**Fig. 16.6** Quantization function $q(x)$ for two-bit (four-level) quantization, showing the magnitude threshold $L$ and the quantization levels $\{-a_2, -a_1, a_1, a_2\}$

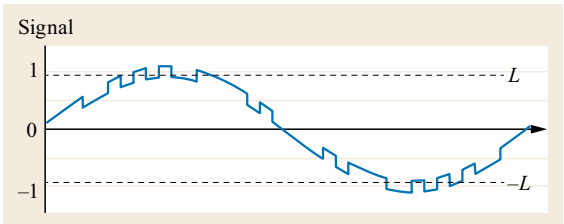

**Fig. 16.8** Example threshold value $L$ for two-bit quantization of a binary spread-spectrum signal in the presence of strong unity-amplitude tone interference. As the signal-to-interference power ratio decreases from the −20 dB ratio shown, the curve's distribution approaches that of Fig. 16.7, and the optimal value of $L$ approaches 1

$L = \sigma$) to a new value that places $L$ near the edge of the $p(x)$ distribution (equivalently, the AGC can lower its gain until this condition is reached). The optimal value of $L$ depends on the relative strengths of the GNSS signal, the constant-amplitude interference, and the Gaussian noise and interference. Figure 16.9 shows the quantizer conversion gain for several example scenarios with different relative signal, noise, and interference strengths. A simple suboptimal approach sets $L$ so that $|q(x)| = a_2$ with a predetermined probability (e.g., 10%); in an alternative, higher-performance approach, a feedback signal from the GNSS receiver's baseband processor adjusts $L$ to maximize the average $C/N_0$ of the tracked GNSS signals. Note that as the constant-amplitude interference power increases relative to the Gaussian interference, the quantizer can more effectively suppress the former, but its performance becomes more sensitive to choice of $L$. For best performance, the ratio $a_2/a_1$ should also be adjusted upward from its Gaussian-adapted setpoint (approximately $a_2/a_1 = 3$), but this is less important than adjusting $L$. An example of adaptive multibit quantization implementation can be found in [16.14, Fig. 6.1].

Three-bit (8-level) and higher quantization bring further reduction of SNR degradation for all interference and noise types, but the marginal improvement above two-bit quantization is modest and decreases rapidly with additional bits. In uncorrelated Gaussian noise and interference, the SNR degradation through a three-bit quantizer is 0.272 dB (versus 0.55 dB for a two-bit quantizer) [16.27]. Details on three-bit quantizer performance can be found in [16.24].

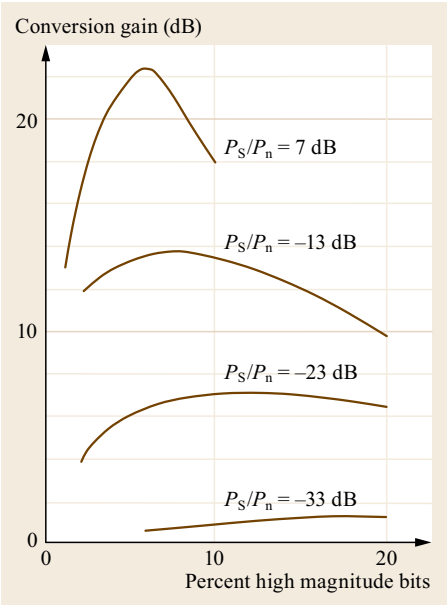

**Fig. 16.9** Two-bit quantizer conversion gain (ratio of quantizer output SNR to input SNR) for a scenario in which the incoming spread-spectrum signal is corrupted by both Gaussian noise (or interference) and constant-amplitude interference, as a function of the percentage of high magnitude bits (percentage of samples for which $|q(x)| = a_2$). The different curves correspond to different values of the signal power to Gaussian noise (or interference) ratio $P_S/P_n$. For all curves, the ratio of the signal power to the constant-amplitude interference is $P_S/P_{ca} = -40$ dB, and $a_2/a_1 = 8$ (after [16.29], courtesy of the Institute of Electrical and Electronics Engineers (IEEE))

## 16.4 Specific Interference Waveforms and Sources

### 16.4.1 Solar Radio Bursts

Solar radio bursts (SRBs) are intense outbursts of radio emissions from the Sun, with spectral power ranging from HF to above the L band. They are typically associated with solar flares, which are caused by the acceleration of electrons in the solar atmosphere and whose rate of occurrence follows the 11 yr sunspot cycle [16.30, 31]. SRBs' jamming effect on radio equipment was first noted during World War II when strong SRBs jammed British anti-aircraft radar on many occasions [16.32]. SRBs can cause greater than 10 dB fades in a GNSS signal's $C/N_0$ [16.33, 34].

Given their broad-spectrum power distribution, SRBs are typically modeled as contributing to a receiver's thermal noise $n(t)$. In particular, they raise a GNSS receiver's antenna temperature $T_A$, which is related to the receiver's noise density $N_0$ by

$$N_0 = k_B(T_R + T_A) ,$$

where $k_B$ is Boltzmann's constant and $T_R$ and $T_A$ are respectively the receiver and antenna noises in degrees Kelvin. $T_R$ is the equivalent temperature of noise sources internal to the receiver, primarily those in the first-stage low-noise amplifier (LNA). $T_A$ is the temperature equivalent of noise impinging on the antenna, including radiation from the warm Earth, cosmic noise, and solar radio noise. $T_A$ varies with antenna motion (as more or less warm Earth radiation is visible), antenna blockage (e.g., an increase in $T_A$ due snow accumulation [16.35]), and variable solar radiation. Note that

these are difficult or impossible for a stand-alone (non-networked) GNSS receiver to predict. Of these, solar radiation is least site-specific: All GNSS receivers in view of the Sun are similarly affected.

To judge the impact of SRBs on GNSS receivers, it is instructive to examine the rate of occurrence of those SRBs that significantly increase a receiver's $P_T$. Such events not only reduce $C/N_0$ but also lead to false alarms in received power monitoring, a technique whereby intentional interference is detected based solely on $P_T$ (discussed further in Sect. 16.6.2). Table 16.2 shows the SRB occurrence rate for three different levels of increased $P_T$. Let $P_T/P_{T,nom}$ be the ratio of received power in the presence of a SRB to nominal received power. Assume that non-SRB interference is negligible so that $P_I = 0$, leaving $P_T = P_S + P_n$, where

$$P_n = W_{FE}N_0 = W_{FE}k_B(T_R + T_A) \, .$$

Let the antenna temperature be $T_A = T_{A0} + T_{As}$, where $T_{A0}$ is a nominal value for $T_A$ and $T_{As}$ is the increase in $T_A$ due to solar radiation.

Table 16.2 is interpreted as follows. Each value of $P_T/P_{T,nom}$ can be related to a value of $T_{As}$ by

$$\frac{P_T}{P_{T,nom}} = \frac{P_S + k_B B(T_R + T_{A0} + T_{As})}{P_S + k_B B(T_R + T_{A0})}$$

assuming the following reasonable parameter values: $P_S = -146\,\text{dBW}$, $W_{FE} = 2\,\text{MHz}$, $T_R = 188\,\text{K}$, and $T_{A0} = 100\,\text{K}$. Each $T_{As}$, in turn, is related to a change in $C/N_0$ by

$$\Delta C/N_0 = \frac{T_R + T_{A0}}{T_R + T_{A0} + T_{As}}$$

and to a solar flux density $S_1$ by

$$S_1(\text{SFU}) = \frac{2k_B T_{As}}{A_e 10^{-22}} \, ,$$

where the effective antenna area is taken to be $A_e = 7.23 \cdot 10^{-3}\,\text{m}^2$, which is a good approximation for a single-element GNSS antenna, and where the additional factor of 2 in the numerator reflects the assumption that only half the total-polarization solar radiation contributes to $T_{As}$ through a GNSS antenna, which is designed to received right-hand circularly polarized signals [16.34]. The factor $10^{-22}$ converts $\text{W/m}^2/\text{Hz}$ to solar flux units (SFU). The resulting $S_1$ values listed in Table 16.2 are those above which $P_T$ would increase by the amount shown. As a final step, the model $N(S > S_1, \nu_1, \nu_2)$ from [16.36] is invoked (with the correction factor $C_{geo}$) to approximate the total number of bursts exceeding $S_1$ in the frequency range ($\nu_1 = 1\,\text{GHz}$, $\nu_2 = 1.7\,\text{GHz}$) over a 40 yr historical period. This is used to estimate $T_e$, the time between triggering events, for solar maximum years and for all years.

**Table 16.2** Time between threshold-exceeding solar radio burst events for various values of the ratio $P_T/P_{T,nom}$

| Threshold values | | | | $T_e$ (days) | |
|---|---|---|---|---|---|
| $P_T/P_{T,nom}$ (dB) | $T_{As}$ (K) | $\Delta C/N_0$ (dB) | $S_1$ (SFU) | Solar max. | All years |
| 0.44 | 40.9 | −0.6 | 1560 | 9.2 | 22.0 |
| 0.93 | 91.3 | −1.2 | 3488 | 17.3 | 42.9 |
| 1.5 | 157.7 | −1.9 | 6022 | 26.5 | 67.4 |

Table 16.2 reveals that solar radio bursts causing a degradation in $C/N_0$ of 1.9 dB or greater are rare, occurring approximately once per month during solar maximum. Truly intense SRBs causing 10 dB or more of degradation and interrupting signal tracking, as in the 2006 storm [16.33], are extremely rare. Nonetheless, SRBs can be problematic for signal authentication techniques based solely on $P_T$, as will be discussed in Sect. 16.6.2.

### 16.4.2 Scintillation

A transionospheric radio wave can exhibit temporal fluctuations in phase and intensity caused by electron density irregularities along its propagation path, a phenomenon called scintillation, or fading. At GNSS frequencies (L band), strong scintillation is manifest in deep power fades (> 15 dB) that are often associated with rapid phase changes. Such vigorous signal dynamics stress a receiver's carrier tracking loop and, as their severity increases, lead to navigation bit errors, cycle slipping, and complete loss of carrier lock [16.37, 38].

