaring loop, an equivalent loop SNR is defined as [16.17, p. 206]

$$\rho_{eq} \equiv \frac{\rho_L S_L}{4} , \tag{16.6}$$

which leads to $\rho_{eq} \approx 1/\sigma_{2\varphi}^2$ for small $\varphi$.

At large values of $\varphi$, the assumption of PLL linearity breaks down and analysis becomes more difficult. An exact expression for $\sigma_\varphi^2$ for a first-order nonsquaring PLL driven by white Gaussian noise is found in [16.18, Chap. 4]. Precise phase error statistics for all but this standard first-order loop are typically obtained via simulation. Fortunately, one can show that the exact phase error variance for the standard first-order loop is a reasonable proxy for that of higher-order loops. Thus, one can identify the region of approximate linear PLL operation by noting that, for the standard first-order loop, the linear model in (16.5) is reasonably accurate (within 20%) for $\rho_L > 4$, or $\sigma_\varphi < 28.6°$ [16.18, Chap. 4]. Likewise, a squaring loop behaves approximately linearly for $\rho_{eq} > 4$, or $\sigma_\varphi < 14.3°$.

### Cycle Slipping

A PLL's phase detector is periodic, meaning that it cannot distinguish between the phase errors $\varphi$ and $\varphi + 2n\pi$ (nonsquaring loop) or $\varphi$ and $\varphi + n\pi$ (squaring loop), where $n$ is an integer. As a result, an infinite set of stable attractors exists for the nonlinear difference equations that describe the PLL error dynamics. At low loop SNR, the phase error can slip from one stable attractor to another, leading to infinite $\sigma_\varphi^2$ in the steady state. This is the familiar cycle slip phenomenon associated with PLLs [16.19, 20], [16.15, Chap. 6].

The mean time to first cycle slip $T_s$ is defined as the average time required for the loop phase error to reach $\pm 2\pi$ ($\pm\pi$ for the squaring loop) for the first time, starting from an initial condition of zero phase error. For first-order loops, and in other cases where cycle slips occur as isolated events, $T_s$ is the same as the mean time between cycle slips; if cycle slips occur in bursts – as may happen for $\rho_L, \rho_{eq} < 5$ in second- or higher-order loops – then $T_s$ and the mean time between cycle slips are not related simply [16.20].

As with the calculation of $\sigma_\varphi^2$, an analytical solution for $T_s$ has only been possible for the simple case of a first-order unstressed (zero static phase error) PLL driven by white Gaussian noise, in which case [16.18, p. 101]

$$T_s = \frac{\pi^2 \rho_L I_0^2(\rho_L)}{2B_n} \tag{16.7}$$

is the time to first slip/mean time between slips for a nonsquaring loop, $I_0(\cdot)$ being a modified Bessel function of the first kind. An approximate $T_s$ for first-order squaring loops is obtained by substituting $\rho_{eq}$ for $\rho_L$. Unstressed second- and higher-order loops have lower $T_s$ than unstressed first-order loops, and stressed loops are more prone to cycle slipping than unstressed loops; nonetheless, (16.7) remains a useful upper bound. For GNSS applications, a second- or third-order loop is required to accurately track carrier-phase in the presence of Doppler-induced quadratic phase growth. In fact, even the second-order loop experiences significant loop stress ($\approx 1^\circ$ static phase error) during the largest GNSS line-of-sight accelerations. Only the third-order loop maintains near-zero static phase error for all GNSS geometries.

### Frequency Unlock

The general term *phase unlock* refers to single or successive cycle slips. At very low loop SNR, a PLL may never recover phase lock after a long succession of cycle slips. This phenomenon, called *drop lock* in the PLL literature, is related to the PLL's frequency pull-in range. For reasons that will become clear, the term *frequency unlock* is a more precise descriptor than drop lock for the phenomenon as it relates to the discrete-time PLLs used in modern GNSS receivers.