Signal refraction, caused by large-scale irregularities, results in low-frequency variations in group delay (measured by the code phase, or pseudorange, observable) and carrier phase. Signal diffraction, caused by smaller-scale (approximately 400 m) irregularities, scatters L-band signals so that the radio waves reach terrestrial receivers through multiple paths. Interaction between signals from multiple directions occurs at the carrier-phase level, yielding constructive and destructive interference patterns that produce variations in both the phase and amplitude of received signals.

It may at first seem out of place to treat ionospheric scintillation as interference, but the mutual interference caused by diffraction can challenge signal tracking as much as intermittent jamming, and diffractive interference shares characteristics with structured interference such as GNSS spoofing. The same argument can be made for nonionospheric multipath effects – those due to signal reflections – but these are treated separately in Chap. 15. Chapter 39 also treats scintillation, but

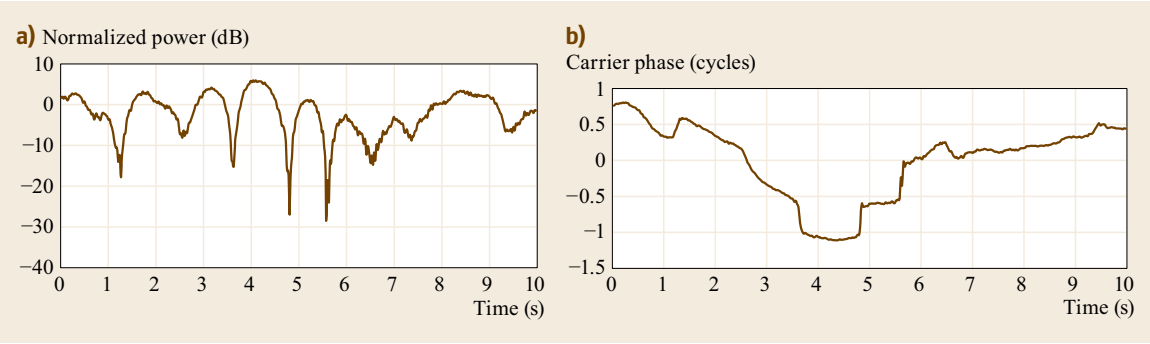

**Fig. 16.10a,b** Normalized signal power **(a)** and carrier phase **(b)** time histories from a record of GPS $L_1$ data with $S_4 \approx 0.9$ (after [16.37], courtesy of IEEE)

with an eye to phenomenology rather than receiver effects.

Severe L-band scintillation is both infrequent and geographically confined. The type known as equatorial scintillation, or equatorial spread F, generally occurs between local sunset and 2400 local time in the region extending $\pm 15°$ about the magnetic equator [16.39]. Another common type of scintillation occurs at high latitudes [16.40]. Significant effects have also been noted in the mid-latitude region, but they occur infrequently [16.41]. This section concentrates on equatorial scintillation because it is the most interference-like, making signals particularly difficult to track.

The severity of scintillation can be succinctly characterized by two parameters, the scintillation index, $S_4$, and the decorrelation time $\tau_0$ [16.42]. $S_4$ measures the intensity of scintillation, and is defined by

$$S_4^2 = \frac{\langle I^2 \rangle - \langle I \rangle^2}{\langle I \rangle^2} \,,$$

where $I = \alpha^2$ is signal intensity, $\alpha$ being the signal amplitude, and $\langle \cdot \rangle$ denotes time average. The scintillation decorrelation time $\tau_0 > 0$ is a measure of the rapidity of scintillation. A small $\tau_0$ (e.g., $< 0.5$ s) implies a scintillating channel that changes rapidly with time.

A short sample from the scintillation library introduced in [16.37] is presented in Fig. 16.10. The sample manifests strong scintillation, with $S_4 \approx 0.9$. The most striking features of the plot are the deep power fades that occur simultaneously with abrupt, approximately half-cycle phase changes whose sense (downgoing or upgoing) appears random. Such fades appear to be a universal feature of strong equatorial scintillation, and they are the primary cause of phase unlock for PLLs tracking strongly scintillating signals.

PLLs are affected by scintillation in two related ways: (1) increased phase error variance and (2) phase unlock.

### Phase Error Variance

The phase error variance models given in Sect. 16.1.4 assume that all phase errors are due to constant-intensity white measurement noise. Furthermore, (16.5) and (16.6) assume PLL linearity. These assumptions are violated during severe scintillation: Amplitude fading causes variations in the loop SNR, phase changes are time correlated, and, when attempting to track through the large, rapid phase changes associated with deep fading, the PLL cannot be expected to operate in its linear regime. For these reasons, calculating the phase error variance for a PLL tracking through strong scintillation is not straightforward [16.38]. Figure 16.11 shows how

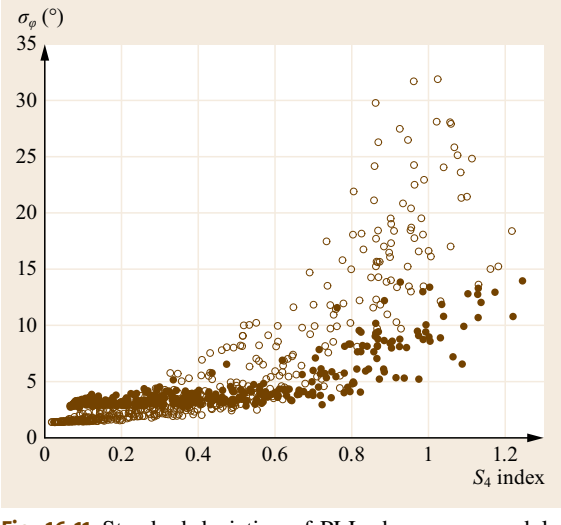

**Fig. 16.11** Standard deviation of PLL phase error modulo $\pi$ for a decision-directed arctangent phase discriminator over 30 s test records versus $S_4$ for ultra-high frequency (UHF) signals at $C/N_0 = 43$ dB Hz (*open circles*) and for GPS $L_1$ signals within $40 < C/N_0 < 44$ dB Hz with mean $C/N_0 = 43$ dB Hz (*filled circles*) (after [16.38], courtesy of IEEE)

$\sigma_\varphi$, the standard deviation of the phase measurement error modulo π, increases with increasing $S_4$, a dependence that is both due to the fade-induced reductions in loop SNR and to phase scintillation with frequency components that exceed the PLL's bandwidth. The large values of $\sigma_\varphi$ at high $S_4$ contribute to the degradation of carrier-phase-dependent GNSS systems during strong scintillation.

#### Phase Unlock

The general term *phase unlock* refers to single or successive cycle slips. Phase and amplitude scintillation cause cycle slipping by either deep rapid fading or prolonged fading. In the limit as the fade depth increases, the accompanying abrupt, nearly $\pi$-rad phase transition looks like bi-phase data modulation, to which a squaring-loop PLL is insensitive by design. Hence, the PLL detects no phase shift and a half-cycle slip occurs. In marginal cases, where the PLL might be capable of distinguishing a scintillation-induced phase transition from a data-bit-induced phase transition, the sudden drop in loop SNR increases the likelihood of a cycle slip. In short, simultaneous power fades and abrupt phase changes are a particularly challenging combination.

Prolonged amplitude fading is the second mechanism by which scintillation causes cycle slipping. This phenomenon may be considered a special case of fading in which the fading time scale is elongated so that the amplitude fade is accompanied by phase dynamics that are slow compared to a typical 10 Hz PLL noise bandwidth. In this case, broadband measurement noise dominates and (16.7) applies. Cycle slips occur rarely by this mechanism.

Figure 16.12 presents results in terms of cycle slip rate on the left vertical axis, and, for convenience, in terms of the mean time between slips, $T_s$, on the right vertical axis. As would be expected, a general increase in the rate of cycle slips accompanies increasing $S_4$. The lack of cycle slips below $S_4 \approx 0.4$ suggests that, whatever its other characteristics (e.g., $\tau_0$), scintillation with $S_4 \lesssim 0.4$ can be considered benign.

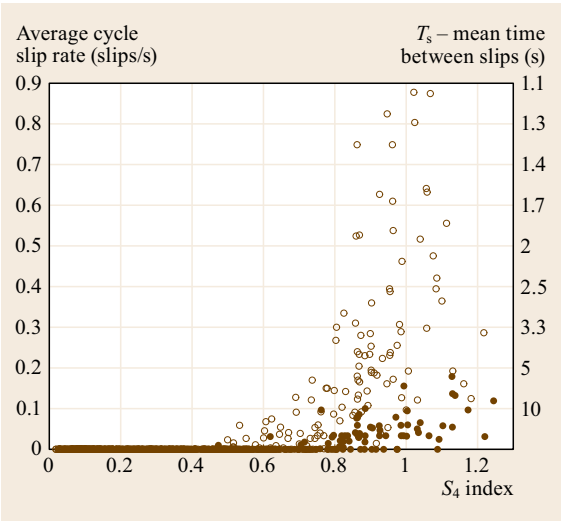

**Fig. 16.12** Average cycle slip rate for the decision-directed arctangent phase discriminator over 30 s test records versus $S_4$ for UHF signals at $C/N_0 = 43$ dB Hz (*open circles*) and for GPS $L_1$ signals within $40 < C/N_0 < 44$ dB Hz with mean $C/N_0 = 43$ dB Hz (*filled circles*). The *right vertical axis* expresses the cycle slip rate in terms of $T_s$ (after [16.38], courtesy of IEEE)

### 16.4.3 Unintentional Interference

Spectral surveys of the GNSS bands reveal that in rural areas the bands are largely free of interference, but in urban areas they are often corrupted by intermittent interference sources [16.43]. Most of these interference events are unintentional. Similarly, radio frequency interference (RFI) can disturb signal tracking when a GNSS receiver's antenna is packaged closely to other electronic equipment, as on a small satellite. Following are some examples of unintentional interference sources.

#### Harmonics

Nonlinearity in any one of several stages involved in RF transmission generates power not only at the intended transmission frequency but also at integer multiples, or harmonics, of that frequency. For example, UHF television signals with carrier frequencies near 525 MHz are notorious for injecting third-harmonic power into the GNSS L1 band [16.44, 45].