A PLL's frequency pull-in range is the maximum frequency step input that a PLL is able to *pull in* and eventually achieve phase lock. For example, a continuous-time first-order nonsquaring PLL has a pull-in range equal to the loop gain $K$ [16.19]. For higher-order PLLs, the frequency pull-in range can be thought of as the maximum tolerable mismatch $\Delta\omega = |\omega_c - v|$ between the carrier frequency $\omega_c$ and the PLL's internal estimate of carrier frequency $v$, assuming that higher-order loop filter states (e.g., the estimate of carrier frequency rate) are relaxed, where applicable.

Continuous-time PLLs whose loop filters contain one or more perfect integrators have an infinite frequency pull-in range [16.15, Chap. 8]. On the other hand, the frequency pull-in range of second- and higher-order discrete-time PLLs is limited by the loop update (accumulation) interval $T_a$. When the frequency mismatch $\Delta\omega$ exceeds a certain threshold $\Delta\omega_m$, then $v$ is attracted toward a stable equilibrium value that satisfies $T_a\Delta\omega = n\pi$ (nonsquaring loop) or $T_a\Delta\omega = n\pi/2$ (squaring loop), $n = 1, 2, 3, \ldots$. Intuitively, these equilibrium values exist because the loop cannot detect a phase error change of $2n\pi$ (nonsquaring loop) or $n\pi$ (squaring loop) between loop updates. The value of $\Delta\omega_m$ is a function of the particular loop configuration. It can be surprisingly small for PLLs common in GNSS receivers: for a third-order Costas loop with $T_a = 10\,\text{ms}$ and $B_n = 10\,\text{Hz}$, $\Delta\omega_m = 81\,\text{rad/s} \approx 13\,\text{Hz}$. At very low loop SNR, cycle slips can occur in bursts as noise and phase dynamics force $v$ momentarily away from $\omega_c$ [16.20]. If, due to such forcing, $\Delta\omega$ exceeds $\Delta\omega_m$, then there is a high probability that $v$ will become trapped at one of the incorrect stable equilibrium values. Thus, the PLL experiences frequency unlock.

Frequency unlock and momentary phase unlock have rather different practical consequences. Unlike momentary phase unlock (i. e., cycle slipping), frequency unlock often leads to complete loss of the GNSS signal link – a result of signal attenuation due to frequency detuning. If $v$ settles on an equilibrium value such that $n \geq 2$ (nonsquaring loop) or $n \geq 4$ (squaring loop), then the baseband signal power drops by more than 13 dB, making it likely that the PLL will experience further frequency detuning and eventually lose the signal entirely. Worse yet, re-acquisition may not be possible at low SNR.

## 16.2 Canonical Interference Models

### 16.2.1 Wideband Interference

The simplest variants of $r_I(t)$ are the extreme cases of wideband and narrowband interferences. Consider first wideband interference. Suppose that $r_I(t)$ is spectrally flat with power density $S_I(f) = P_I/W_{FE}$ over a two-sided front-end bandwidth $W_{FE} >> 1/T_C$, where $T_C$ is the chip interval of $C(t)$ (e.g., $1/T_C = 1.023\,\text{MHz}$ for the GPS L1 C/A code). In this case, $S_I(f) = S_{C_l}(f) * S_{r_I}(f + \hat{f}_D) \approx S_{r_I}(f) = P_I/W_{FE}$, which implies that $I_0 \equiv S_I(0) = P_I/W_{FE}$. Hence, post-correlation error analysis can proceed by approximating the carrier-to-noise ratio as

$$\text{CINR} = \frac{C}{N_{0,\text{eff}}} = \frac{P_S}{N_0 + P_I/W_{FE}} \,. \tag{16.8}$$

Continuous Gaussian wideband interference is interesting because it is dense in both frequency and time and its amplitude distribution is shaped like that of receiver thermal noise. Thus, from the perspective of an adversarial jammer, wideband Gaussian interference is a conservative strategy: Although it demands significant power, it affords receivers in the target area no more effective interference mitigation techniques than those commonly applied for weak GNSS signal tracking.

### 16.2.2 Narrowband Interference

Suppose $r_I(t)$ is a narrowband interference signal offset by $f_I$ Hz from the GNSS carrier frequency. As an extreme case, consider perfect tone interference

$$\begin{aligned} r_I(t) &= \sqrt{P_I}\exp(\mathrm{j}2\pi f_I t) \\ S_{r_I}(f) &= P_I\delta(f - f_I) \,. \end{aligned}$$

In this case, the power spectrum $S_I(f)$ is simply a scaled and frequency-shifted version of $S_{C_l}(f)$

$$\begin{aligned} S_I(f) &= S_{C_l}(f) * S_{r_I}(f + \hat{f}_D) \\ &= P_I S_{C_l}(f) * \delta(f + \hat{f}_D - f_I) \\ &= P_I S_{C_l}(f + \hat{f}_D - f_I) \,. \end{aligned}$$

#### Smooth Spectrum Approximation

As a first approximation, let $S_{C_l}(f)$ be any smooth (no spectral lines) function with an equivalent rectangular bandwidth of $W_C > 2|f_I|$. Then, interference power $P_I/L_C$ passes into the correlation products, where $L_C = W_C/W_a$ is termed the spread-spectrum processing gain. In this approximation, $I_0 = P_I/W_C$, so that

$$\text{CINR} = \frac{P_S}{N_0 + P_I/W_C} \,.$$

For a large jamming-to-signal power ratio $P_I/P_S$, $N_0$ becomes negligible compared with $P_I/W_C$, in which case CINR can be approximated as

$$\text{CINR} = 10\log_{10}(W_C) - 10\log_{10}\left(\frac{P_I}{P_S}\right) \quad \text{dB Hz} \,.$$

For example, if $W_C = 1\,\text{MHz}$, then a tone interference source with a jamming-to-signal power ratio of $P_I/P_S = 25\,\text{dB}$ would result in a CINR of approximately $60 - 25 = 35\,\text{dB Hz}$.

Moving toward a more accurate analysis of tone interference, consider now the actual shape of $S_{C_l}(f)$ while retaining the assumption of smoothness (no spectral lines). In particular, suppose that $S_{C_l}(f) = T_C\text{sinc}^2(fT_C)$, which would be the case for a local replica matched to a random binary spreading code $C(t)$ with chip interval $T_C$. Then, for tone interference with power $P_I$ it follows that

$$\begin{aligned} S_I(f) &= P_I S_{C_l}(f) * \delta(f + \hat{f}_D - f_I) \\ &= P_I T_C \text{sinc}^2[(f + \hat{f}_D - f_I)T_C] \,. \end{aligned}$$

From this expression, it is clear that the tone interference will minimize CINR (by maximizing $I_0 \equiv S_I(0)$) when $f_I = \hat{f}_D$. In other words, under the smooth spectrum approximation with $S_{C_l}(f) = T_C\text{sinc}^2(fT_C)$, the greatest degradation to CINR occurs when the tone is aligned with the Doppler-shifted carrier frequency of the desired signal.

One can apply a similar analysis to modern GNSS signals with binary offset carrier (BOC) spreading code modulation. In this case, the worst-case tone interference occurs when $f_I$ coincides with the Doppler-shifted peak of one of the offset side lobes. However, due to the additional spreading afforded by BOC-type signals, the resulting interference is, in general, less severe than for a $\text{sinc}^2$-type waveform with equivalent $T_C$ [16.21].