When broadcast transmitters are powerful, as with television transmitters, a harmonic near the GNSS bands can substantially degrade GNSS tracking performance. If a harmonic lies within a GNSS band of interest, then it cannot be attenuated by standard RF filters designed to isolate the GNSS signals. If powerful enough, the interfering harmonic will drive a GNSS receiver's dominant LNA into its nonlinear regime, causing a loss of sensitivity and leaving spurious tones across the target GNSS band [16.45].

#### DME/TACAN

The GPS L5 band and the Galileo E5a and E5b bands are situated in an ARNS band also allocated to distance measuring equipment (DME) and Tactical Air Navigation (TACAN) systems whose strong pulsed emissions act to significantly degrade GNSS

tracking [16.1]. DME/TACAN systems, which operate between 960 and 1215 MHz, produce emissions that are sparse in both the time and frequency domains. Pulses are transmitted in pairs 12 μs apart, with each pulse lasting 3.5 μs. The maximum practical transmission rate is 2700 pulse pairs per second, which means that interference from a single DME/TACAN transmitter is limited to less than 2% of a 1 s time interval. In the frequency domain, a single DME/TACAN signal occupies only 100 kHz, with channels spaced by 1 MHz. Thus, the total time-frequency occupancy of a single DME/TACAN transmitter in a 10 MHz band is only 0.02%. Such sparsity permits mitigation techniques that render DME/TACAN interference harmless even when GNSS receivers are airborne over so-called hot spots having a high density of DME transmitters [16.1].

#### Powerful Near-Band Transmissions

The radio spectrum between 700 MHz and 2 GHz, which includes all current GNSS bands, is particularly attractive for the provision of data to mobile units such as smartphones because the wavelengths of signals in this band are short enough that small antennas can be effective yet long enough to penetrate indoors. These desirable properties, coupled with the intense and rising demand for mobile data, portend the eventual placement of powerful transmissions in the radio bands adjacent to GNSS bands.

The 2010–2012 debate over whether to allow powerful terrestrial long term evolution (LTE) signals to be broadcast in the mobile satellite service (MSS) band just below the GNSS L1 band brought to the fore the susceptibility of contemporary GNSS receivers, especially high-precision receivers, to powerful near-band transmissions [16.46]. It was shown, for example, that typical GPS and Galileo receivers tracking signals centered at 1575.42 MHz suffered $C/N_0$ degradation greater than 3 dB when exposed to communications signals with received power exceeding −80 dBm in the 1545.2–1555.2 band even when the latter were filtered with a high-quality bandpass filter [16.8].

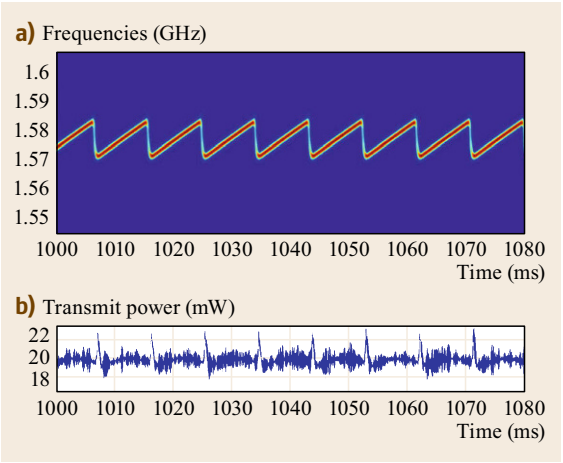

**Fig. 16.13a,b** Time histories of frequency spectrum **(a)** and transmit power **(b)** for a typical chirp-style PPD (after [16.47])

### 16.4.4 Intentional Interference

Intentional interference, or jamming, has been a staple of navigation warfare since World War II [16.32]. With the emergence of PPDs [16.7] and incidents of nation-scale intentional disruption of civil GNSS [16.48], intentional interference is now also a civil concern.

PPDs are by far the most common source of intentional interference. The PPD user may intend only to jam GNSS tracking devices in his near vicinity (e.g., on his person or vehicle), but in fact such devices can disrupt GNSS signal tracking out to an effective radius of from 100 m to several kilometers [16.47].

Virtually all PPDs transmit a swept tone waveform (chirp) similar to that shown in Fig. 16.13. This waveform can be generated from inexpensive components and is quite effective in rendering GNSS receivers inoperable unless these have been especially designed for jam resistance [16.49]. The frequency sweep period of the 18 units tested in [16.47] ranged from 1 to 27 μs, with total transmit power in a 20 MHz band centered at L1 ranging from −14 to 28 dBm.

## 16.5 Spoofing

A GNSS spoofing signal is a type of structured interference that adheres closely enough to a GNSS signal specification so as to appear authentic to an unsuspecting GNSS receiver. Whether intentional, as in a deliberate attempt to manipulate the PVT readout of a target GNSS receiver [16.50, 51], or unintentional, as in an errant GNSS simulator or repeater signal, spoofing signals similarly affect a GNSS receiver. For convenience of presentation, the following discussion will treat all spoofing as intentional, with the term spoofer referring both to the spoofing device and its operator.

Spoofing was once only a threat to military GNSS receivers and applications, but has now become a more

general concern as civil GNSS spoofing becomes easier and its consequences are more serious. The emergence of low-cost off-the-shelf software-defined radio hardware has significantly reduced the cost and complexity of spoofing. With such hardware, a competent programmer sufficiently familiar with the openly documented GNSS protocols [16.23, 52] can generate realistic civil GNSS signals despite having minimal knowledge of RF electronics. Easier still, low-cost GNSS signal simulators and record-and-replay devices enable even GNSS neophytes to conduct a limited but potent form of spoofing. Against a backdrop of increasing economic dependence on civil GNSS for transportation, communication, finance, and power distribution, the increased accessibility of civil GNSS spoofing raises the risk of attack and the urgency of finding effective antispoofing measures.

Spoofing is different from unstructured interference in two primary respects. First, it can be surreptitious: Neither the target GNSS receiver nor its operator may detect that an attack is underway because the spoofer can seamlessly supplant counterfeit signals for their authentic counterparts. Second, in a spoofing attack, the received interference $r_I(t)$ is statistically correlated with the received authentic signal $r_S(t)$; consequently, the total received power $P_T$ is neither the sum of $P_S$, $P_I$, and $P_n$, as in (16.2), nor does the autocorrelation function of the interference component $I(t)$ decompose, as in (16.4), because the cross-terms do not average to zero. As a result, the analysis of spoofing effects is, in general, more challenging than the analysis of statistically independent interference. To be sure, spoofing effects bear a strong resemblance to multipath effects, but multipath-induced structured interference is accidental, whereas spoofing may involve a strategic attacker who can arbitrarily adjust signal power, code phase, carrier phase, and signal structure for maximum effect.

To generalize the treatment of spoofing in what follows, the authentic signal model will allow for digital modulation that is unpredictable to a would-be spoofer. A modulation sequence that is entirely unpredictable or has unpredictable segments will be termed a security code, and a security-code-bearing GNSS signal will be termed security enhanced [16.53–57]. A nonsecurity-enhanced GNSS signal can be represented by a special case of this model in which the security code is replaced by a sequence of ones.

### 16.5.1 Generalized Model for Security-Enhanced GNSS Signals

From the perspective of a GNSS receiver, current and proposed security-enhanced GNSS signals can be represented by a simple adaptation of the baseband received signal model introduced in (16.1):

$$\begin{aligned} r_S(t) &= \sqrt{P_S}W(t-\tau)D(t-\tau)C(t-\tau)\exp(j\theta(t)) \\ &= \sqrt{P_S}W(t-\tau)X[\tau,\theta(t)]\,. \end{aligned} \tag{16.12}$$

Compared to (16.1), the novel component here is $W(t)$, which represents a $\pm 1$ valued security code with chip length $T_W$. For notational simplicity, the product of the authentic signal's navigation data stream $D(t-\tau)$, spreading (ranging) code $C(t-\tau)$ and baseband phasor $\exp(j\theta)$ is abbreviated as $X(\tau,\theta)$ for code phase $\tau$ and carrier phase $\theta$. The chip length of the spreading code $C(t)$ is denoted as $T_C$. For convenience, receiver time $t$ is assumed to be equivalent to true time (e.g., GPS system time).

The security code $W(t)$ is either fully encrypted or contains periodic authentication codes. The defining feature of $W(t)$ is that some or all of its symbols are unpredictable to a would-be spoofer prior to broadcast from a legitimate GNSS source. The unpredictable symbols in $W(t)$ serve two related functions: (1) they enable verification of $W(t)$ as originating from a GNSS Control Segment (standard message authentication), and (2) they increase the complexity of a spoofing attack by forcing the spoofer to either replay a received $W(t)$ or attempt to estimate $W(t)$ on-the-fly. Note that if a GNSS signal is not security enhanced (has no unpredictable modulation), the model in (16.12) still applies, with $W(t) = 1$.

### 16.5.2 Attacks Against Security-Enhanced GNSS Signals

The unpredictability of the security code $W(t)$ is an obstacle for a would-be spoofer. A simple spoofing technique, such as discussed in [16.58], relies on the known signal structure of the GPS L1 C/A signal and the near-perfect predictability of its navigation data stream. However, if a GNSS signal is security enhanced, then the spoofer of [16.58] cannot perfectly match its counterfeit signals chip-for-chip to the authentic signals.

A spoofer could, of course, ignore the broadcast security codes altogether, filling in dummy values for $W(t)$, but such a scheme is easily detected. In an attack against a GNSS signal modulated by a low-rate security code ($T_W \gg T_C$) (e.g., navigation message authentication (NMA), as proposed in [16.55–57, 59]), the dummy $W(t)$ values would fail the cryptographic validation test. Against a high-rate security code ($T_W \approx T_C$), the dummy $W(t)$ values would yield zero av-

erage power when correlated with the true $W(t)$ sequence [16.53, 59].

Therefore, to be effective while evading detection, a spoofer must attempt to match both the structure and content of the authentic signal. It can do this via one of the following specialized spoofing attacks.

### Meaconing

A meaconing, or replay, attack is a specialized spoofing attack in which an entire segment of RF spectrum is captured and replayed [16.60]. If the meaconer employs a single receiving antenna element, then no individual signal is isolated in a meaconing attack. Thus, in this case, a GNSS meaconer cannot arbitrarily manipulate the PVT of a target receiver. Rather, the target receiver will display the position and velocity of the meaconer's receive antenna and a time in arrears of true time. If this antenna is on a dynamic platform, then the meaconer can adjust the position and velocity implied by its signals for greater effect in the attack.

If the meaconer employs multiple antenna elements whose RF signals are individually digitized, then it can isolate individual GNSS signals by pointing a gain enhancement toward each overhead GNSS satellite. For example, a 16 element antenna array could be used to direct a narrow $\approx 12\,\mathrm{dB}$ enhancement toward each satellite. By combining the separate digital streams while manipulating the phasing of each stream within the ensemble, a meaconer can dictate the ensemble's implied PVT within a wide range about the true PVT (with the implied timing always in arrears of true time).

For a single GNSS signal corresponding to a particular satellite, the combined meaconed and authentic received signals can be modeled as (16.1) but with $r_S(t)$ as in (16.12) and

$$r_I(t) = \alpha\sqrt{P_S}W(t-\tau_c)X[\tau_c, \theta_c(t)] + n_c(t)\ .$$

Here, $\tau_c > \tau$ and $\theta_c$ are the code phase and carrier phase of the counterfeit meaconing signal, respectively, and $n_c(t)$ is the noise introduced by the meaconer's RF front end. The meaconed signal arrives at the target receiver's antenna with a delay $d = \tau_c - \tau > 0$ seconds relative to the authentic signal, an unavoidable consequence of the triangle inequality and the processing delay through the meaconing device. The coefficient $\alpha$ is the meaconed signal's amplitude advantage factor relative to the authentic signal.

High-performance digital signal processing hardware permits a meaconer located close to its intended target to drive the delay $d$ to under a few tens of nanoseconds. In the limit as $d$ approaches zero, the attack becomes a zero-delay meaconing attack in which the meaconed signals are code-phase-aligned with their authentic counterparts. Such alignment enables a seamless liftoff of the target receiver's tracking loops, following which a meaconer can increase $d$ at a rate that is consistent with the target receiver's clock drift and gradually impose a significant timing delay.

Note that, unless $d \approx 0$, a meaconer with $\alpha \approx 1$ will cause significant variations in the target receiver's PVT estimate: the meaconing signals will act as severe multipath. Thus, if the meaconer cannot ensure $d \approx 0$, it is better off transmitting with an overwhelming amplitude advantage ($\alpha \gg 1$) to quickly stabilize the target's perceived PVT at the meaconer's intended value. Therefore, a meaconer with $d$ a significant fraction of $T_C$ is detectable at $\alpha \approx 1$ due to multipath-like PVT variations and at $\alpha \gg 1$ due to anomalous high received power. Furthermore, if $d > 2T_W$, then the meaconer will be unable to capture a code tracking loop that is locked to an authentic signal for any value of $\alpha$: The meaconing signal will not be close enough in time to the authentic signal to dislodge the receiver's code tracking loop. Instead, the meaconer will be forced to jam the target receiver to force re-acquisition, which will alert the target to the attack. In any case, GNSS system designers have an incentive to make $T_W$ as small as possible to increase the difficulty of a meaconing attack.

### Security Code Estimation and Replay Attack

A Security Code Estimation and Replay (SCER) attack allows greater flexibility than a meaconing attack in manipulating the target receiver's PVT solution. In a SCER attack, a spoofer receives and tracks individual authentic signals and attempts to estimate the values of each signal's security code on-the-fly. It then reconstitutes a consistent ensemble of GNSS signals, with the security code estimates taking the place of the authentic security codes, and transmits the ensemble toward the target receiver. For a single GNSS signal corresponding to a particular satellite, the combined SCER-spoofed and authentic received signals can be modeled as (16.1) but with $r_S(t)$ as in (16.12) and

$$r_I(t) = \alpha\sqrt{P_S}\hat{W}(t-\tau_c)X[\tau_c, \theta_c(t)] + n_c(t)\ ,$$

where $\hat{W}(t-\tau_c)$ represents the security code estimate arriving with a delay of $d = \tau_c - \tau > 0$ seconds relative to the authentic security code $W(t-\tau)$, $n_c(t)$ is noise introduced by the spoofer (e.g., due to quantization effects in the signal generation), and other quantities are as introduced previously. The delay $d$ can be modeled as the sum $d = p + e$ of a processing and transmission delay $p > 0$ and an estimation and control delay $e > 0$. The delay $p$ represents the combined minimum signal processing delay and additional propagation time and

does not contribute to better estimates of the security code chips. The delay $e$ represents an additional delay imposed by the spoofer to improve its estimate of the security code chip values and to control the relative phasing of the spoofing signals so as to impose spoofer-defined position and timing offsets on the defender.

Mounting a stealthy SCER attack is challenging if the target receiver has been designed to detect SCER spoofing. The attacker must keep $d = p + e$ small enough to remain within the target receiver's clock uncertainty but must extend $e$ enough to reliably estimate the security code chip values. The following two SCER attack strategies serve to illustrate this tradeoff.

*Zero-Delay Attack.* Consider a spoofer that is colocated with the target GNSS receiver's antenna and has negligible processing delay so that $p \approx 0$. Assume that $e = 0$, meaning that the spoofer adds no estimation and control delay. Thus, $d = p + e \approx 0$. In this zero-delay attack, $\tau_c \approx \tau$, which implies that each spoofing signal is approximately code-phase-aligned with its authentic counterpart as received by the target receiver.

Despite such code phase alignment, a zero-delay attack can still alter the target receiver's position and time by injecting false messages through $D(t)$ (e.g., erroneous satellite ephemeris or clock model parameters or an erroneous leap second). However, with $e = 0$, the spoofer's security code estimate $\hat{W}(t)$ will be highly erratic for the first few microseconds following an unpredictable chip transition in $W(t)$. This is illustrated in Fig. 16.14, which shows simulated time histories of $\hat{W}(t)$ for two different chip value estimation strategies over the first 20 μs after the beginning of a security code chip with $T_W > 20$ μs. In this scenario, for which the spoofer $C/N_0$ is an unusually high 54 dB Hz, the spoofer's chip estimates become reliable after about 8 μs. For each 3 dB drop in spoofer $C/N_0$, the interval required for reliable chip estimates doubles.

The key to zero-delay SCER attack detection, as explained in [16.54], is to develop a detection statistic that is sensitive to the increased error variance in $\hat{W}(t)$ in the crucial early moments immediately following unpredictable transitions in $W(t)$.

*Nonzero-Delay Attack.* In a nonzero-delay SCER attack, the spoofer rebroadcasts a counterfeit signal that arrives at the defender's RF front end with a delay $d > 0$ relative to the authentic signal. Any significant delay $d$ (e.g., greater than about 20 ns) in the spoofer's counterfeit signal at the beginning of an attack would be immediately obvious to a target receiver that has been continuously tracking authentic signals since before the beginning of the attack. Therefore, the spoofer's strategy in the nonzero-latency SCER attack is typically to break the target receiver's tracking continuity by jamming or blocking the authentic signals for an interval of time before initiating the spoofing attack, thus, widening the target receiver's timing uncertainty, or *window of acceptance* [16.53, 55, 61]. The required duration of the signal-denial interval depends on the desired delay $d$ and on the assumed stability of the target receiver's clock (for stationary receivers) or clock and inertial measurement unit (for moving receivers). For the low-cost temperature-compensated crystal oscillators (TCXOs) typical in commercial GNSS equipment, in-the-field stability is approximately $10^{-7}$. Ovenized crystal oscillators (OCXOs), common in more demanding timing applications, have stability of approximately $10^{-10}$. Thus, widening a TCXO-driven static target receiver's time uncertainty by 8 μs would require approximately 80 s of jamming or blockage, and widening an OCXO-driven static receiver's time uncertainty by the same amount would require approximately one day of jamming or blockage.

After the jamming-or-blockage prelude, the nonzero-delay SCER attacker initiates a spoofing attack in which $d$ can be as large as the target receiver's tim-

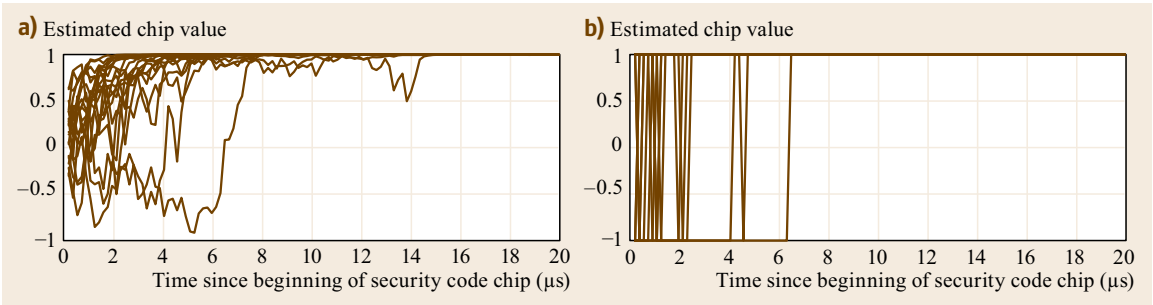

**Fig. 16.14a,b** Simulated time histories of security code chip estimates $\hat{W}(t)$ for a minimum mean square error (MMSE) estimator **(a)** and for a maximum a posteriori (MAP) estimator **(b)** over the first 20 μs after the beginning of a unity-valued security code chip for a spoofer with received $C/N_0 = 54$ dB Hz (after [16.54], courtesy of IEEE)

ing uncertainty. The attacker exploits the component $e$ of this delay to more accurately estimate the value of each unpredictable chip in $W(t)$ so that $\hat{W}(t)$ appears accurate to the target receiver. Long security code chips (e.g., $T_W = 40\,\text{ms}$ as suggested for civil navigation message (CNAV) NMA in [16.54, 56]) allow the spoofer to significantly increase $e$ and thereby generate highly accurate chip estimates. However, a large delay $d = p + e$ is itself a liability for the spoofer because of the long jamming-or-blockage interval required. Thus, the spoofer finds itself vulnerable to detection at low $d$ due to poor security code chip estimates and at high $d$ due to a noticeable timing delay.