#### Effect of Spectral Lines

The smooth-spectrum approximation is appropriate for pseudorandom spreading codes $C(t)$ with a long code repetition period, such as the encrypted legacy military GPS spreading codes, for which the period is not publicly known but surely exceeds one week [16.22], and for the GPS L2CL code, which has a period of 1.5 s [16.23]. For short-period pseudorandom codes, however, the approximation is not appropriate because interference can be narrower than the spacing between spectral lines. Assume that $C(t)$ is a repeating code with period $T_p = T_C N_p$, where $N_p \in \mathbb{N}$ is the number of chips per code period. As a periodic function, $C(t)$ can be

decomposed as a Fourier series, which means that its power spectrum $S_C(f)$ is expressable as a weighted sum of Dirac delta functions

$$S_C(f) = \sum_{i=-\infty}^{\infty} c_i \delta\left(f - i\Delta f_\mathrm{p}\right), \quad i \in \mathbb{Z} \tag{16.9}$$

with constraint

$$\sum_{i=-\infty}^{\infty} c_i = 1$$

and spectral line spacing $\Delta f_\mathrm{p} = 1/T_\mathrm{p}$. Assuming a matched local code replica $[C_l(t) = C(t)]$, Fig. 16.4 shows the spectral line structure of $S_{C_l}(f)$ for an example GPS L1 C/A code.

For tone interference $S_{r_\mathrm{I}}(f) = P_\mathrm{I}\delta(f - f_\mathrm{I})$, $S_\mathrm{I}(f)$ is simply a scaled and shifted version of $S_{C_l}(f)$

$$\begin{aligned} S_\mathrm{I}(f) &= S_{C_l}(f) * S_{r_\mathrm{I}}\left(f + \hat{f}_D\right) \\ &= P_\mathrm{I} S_{C_l}\left(f - f_\mathrm{I} + \hat{f}_D\right). \end{aligned} \tag{16.10}$$

Interestingly, if none of the tines in the comb of spectral lines that constitute $S_\mathrm{I}(f)$ falls within the passband of the accumulate-and-dump filter $H_\mathrm{a}(f)$, then the tone interference will have a negligible effect on the accumulation products. This can be quantified probabilistically as follows. If the frequency offset $f_\mathrm{I}$ is modeled as a random variable uniformly distributed over a range wider than $\Delta f_\mathrm{p}$, then the probability that one of the spectral lines in $S_\mathrm{I}(f)$ will fall within the noise-equivalent bandwidth $W_\mathrm{a}$ of the accumulate-and-dump filter is

$$P_X = \left[\mathrm{mod}(|f_\mathrm{I}|, \Delta f_\mathrm{p}) \le W_\mathrm{a}\right] = \frac{W_\mathrm{a}}{\Delta f_\mathrm{p}}.$$

For $N_\mathrm{s}$ signals tracked, each with independent random $f_D$, the probability of significant interference in any tracking channel rises to

$$P_{X_\mathrm{T}} = 1 - (1 - P_X)^{N_\mathrm{s}}.$$

By way of example, for GPS L1 C/A-code tracking with $T_\mathrm{a} = 20\,\mathrm{ms}$ and $N_\mathrm{s} = 10$, $P_X = 0.05$ for each tracking channel and $P_{X_\mathrm{T}} = 0.4$ for the ensemble.

From (16.9) and (16.10), it is evident that tone interference is most damaging when $f_\mathrm{I}$ is aligned with the Doppler-shifted spectral line having the largest weighting coefficient $c_i$. For example, for the spectrum shown in Fig. 16.4, the largest $c_i$, located at $\pm 72\,\mathrm{kHz}$, is 23 dB below the total power in $S_{C_l}(f)$. Therefore, when targeting this signal, a tone interferer with power $P_\mathrm{I}$ would be attenuated by at least 23 dB before passing into the accumulate-and-dump filter. (Interestingly, tone interference targeting a C/A signal at exactly the Doppler-shifted L1 carrier frequency is ineffective because the balanced C/A Gold codes, which have only one more 1 than 0, produce a nearly insignificant $-60.2\,\mathrm{dB}$ line component at zero offset.) In general, the largest spectral line components among all GPS L1 C/A Gold codes attenuate tone interference by only 18.3 dB [16.24]. By way of comparison, a perfectly random code sequence with the same chip interval ($T_\mathrm{C} \approx 1\,\mu\mathrm{s}$) would attenuate the interferer by at least 60 dB.

In general, one can say that spectral lines in $S_{C_l}(f)$ have two contrary effects on tone interference: (1) line sparsity reduces the probability that interference will have a significant effect – most likely the interference will fall harmlessly between the lines, but (2) in the event that tone interference does coincide with a powerful line component, the interference effect is severe.

Of course, pure tone interference is only a convenient fiction; all interference encountered in practice will have a nonzero spectral width. Convolving an arbitrary $S_{r_\mathrm{I}}(f)$ with an $S_{C_l}(f)$ of the form in (16.9) results in an interference spectrum of the form

$$\begin{aligned} S_\mathrm{I}(f) &= S_{C_l}(f) * S_{r_\mathrm{I}}\left(f + \hat{f}_D\right) \\ &= P_\mathrm{I} \sum_{i=-\infty}^{\infty} c_i S_{r_\mathrm{I}}\left(f - \Delta f_\mathrm{p} + \hat{f}_D\right). \end{aligned} \tag{16.11}$$

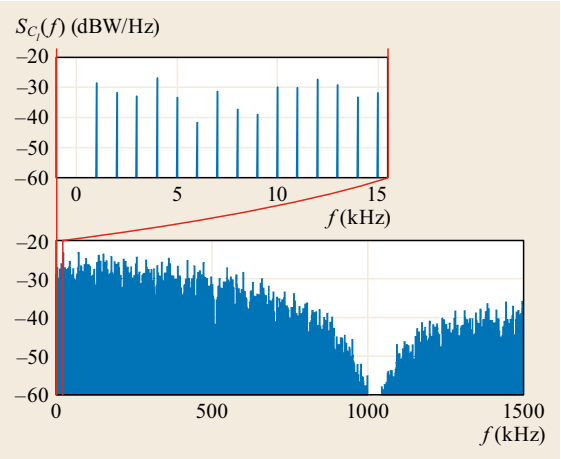

**Fig. 16.4** Power spectrum $S_{C_l}(f)$ corresponding to the GPS L1 C/A code replica for pseudo-random number sequence (PRN) 31. The units of $S_{C_l}(f)$ assume that the power of $C_l(t)$ is normalized to 1 W. Because $S_{C_l}(f) = S_{C_l}(-f)$, only positive frequencies are shown. Bottom panel: The interval $0 \le f \le 1500\,\mathrm{kHz}$ showing the code's approximate $T_C \mathrm{sinc}^2(fT_C)$ spectral envelope. Top panel: Expanded view of the first 15 kHz, showing distinct spectral lines with irregular weighting spaced at $\Delta f_p = 1/T_p = 1\,\mathrm{kHz}$

Thus, each tine in the comb now assumes the shape of $S_{r_I}(f)$. For interference that is narrow with respect to $\Delta f_p$, each tine remains distinct from its neighbors and is weighted according to the corresponding $c_i$; as the interference widens, the tines blend together and the spectrum flattens.

### 16.2.3 Matched-Spectrum Interference

An inescapable property of multiaccess spread-spectrum systems such as GNSS is that, from the perspective of a receiver channel tracking a particular GNSS signal (a unique combination of spreading code and center frequency), all other signals at the same frequency act as interference. Moreover, many of these interfering signals will have a power spectrum that is closely matched with that of the desired signal. This matched-spectrum interference is a particularly potent nuisance because it allocates power, as a function of frequency, in exact proportion to the weighting that the receiver applies with its local replica in attempting to track the desired signal. Thus, the most powerful spectral lines – the most important contributors to the total received GNSS signal power – are affected by the greatest amount of noise. In recognition of this, adversarial interferers often adopt matched-spectrum interference as their waveform of choice. In the case of nonmalicious intrasystem (e.g., within GPS) or intersystem (e.g., between GPS and Galileo) interference, the competing waveforms are by design weak and approximately power-matched so that the interference is small compared to the ever-present thermal noise, though not entirely insignificant – especially with the proliferation GNSS satellites.