Note that, with a SCER attack, the attacker can eventually specify an arbitrary position and an arbitrary delayed time as the spoofer slowly pulls each signal's code phase to the desired offset. Note also that if $W(t) = 1$ (i. e., the GNSS signal is not security enhanced), then the attacker need not delay at all: He can exploit the near-perfect predictability of $D(t)$ to anticipate the next navigation data symbol value and ensure that it arrives at the target receiver's antenna just on time – perfectly aligned with the true $D(t)$ [16.58]. Thus, the unpredictability of the security code – even a low-rate code such as in NMA – forces a SCER spoofer to expose himself with a jamming-or-blockage attack prelude. Finally, note that signal jamming or blockage for any significant interval of time (relative to the receiver clock stability) must be viewed not only as a temporary nuisance but also as a security threat that persists even after the interference apparently subsides. This is because, in the absence of some other means of verifying the authenticity of GNSS signals, a SCER attack detector's probability of detection is irrecoverably reduced by a loss of signal continuity [16.55].

### Effect of Coherence

In a spoofing attack, the complex correlator output modeled in (16.3) contains a desired component $S(t) \equiv r_S^*(t)l(t)$ and an interference component $I(t) \equiv r_I^*(t)l(t)$, both of which are dependent on the local replica's code phase $\hat{\tau}$ and carrier phase $\hat{\theta}$. Denote these as $S(t, \hat{\tau}, \hat{\theta})$ and $I(t, \hat{\tau}, \hat{\theta})$. Also, for a given authentic and spoofing signal pair $r_S(t)$ and $r_I(t)$, let $\varphi(t) \equiv \theta_c(t) - \theta(t)$ be the relative carrier phase.

If a spoofing attack is code-phase aligned so that $|\tau_c - \tau| < T_C$, and Doppler matched so that

$$\frac{1}{2\pi}\left|\frac{d\varphi}{dt}\right| < \frac{1}{T_a}$$

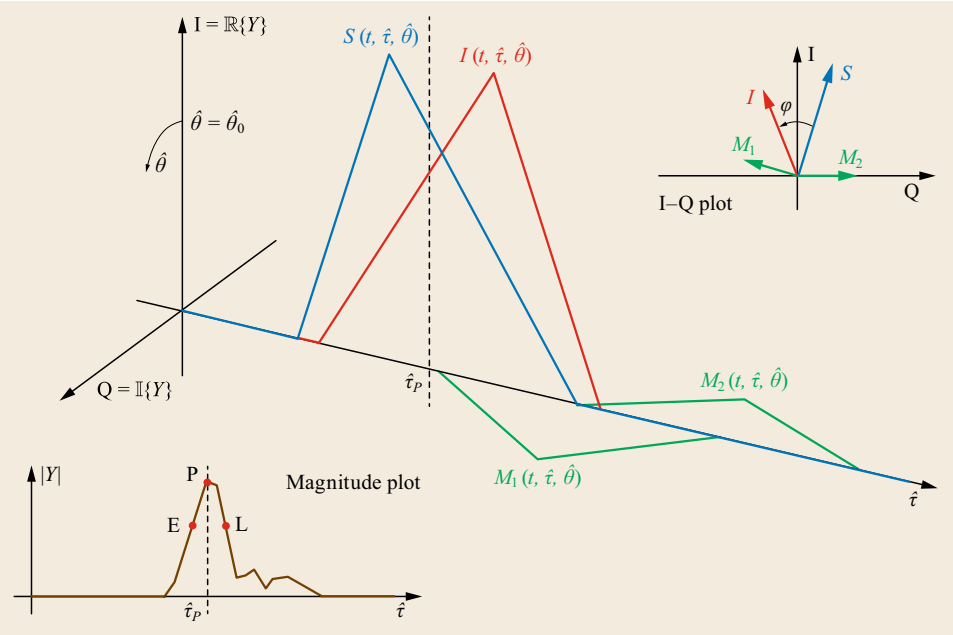

**Fig. 16.15** Stylized complex correlation functions depicting a spoofing attack in which $|\tau_c - \tau| < T_C$ and $d\varphi/dt \approx 0$. The *blue trace* marked $S(t, \hat{\tau}, \hat{\theta})$ represents the desired signal correlation function, the *red trace* marked $I(t, \hat{\tau}, \hat{\theta})$ represents the interference (spoofing) signal correlation function, and the *green traces* marked $M_i(t, \hat{\tau}, \hat{\theta})$, $i = \{1, 2\}$, represent two multipath correlation functions. The receiver's code and carrier tracking loops track the composite correlation function, $Y(t, \hat{\tau}, \hat{\theta})$, whose magnitude is shown in the *lower inset plot* along with the early, prompt, and late correlation taps

with $T_a$ is the accumulation interval from Fig. 16.2, then $r_S(t)$ and $r_I(t)$ are substantially frequency coherent and thus cannot be considered statistically independent. As a consequence, the combined signal power $P_T$ is not simply the sum $P_T = P_S + P_I + P_n$, as in (16.2), but depends on $\tau_c - \tau$, $\varphi$, and the relative spoofing amplitude $\alpha$. Figure 16.15 shows the relationship between $S(t, \hat{\tau}, \hat{\theta})$ and $I(t, \hat{\tau}, \hat{\theta})$ in this regime.

The interference power $P_I$ can be decomposed as $P_I = \alpha^2 P_S + P_{nc}$, where $P_{nc}$ is the power in the noise component $n_c(t)$. If code-phase alignment and Doppler matching are approximately achieved in a spoofing attack ($|\tau_c - \tau| \approx 0$ and $d\varphi/dt \approx 0$), the possibility of which was demonstrated in [16.50] against a nonsecurity-enhanced GNSS signal, then $P_T$ can be expressed as

$$P_T = \left[\sqrt{P_S} + \sqrt{\alpha^2 P_S}\cos(\varphi)\right]^2 + \alpha^2 P_S \sin^2(\varphi) + P_{nc} + P_n \,. \quad (16.13)$$

This expression indicates that the noise components $P_{nc}$ and $P_n$, which are noncoherent with the authentic signal, add directly to $P_T$, as does $\alpha^2 P_S \sin^2(\varphi)$, which is the power in the spoofing signal's frequency-coherent component that lies in phase quadrature to the authentic signal. By contrast, $\alpha^2 P_S \cos^2(\varphi)$, which is the spoofing power component that is phase aligned with the authentic signal, does not add directly to $P_T$ but instead interacts with the authentic signal as shown. For $k \in \mathbb{Z}$, the spoofing signal contributes maximally to $P_T$ when $\varphi = k2\pi$ (phase alignment), minimally when $\varphi = (1+2k)\pi$ (antiphase alignment), and power-additively – as if it were a purely noncoherent signal – when $\varphi = (1/2+k)\pi$ (orthogonal alignment).

It is interesting to note that if $\varphi$ is treated as a random variable uniformly distributed on $[0, 2\pi]$, then the expected value of $P_T$ is equivalent to the $P_T$ that arises in the case of purely noncoherent interference signals; that is, $E[P_T] = P_S + P_I + P_n$. Hence, for an ensemble of statistically independent spoofer-and-authentic signal pairs, (16.2) remains a useful approximation for the power contributed by each pair even when the spoofer can achieve Doppler frequency alignment ($d\varphi/dt = 0$) but has no finer control over the carrier phase. By distinction, if the spoofer has knowledge of the target receiver's antenna position to within a small fraction of a carrier wavelength, then it can arbitrarily adjust $\alpha$ and $\varphi$ to exercise full control over $P_T$ according to (16.13). Figure 16.16 demonstrates that frequency-coherent spoofing signals affect $P_T$ as expected.

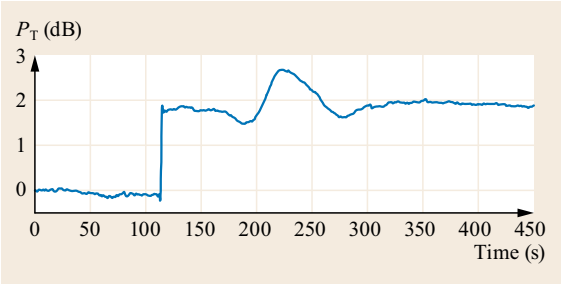

**Fig. 16.16** Total received power $P_T$ in a 2 MHz band centered at the GPS L1 frequency showing the onset of a spoofing attack using the testbed described in [16.62], normalized by the average value of $P_T$ prior to the attack. The attack begins with a sudden increase in $P_T$ just before 100 s. Thereafter, the total authentic signal power and total spoofing power were maintained constant; thus, the oscillations in $P_T$ are due to the frequency coherence between the spoofing and authentic signals, with each pair of spoofing-and-authentic signals having similar values of $\varphi$

An important consequence of a spoofer's having arbitrary control over $\alpha$ and $\varphi$ is that, by choosing $\alpha = 1$ and $\varphi = \pi$ for each spoofing and authentic signal pair, a spoofer can effectively annihilate the authentic signals at the location of the target antenna. Such a nulling attack has the effect of jamming the target receiver while *reducing* the total received power $P_T$ in the GNSS band of interest. Moreover, the nulling signals could be paired with an independent ensemble of spoofing signals to simultaneously eliminate the authentic signals while presenting clean counterfeit signals to the target receiver. The attacker could thus evade tests, such as the received power test proposed in [16.35] and the pincer defense proposed in [16.63], designed to detect anomalies in the total received power or distortion in the correlation function caused by interaction of the authentic and spoofing signals. GNSS antennas that are clearly visible to the public from close range and those whose coordinates are publicly posted to subdecimeter accuracy are at greatest risk of such nulling attacks.

## 16.6 Interference Detection

Many schemes for detecting and mitigating GNSS interference have been proposed since the early days of GPS. These schemes apply at one or more of three application points in the GNSS signal processing chain, as shown in Fig. 16.17: (1) the analog stage, (2) the post-digitization but precorrelation stage, and (3) the correlation and post-correlation stage. Several effective interference detection schemes are detailed in this section; the following section treats interference mitigation.

### 16.6.1 $C/N_0$ Monitoring

A drop in a receiver's measured $C/N_0$ on any channel that cannot be explained by signal shadowing indicates interference of some type. $C/N_0$ is related to the SNR of the complex accumulations $Y_k$ (Fig. 16.2) on which code and carrier tracking are based by SNR $= CT_a/N_0$. As $C/N_0$ measurements are generated post-correlation, $C/N_0$ monitoring applies at point (3) in Fig. 16.17.

Given measured $C/N_0$, one can be assured that code and carrier tracking will perform no better than what would be expected for SNR $= CT_a/N_0$. Nominal $C/N_0$ values across all tracking channels do not, however, guarantee the absence of interference, since spoofing interference, whether intentional or not, can cause the affected receiver to report perfectly normal $C/N_0$ values. For example, the spoofer described in [16.62] can dictate the received $C/N_0$ for each signal by adjusting the relative magnitudes of its output signals and adding artificial noise to the signal ensemble.

Given that $C/N_0$ loss is often caused by signal shadowing, and that nominal $C/N_0$ values are no guarantee of the absence of interference, a $C/N_0$ monitor such as proposed in [16.64] is best applied in combination with other complementary techniques for GNSS interference.

### 16.6.2 Received Power Monitoring

Monitoring the total received power $P_T$ in a GNSS band of interest, known as received power monitoring (RPM), is one of the simplest and most effective strategies for detecting interference [16.35, 65, 66]. For systems with multibit-quantized sampling and automatic gain control (AGC) in the RF front end, estimating $P_T$ is as easy as measuring the voltage applied by the AGC unit to adjust the signal amplitude before quantization. In a constant-gain system with sufficient dynamic range to prevent quantization saturation, $P_T$ can be estimated directly from the precorrelation samples. In any case, RPM can be thought of as applying at point (2) in Fig. 16.17.

Figure 16.18 shows the nominal power spectrum about the GPS L1 frequency as measured at the output of a high-quality GNSS antenna and front-end system. Despite their statistical independence and low power, the received GPS L1 C/A signals combine to yield an obvious enhanced density in the familiar $\mathrm{sinc}^2(fT_C)$ pattern near L1 that rises above the noise floor.

For interference detection with a suitably low false alarm rate, one must examine the size and predictability of variations in $P_T$ that can be considered natural or otherwise innocuous. Figure 16.19 shows a two-day record of $P_T$ for the setup in Fig. 16.18 in the 2 MHz band centered at L1. The time history reveals marked diurnal variations, the result of diurnal patterns in temperature, solar radiation, and the overhead satellite constellation. Even though the record's diurnal repeatability is evidently only good to approximately 0.3 dB, its predictability given knowledge of local temperature and satellite orbital ephemerides is actually better than this.

Figure 16.20 offers an expanded view of a 7.5 min interval using the same setup and showing both the 2 and 10 MHz traces. The different size of the variations in the two traces at time scales less than about 150 s indicates that the variations do not originate in broadband noise; they are likely due to multipath effects at the carrier-phase level caused by reflections off nearby surfaces and by atmospheric diffraction and refraction. Close examination of multi-day records of $P_T$ reveals that these short-time-scale variations do not repeat appreciably at the solar or sidereal day. In sum-

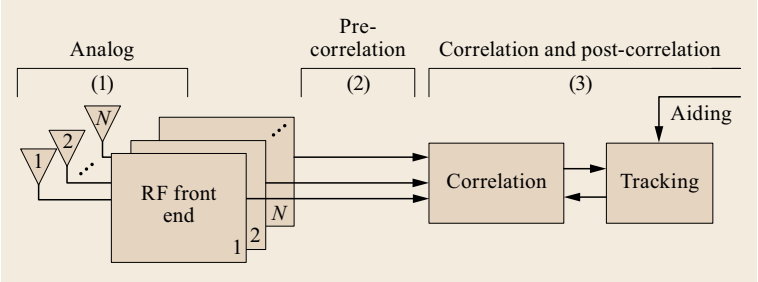

**Fig. 16.17** Application points for interference detection and mitigation: (1) in the analog stage prior to digitization, (2) after digitization but before correlation, and (3) in correlation and in post-correlation tracking and PVT estimation

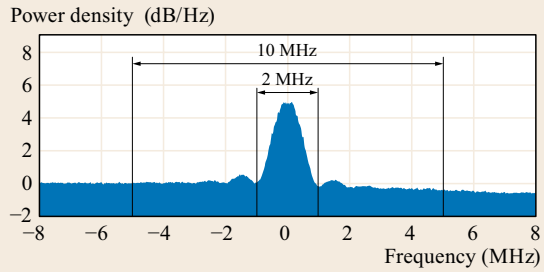

**Fig. 16.18** Power spectrum centered at the GPS L1 frequency as estimated from a 1 s interval of data captured via a high-quality static antenna and RF front-end combination in a moderately quiet outdoor RF environment. Bands for 2 and 10 MHz power measurements are shown. The power density scale has been centered near the noise floor for ease of viewing. In absolute units, the noise floor sits at approximately −204 dBW/Hz

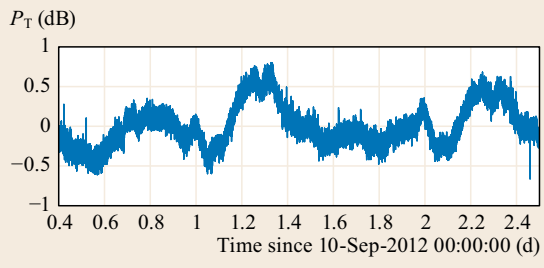

**Fig. 16.19** A two-day record of received power $P_T$ in the 2 MHz band shown in Fig. 16.18, normalized by the average received value over the interval

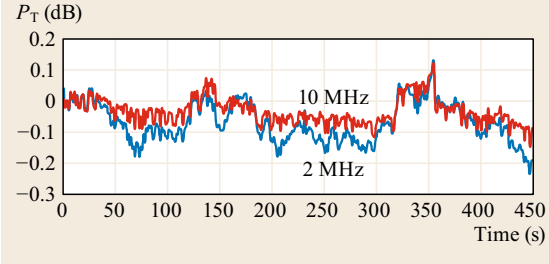

**Fig. 16.20** A 7.5 min record of received power in the 2 and 10 MHz bands shown in Fig. 16.18, normalized by the initial values of $P_T$ in each band

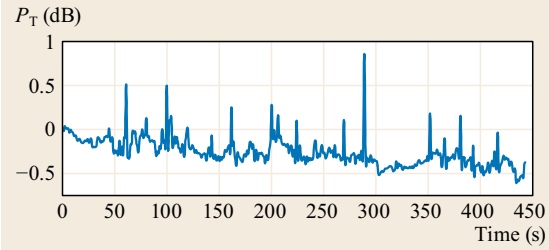

**Fig. 16.21** Received power $P_T$ in a 2 MHz band centered at the GPS L1 frequency averaged over 1 s intervals for a receiver mounted on a vehicle driving through the streets of downtown Austin, Texas. The data correspond to the *clean dynamic* data record from [16.67]

mary, it appears that for a static antenna, the practically unpredictable variations in $P_T$ about L1 have root-mean-squared deviations of at least 0.1 dB for a 2 MHz band and 0.05 dB for a 10 MHz band.

For a dynamic antenna, $P_T$ can be much more variable. Figure 16.21 shows a time history of $P_T$ for a receiver mounted on a vehicle driving through the streets of downtown Austin, Texas. The $P_T$ excursions, the largest of which exceeds 1 dB, would be unpredictable to a GNSS user without an up-to-date RF interference map of the area.

Against background variations that are unpredictable at the 0.1 dB level, or even the 1 dB level, deliberate jamming from close range remains obvious, as revealed by the effect on $P_T$ of highway motorists using PPDs shown in Fig. 16.22. Naive spoofing also has an obvious effect: consider the sudden 2 dB uptick of $P_T$ in Fig. 16.16. However, contrary to the claims in [16.35], RPM is not a generally effective means of detecting spoofing. This is because the increase in $P_T$ during a spoofing attack may be smaller, or not significantly larger, than unpredictable variations in $P_T$ due to causes other than spoofing. As mentioned in Sect. 16.5.2, a spoofer able to arbitrarily control the relative amplitude $\alpha$ and phase $\varphi$ of each spoofing signal can annihilate the authentic signals and supplant them with counterfeit signals of equal power, thereby, maintaining $P_T$ constant.

A spoofer lacking precise control over $\varphi$ cannot prevent an increase in $P_T$ while successfully capturing the target receiver's tracking loops, but the increase in $P_T$ can be small: For a commercial-grade GNSS receiver, the uptick in $P_T$ may be as small as 0.56 dB [16.62]. If unpredictable natural variations in $P_T$ are modeled as a Gaussian process with a 0.1 dB standard deviation and a 150 s decorrelation time, then a detection threshold equal to $\gamma = 0.44$ dB would be sufficient to detect such an uptick with high probability while maintaining a once-per-year false alarm rate. However, the natural variations in $P_T$ have a much thicker high-side probability distribution tail than a Gaussian process. For example, as detailed in Table 16.2, solar radio bursts would cause $P_T$ to exceed $\gamma = 0.44$ dB every 9.2 days on average during solar maximum. Note that

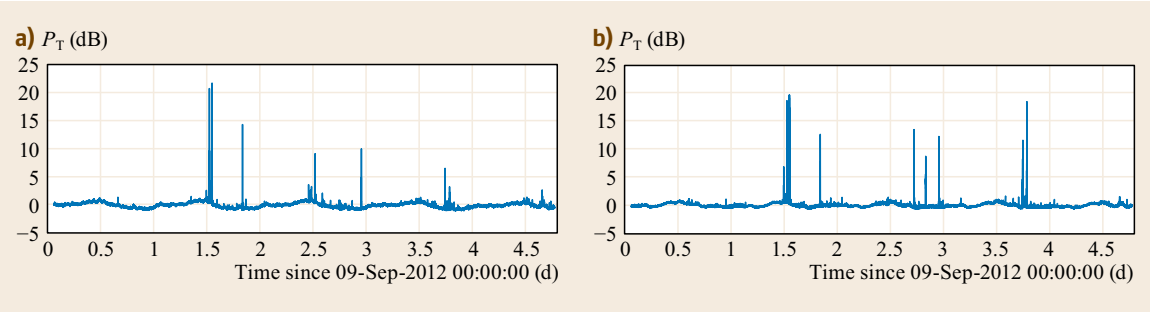

**Fig. 16.22a,b** Received power in the 10 MHz band centered at GPS L1 at two sites 1 km apart that straddle State Highway 1, west of Austin, TX. **(a)** Data from site located at the Center for Space Research. **(b)** Data from site located at Applied Research Laboratories. Both traces are normalized by the average value of $P_T$ over the interval. The large excursions in $P_T$ are due to motorists using PPDs as they travel along the highway

although spoofing alarms could be dismissed during known solar radio burst events, which can be independently monitored – even predicted [16.68], this offers little protection, for a clever attacker could time his attack to coincide with the arrival of a sizable burst.