When matched-spectrum interference originates from GNSS satellites, it is termed multiaccess interference. As an illustration of the effects of such interference, consider a pseudorandom binary spreading code whose power density under a smooth-spectrum approximation is

$$S_C(f) = P_C T_C \mathrm{sinc}^2(fT_C) \,,$$

where $P_C$ is the received signal power and $T_C$ is the spreading code chip interval. This model applies, for example, to the spreading codes of GPS L1 C/A and P(Y), L2 C and P(Y), and L5 I and Q. Assume, for simplicity, that the receiver's power-normalized code replica is perfectly matched to the incoming code so that $S_C(f) = P_C S_{C_l}(f)$ (i. e., band-limiting effects in the RF front end are ignored).

Treating $S_C(f)$ as an interference spectrum and assuming $\hat{f}_D$ is negligible compared to the bandwidth of $S_C(f)$, we have

$$\begin{aligned} S_I(f) &= S_{C_l}(f) * S_{r_I}(f) \\ &= P_C S_C(f) * S_C(f) \\ &= P_C \int_{-\infty}^{\infty} S_C(f-\nu) S_C(\nu) \mathrm{d}\nu \\ &= P_C \int_{-\infty}^{\infty} S_C(\nu-f) S_C(\nu) \mathrm{d}\nu \,, \end{aligned}$$

where the last equality follows from $S_C(f) = S_C(-f)$. Hence,

$$\begin{aligned} I_0 \equiv S_I(0) &= P_C \int_{-\infty}^{\infty} S_C^2(\nu) \mathrm{d}\nu \\ &= P_C \int_{-\infty}^{\infty} \left[T_C \mathrm{sinc}^2(\nu T_C)\right]^2 \mathrm{d}\nu \end{aligned}$$

which, by the change of variables $q = \nu T_C$, becomes

$$I_0 = P_C T_C \int_{-\infty}^{\infty} \mathrm{sinc}^4(q) \mathrm{d}q = \left(\frac{2}{3}\right) P_C T_C \,.$$

Thus, the effect of a single multiaccess interference signal with received power $P_C$ is to raise the effective thermal noise density from $N_0$ to

$$N_{0,\mathrm{eff}} = N_0 + \left(\frac{2}{3}\right) P_C T_C \,.$$

The significance of multiaccess interference is measured with respect to $N_0$. Suppose there are $M$ multiaccess signals whose average received power is $\bar{P}_C$. Then, from the perspective of a single desired signal, the multiaccess power density becomes equivalent to $N_0$ when

$$\left(\frac{2}{3}\right) \bar{P}_C T_C (M-1) = N_0 \,.$$

Thus, to ensure that multiaccess density does not exceed $N_0$ requires

$$M \le 1 + \frac{3/2}{\left(\bar{P}_C/N_0\right) T_C} \,.$$

Figure 16.5 shows this bound for $T_C = 1\,\mu\mathrm{s}$, which applies to GPS L1 and L2C, and for $T_C = 0.1\,\mu\mathrm{s}$, which

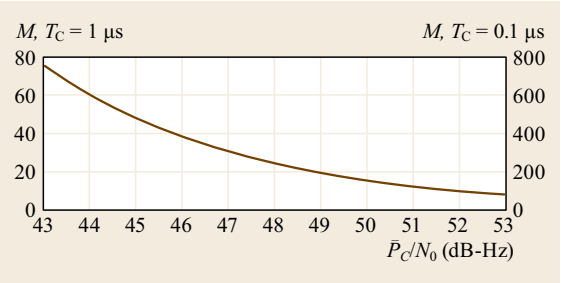

**Fig. 16.5** Maximum number of simultaneously received multiaccess GNSS signals with power spectrum $S_C(f) = P_C T_C \mathrm{sinc}^2(fT_C)$ such that $I_0 \le N_0$, as a function of $\bar{P}_C/N_0$, where $\bar{P}_C$ is the average power of the $M-1$ multiaccess interferers. The left- and right-hand scales correspond, respectively, to $T_C = 1\,\mu s$ and $T_C = 0.1\,\mu s$