Besides solar radio bursts, nonspoofing interference endemic in urban environments and near major thoroughfares can often cause an increase in $P_T$ exceeding $\gamma = 0.44\,\text{dB}$, as shown in Figs. 16.21 and 16.22. One might argue that it is perfectly appropriate for a spoofing detector to alarm in the presence of a solar radio burst or an intentional jammer, but the consequences of spoofing can be much more malign than those of natural interference or jamming, and so it behooves a defender to distinguish between these.

### 16.6.3 Augmented Received Power Monitoring

When acting alone, RPM is effective at detecting strong interference but cannot be considered a reliable detector of weak interference such as low-power spoofing. It can, however, be paired with other tests that are sensitive to GNSS-like structure in the received signal to yield a powerful joint detection test for spoofing, provided the spoofer cannot arbitrarily manipulate $\alpha$ and $\varphi$. Three RPM augmentation strategies are discussed in the following sections.

#### Augmentation with $C/N_0$ Monitoring

A simple $C/N_0$ monitor will not detect spoofing signals whose $C/N_0$ values are matched to those of the authentic signals. But when paired with RPM, $C/N_0$ monitoring becomes a reasonably reliable detection strategy because it is challenging for a spoofer to ensure nominal received $C/N_0$ values without significantly increasing $P_T$. Only with a nulling attack, such as described in Sect. 16.5.2, can a spoofer ensure that $C/N_0$ matching does not increase $P_T$. Without nulling, $C/N_0$ matching (with no unusual variations) requires overwhelming spoofing power, which manifests as increased $P_T$.

#### Augmentation with Precorrelation Structural Power Content Analysis

The precorrelation structural power content analysis method advanced in [16.69] detects the presence of spoofing based on the excessive power content of GNSS-like signals in the received raw samples. In the absence of RPM, a spoofer can evade this detector by transmitting with overwhelming power, thus, driving the received authentic signals into the noise floor as the receiver's AGC compensates for the high received total power. The method of [16.69] will then only measure precorrelation structural power content commensurate with a single signal for each expected received waveform, and will thus fail to alarm. However, when combined with RPM, a structural power detector becomes powerful for spoofing detection. As for $C/N_0$ monitoring, augmentation with RPM forces the spoofer to either mount a nulling attack or be exposed with high likelihood in the joint test statistic.

#### Augmentation with Distortion Monitoring

The pincer defense advanced in [16.63] thoroughly embraces the concept of augmenting RPM for improved spoofing detection. Its name is meant to evoke a pincering, or trapping, of the spoofing signals between an RPM and a signal distortion monitor. As with $C/N_0$ and precorrelation structural power monitoring, distortion monitoring acting on its own cannot detect a spoofing attack executed with overwhelming power because the interaction between the authentic and false signals, which is the source of the signal distortion sought, is eliminated by action of the AGC as the spoofing-to-authentic power ratio increases.

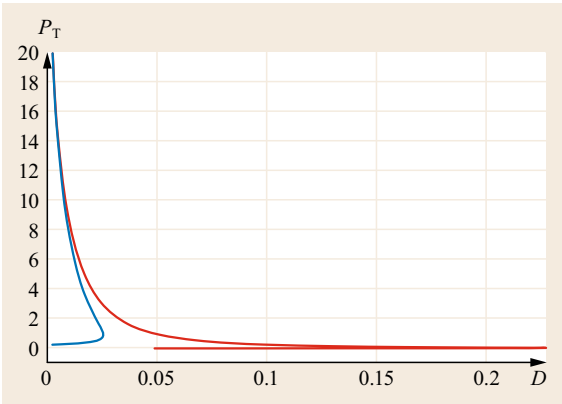

**Fig. 16.23** Distortion (in the same units as accumulation), as a function of $P_T$ for in-phase (*blue*) and antiphase (*red*) multipath or spoofing interference at a fixed delay of 0.15 chips. For the same delay, all other relative phases yield distortion profiles that lie within this envelope (after [16.63]; reprinted with permission)

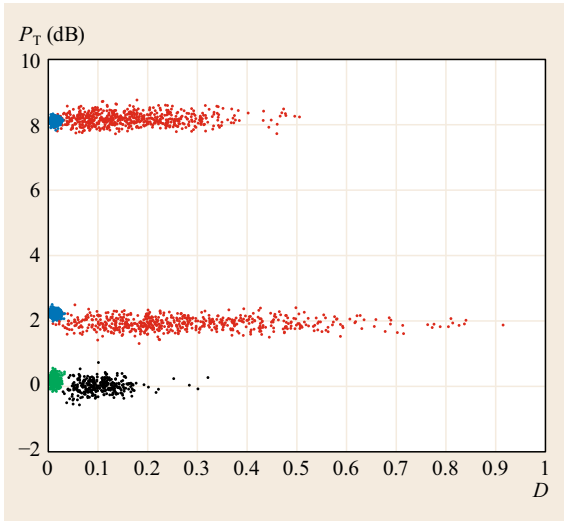

**Fig. 16.24** Scatter plot showing simulated $D$ and $P_T$ for clean (only thermal noise; *green*), multipath (*black*), spoofing (*red*), and jamming (*blue*) scenarios. The spoofing and jamming scenarios are simulated at two different power levels. The simulated accumulation amplitudes were chosen so that $D$ was allowed to range from 0 to 1 (after [16.63]; reprinted with permission)

The GNSS signal quality monitoring literature has proposed several metrics for signal distortion [16.70]. These metrics are all calculated based on correlation products and so apply at point (3) in Fig. 16.17. The pincer defense adopts the so-called symmetric difference $D$. Let $Y_E$ and $Y_L$ be the early and late complex accumulations with a predetermined early late spacing, respectively. Then, $D$ is defined as the magnitude of the complex early-late difference: $D \equiv |Y_E - Y_L|$. Thus, $D$ is sensitive to early-late asymmetry in both magnitude and phase.

Unless a spoofer is capable of a nulling attack, then distortion caused by the interaction between authentic and spoofing signals of comparable amplitude will be evident as $D > 0$. Figure 16.23 shows that $D$ approaches zero in the limit of both weak and powerful spoofing. But weak spoofing affects a GNSS receiver no more than multipath, and powerful spoofing can be detected by a significant increase in $P_T$. Such is the basic premise of the pincer defense.

The pincer defense seeks to classify interference as either spoofing, jamming, or multipath, and to distinguish these categories from normal thermal noise, all on the basis of $D$ and $P_T$. The challenge can be appreciated in reference to Fig. 16.24, which shows a scatter plot of $D$ and $P_T$ values under simulated spoofing (red), jamming (blue), multipath (black), and clean (only thermal noise; green). Clearly, there is overlap between the categories, especially between low-power spoofing and severe multipath.

The pincer defense detection and identification problem can be stated as follows. Given a time history of measurements $\mathbf{z}_k \equiv [D_k, P_{T,k}]^\top, k \in \mathcal{K} \equiv \{1, 2, \ldots, N\}$, determine whether the receiver experienced no interference (the null hypothesis, $H_0$), or, whether for $k \in \mathcal{K}_I \equiv \{k \in \mathcal{K} | k \geq k_o\}$, the receiver experienced multipath ($H_1$), jamming ($H_2$), or spoofing ($H_3$), where $k_o$ is the interference onset index. The problem reduces to a set of generalized likelihood ratio tests conditioned on estimates of $k_o$, on the interference amplitude $\alpha$, and, for $H_2$ and $H_3$, on an estimate of the code delay $\tau_c$.

Figure 16.25 shows an example observation space for a single measurement $\mathbf{z}_k$, partitioned into decision regions for the four hypotheses. The region boundaries depend on the estimates of $\alpha$ and $\tau_c$, on the cost of deciding $H_i$ when $H_j$ is true, $i, j \in \{0, 1, 2, 3\}$, and on the prior probabilities of the four hypotheses.

The problem formulation introduced above is not unique to the pincer defense; indeed, the detection and identification problem for all interference detection techniques can be formulated in terms of $H_0$, $H_1$, $H_2$, and $H_3$. Joint detection and classification offer the dual benefit of increased detection power and actionable information about the nature of the interference; these benefits, however, come at the cost of additional computational complexity [16.71].