applies to GPS L5 I and Q. Assuming that, for the average user, the number of received signals $M$ is approximately one-fourth of the total number of orbiting GNSS satellites and that $\bar{P}_C = 47\,\mathrm{dB\,Hz}$, and assuming all satellites broadcast only the GPS L1 C/A signal, the multiaccess interference density exceeds $N_0$ when the constellation size grows beyond 124 satellites.

It is worth noting that, although a 3 dB rise in the effective thermal noise floor (from $N_0$ to $N_0 + I_0 = 2N_0$) is significant, most GNSS users would gladly trade this degradation for the vastly improved dilution of precision and reduced convergence times for carrier-phase differential GNSS (CDGNSS) positioning and precise point positioning (PPP) that a larger multi-GNSS constellation would afford.

Finally, observe that, from the perspective of an adversarial interferer, matched-spectrum interference is the most efficient use of transmit power among all interference waveforms. For example, in the case of a local replica with density $S_{C_l}(f) = T_C \mathrm{sinc}^2(fT_C)$, it can be shown that for a fixed interference power $P_I$, the interference density assumes its maximum value $I_0 = (2/3)P_I T_C$ when $S_{r_l}(f) = P_I T_C \mathrm{sinc}^2(fT_C)$.

## 16.3 Quantization Effects

The effect of signal quantization on interference depends less on the bandwidth of the interference – whether wideband or narrowband – than on its amplitude distribution. The salient result in this regard is as follows: For white, Gaussian-distributed interference, the quantizer's output SNR is always degraded relative to its input SNR, whereas for constant-amplitude interference (e.g., a swept tone), the quantizer output SNR can actually exceed its input SNR. In any case, an optimal quantization strategy seeks to minimize the SNR degradation through the quantizer.

### 16.3.1 One-Bit Quantization

If the discrete samples entering a one-bit (two-level) quantizer are Gaussian distributed and uncorrelated, then the SNR is degraded by a factor $2/\pi$ or $-1.96\,\mathrm{dB}$ [16.25]. Designers of low-cost GNSS receivers often view this modest loss as a small price to pay for a one-bit quantizer's economy of implementation and low power consumption, which explains the popularity of one-bit quantization in consumer devices.

However, one-bit quantization performs poorly in the presence of strong tone interference [16.24]. To understand why, consider a simple case in which thermal noise is absent and a pure tone interference signal is received phase coherently (in-phase) with the carrier of a desired biphase-modulated GNSS signal. In this case, it is clear that, if the interference amplitude $\alpha$ is greater than the GNSS signal amplitude, then the interference completely suppresses the GNSS signal in one-bit quantization because the signal's noise-free biphase transitions are dominated at every sampling instant by the coherent interference.

In the presence of thermal noise, the desired GNSS signal is no longer completely suppressed by coherent tone interference, but the quantizer SNR degradation remains severe whenever $\alpha > \sigma$, where $\sigma$ is the thermal noise standard deviation. Note that if the tone interference is out of phase by some angle $\theta$, then its effective amplitude becomes $\alpha \cos\theta$. Thus, if $\theta$ is slowly varying and $\alpha > \sigma$, then the GNSS signal is periodically suppressed. When $\theta$ varies rapidly compared to the reciprocal integration time $1/T_a$, as with tone interference significantly offset from the desired GNSS signal carrier frequency – or, more generally, with any constant-amplitude interference – SNR degradation is less severe than in the case of coherent tone interference but still increases rapidly with increasing $\alpha > \sigma$.

It follows from these observations that one-bit quantization is a serious design flaw for receivers meant to operate in the presence of strong constant-amplitude interference.

### 16.3.2 Multibit Quantization

Multibit quantization is preferable to one-bit quantization when constant-amplitude interference may be

present. Not only can multibit quantization prevent total suppression of the desired GNSS signal, but, with properly chosen quantization levels, it can substantially suppress constant-amplitude interference.

Two-bit (four-level) quantization is an especially attractive option for GNSS receivers because it is simple to implement and amenable to low-power processing yet yields significantly less SNR degradation than one-bit quantization in wideband Gaussian noise (0.55 dB versus 1.96 dB [16.24, 26, 27]). The two-bit quantization function $q_2(x)$ is graphically shown in Fig. 16.6. For uncorrelated zero-mean Gaussian noise with standard deviation $\sigma$, both the minimum mean-square-error distortion criterion [16.28] and the minimum SNR degradation criterion [16.26] (in the limit of low SNR) are optimized when the magnitude threshold is chosen as $L = 0.98\sigma$ and the ratio of the quantization levels is approximately $a_2/a_1 = 3.3$. This remains true whether the noise is thermal in origin (i. e., proportional to the receiver system temperature) or is a combination of thermal noise and ambient interference, so long as the combined noise-plus-interference amplitude distribution remains Gaussian and sample-wise uncorrelated. Implementation of this quantization strategy within a GNSS receiver is typically realized by setting $a_1 = 1$, $a_2 = 3$ and adjusting the automatic gain control (AGC) so that $|q_2(x)| = a_2$ with probability 0.33.

When significant non-Gaussian interference is present in the received analog signal, the probability distribution $p(x)$ of the input to the quantizer is no longer approximately Gaussian and the above values for $a_1, a_2$, and $L$ become suboptimal. If $p(x)$ is known, then new mean-square-distortion-minimizing values can be calculated numerically as described in [16.28]. For the special case of unity-amplitude tone interference with a phase that varies rapidly relative to $1/T_a$, and in the limit of low SNR, $p(x)$ assumes the shape shown in Fig. 16.7. In this case, it can be shown numerically that the mean-square distortion is minimized when $L = 0.573$ and $a_2/a_1 = 2.89$. But, importantly, and in contrast to the Gaussian noise-plus-interference case, these distortion-minimizing values do not also minimize SNR degradation. Instead, for spread-spectrum signals with large processing gain (such as GNSS signals), SNR degradation is minimized as $L$ approaches the upper limit of $p(x)$ [16.26]. The key insight is that, for this choice of $L$, the quantizer maximizes the number of captured code transitions, as illustrated in Fig. 16.8.

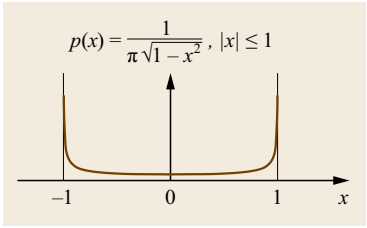

**Fig. 16.7** Probability distribution of the quantizer input $x$ for unity amplitude tone interference in the limit of low SNR

More generally, a properly configured multibit quantizer exhibits *negative* SNR degradation (i. e., there is a positive *conversion gain*) when the incoming interference has a fixed amplitude (e.g., a swept tone). This result holds even when the interference is a combination of fixed-amplitude and Gaussian interference, so long as the fixed-amplitude interference dominates [16.29]. This contrasts with Gaussian interference, for which a two-bit quantizer's output SNR is always degraded by at least 0.55 dB relative to its input SNR.

Within a GNSS receiver, adaptive two-bit quantization for suppression of constant amplitude interference can be implemented as follows. When significant constant-amplitude interference is detected, the adaptive quantizer raises the threshold $L$ from the Gaussian-noise-optimized value for $L$ (approximately