### 16.6.4 Spectral Analysis

If the discrete-time quantized samples produced by a receiver's RF front end are accessible to a module capable

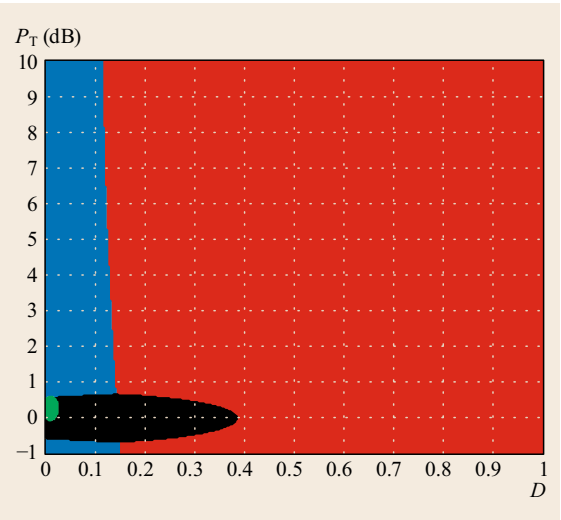

**Fig. 16.25** Example observation space for a single measurement $\mathbf{z}_k$ divided into decision regions for clean (only thermal noise; *green*), multipath (*black*), spoofing (*red*), and jamming (*blue*) (after [16.63]; reprinted with permission)

of performing a discrete Fourier transform (DFT), then the received signal power spectrum can be periodically estimated and analyzed. On multifrequency receivers, this may entail analysis of six or more individual GNSS bands. The computational burden of such analysis can be reduced by use of an efficient DFT implementation and by extending the interval between production of power spectra.

Power spectrum analysis is both a simple and powerful interference diagnostic technique, indicating not only the presence but also the nature of interference, whether wideband or narrowband, constant or fleeting. Figure 16.18 shows the power spectrum centered at L1 produced by a 1 s interval of data from a high-quality static receiver in a quiet RF environment. The spectrum shown is an estimate based on the usual periodogram technique of averaging the spectra produced by overlapping sections of the original data, with each time segment weighted by a windowing function.

The key challenge of interference detection and identification via power spectral analysis is distinguishing actual interference from spectral variability due to signal shadowing, multipath, temperature variation, and the changing overhead GNSS signal constellation. As shown in the example data set in Fig. 16.19, the aggregate power in the 2 MHz band centered at L1 can vary by more than 1 dB even when no interference is present. Much of this variation is periodic and therefore predictable. Sophisticated spectral analysis techniques could apply models or machine learning to distinguish

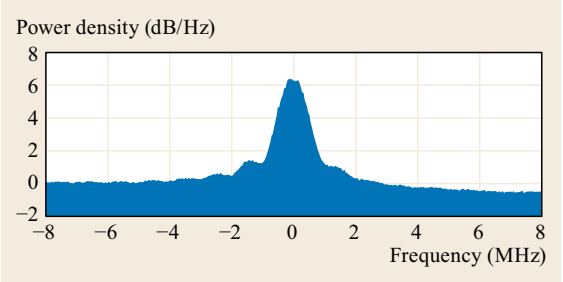

**Fig. 16.26** Power spectrum under the same conditions as Fig. 16.18 except that the receiver is now subject to a GPS spoofing attack using the testbed described in [16.62]

novel interference from background variability. Naturally, the problem is much less challenging for static receivers than for mobile ones.

Spectral analysis, even acting alone, can be effective at discovering spoofing. Figure 16.26 shows the same 16 MHz wide power spectrum as in Fig. 16.18 and for the same receiver but for data captured during a spoofing attack in which a false signal was generated for each authentic signal. The profile in Fig. 16.26 thus represents the power spectrum of an admixture of spoofing and authentic signal ensembles. The attack was designed to be stealthy, achieving approximate authentic signal nulling (as described in Sect. 16.5.2) during the interval of data from which the spectrum was computed. Even so, obvious differences are evident between Figs. 16.26 and 16.18. Besides the approximately 2 dB increase in power in the 2 MHz band centered at L1, the side lobes on both sides of the main lobe are more prominent in the spoofed spectrum. Such differences offer hope that a useful degree of spoofing detection could be provided based solely on power spectral measurements.

### 16.6.5 Cryptographic Spoofing Detection

A GNSS signal modulated with an unpredictable but verifiable security code $W(t)$, as in (16.12), is much more resistant to spoofing than a GNSS signal with no purposeful unpredictability. The security code $W(t)$ is best implemented as a cryptographic sequence. In NMA, $W(t)$ is a low-rate (e.g., 50–250 Hz) binary sequence containing periodic digital signatures that are unpredictable at transmission but can be verified upon receipt to certify the origin of the complete data sequence $D(t)$ [16.55–57]. Alternatively, $W(t)$ can be implemented as a high-rate (e.g., 500–10 000 kHz) binary sequence whose chip interval can be as short as that of the underlying spreading code $C(t)$, as is the case for the GPS Y and M signals, the Galileo PRS signal, and spread-spectrum security codes proposed for civil applications [16.53].

The security of the military GPS Y and M codes is based on symmetric-key cryptography. The GPS control segment generates a pseudorandom binary spreading code sequence based on a combination of secret keys. A military receiver generates a local replica of the same sequence based on a functionally equivalent set of secret keys, enabling despreading and signal tracking. Unauthorized agents are presumably denied access to the secret keys, so, in theory, they can neither generate nor predict the spreading sequence, which means they can neither track nor anticipate the military GPS signals for purposes of spoofing.

It is neither practical nor prudent to base civil security codes on symmetric-key cryptography. Instead, all proposed civil schemes are based on public-key cryptography or on delayed disclosure of secret keys. Even the technique proposed in [16.72], which leverages the military Y code to secure civil GPS receivers, assumes that the Y code is revealed to the receiver some time after receipt.

### Detection

Spoofing of a security-code-enhanced GNSS signal is easily detected if the counterfeit signal's security code fails digital signature verification (for low-rate security codes) or fails to generate significant power when correlated against a replica security code (for high-rate security codes). Only meaconing and SCER attacks are capable of generating counterfeit signals that could satisfy these preliminary tests.

For both meaconing and SCER attacks, the detection techniques discussed previously can be quite effective, particularly augmented received power monitoring and spectral analysis. For SCER attacks, another powerful tailored detection test can be formulated [16.54, 55]. The test's decision statistic is based on received power $P_T$ and on a specialized correlation statistic $L$. Given its dependence on $P_T$, SCER attack detection can be thought of as another type of received power monitoring augmentation, much like $C/N_0$ monitoring or the pincer defense.

The SCER attack detector's specialized correlation statistic $L$ is designed to be sensitive to the high error variance of the spoofer's security code estimate $\hat{W}(t)$ in the moments immediately following each unpredictable chip transition. Reference [16.54] develops the statistic and describes its distribution under $H_0$ (no attack) and $H_1$ (SCER attack). What follows briefly describes how the statistic is generated within a receiver and offers an example test result.

Let $W_k$ be the value of the security code $W(t)$ during the $k$-th chip. For convenience, assume that the receiver's accumulation interval is equivalent to the length of $W_k$, as for NMA. Then, the correlation statistic $L$ can be generated as shown in Fig. 16.27. The lower signal path is the standard matched-filter-type correlation operation previously depicted in continuous time in Fig. 16.2. The product of the incoming samples $r_i$ and a complex local signal replica $l_i = W_k C_l(t_i - \hat{\tau}_i)\exp(-\mathrm{j}(2\pi f_{\mathrm{IF}} t_i + \hat{\theta}(t_i)))$ is accumulated over the interval spanned by $W_k$ to produce the prompt complex correlation products $I_k + \mathrm{j}Q_k$ that get fed to code and carrier tracking loops. The code tracking loop also ingests correlation products from identical paths – not shown – involving early and late versions of $C_l(t_i - \hat{\tau}_i)$.

The upper path in Fig. 16.27 produces the SCER attack detection statistic $L$. The real part of the product $r_i l_i$ is multiplied by a smooth weighting function $\beta(n_{ki})$, defined in [16.54], that gives full weight to the $i_k$-th sample but decays rapidly toward zero for subsequent samples. This weighting has the effect of suppressing those samples over which the error variance in the spoofer's security code chip estimate $\hat{W}_k$ has become small because the spoofer has had sufficient time to obtain an accurate estimate of $W_k$; as illustrated in Fig. 16.14, only the early high-variance samples are useful in distinguishing $H_1$ from $H_0$. The weighted product $\beta(n_{ki})\mathcal{R}(r_i l_i)$ is accumulated over the interval spanned by $W_k$ to produce the single-chip detection statistic $S_k$, $N$ of which are biased, squared, and accumulated as shown to produce the final statistic $L$. The constants $a$ and $b$ are related to the theoretical mean

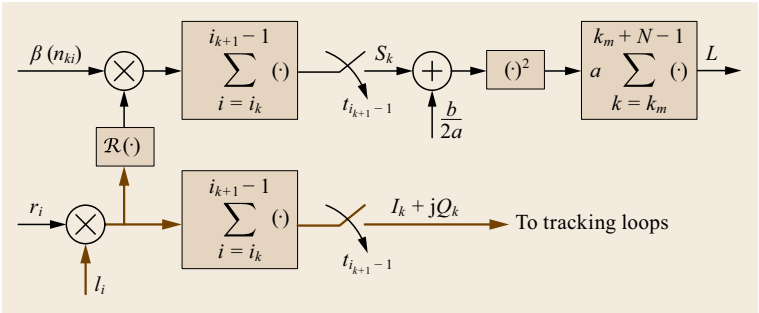

**Fig. 16.27** Block diagram illustrating how generation of the SCER attack statistic $L$ relates to standard GNSS signal correlation. *Thick brown lines* denote complex signals, whereas *thin black lines* denote real-valued signals

$\mu_p$ and variance $\sigma_p^2$ of $S_k$ under $H_p, p = 0, 1$ by

$$a = \frac{1}{\sigma_0^2} - \frac{1}{\sigma_1^2}\,, \qquad b = 2\left(\frac{\mu_1}{\sigma_1^2} - \frac{\mu_0}{\sigma_0^2}\right)\,.$$

### SCER Attack Detection Example

The test results shown in Fig. 16.28 are expressed in terms of the empirical distribution of $L$ at various stages of an example SCER attack performed in the testbed of [16.62]. The top panel shows the attack prelude during which only the authentic signal is present. At this stage, the histogram of $L$ values exhibits good correspondence with the theoretical null-hypothesis probability distribution $p_{L|H_0}(\xi|H_0)$, where $\xi$ is the value at which the probability density of the detection statistic $L$ is evaluated. The center panel shows the situation during the initial stage of the attack when the authentic and spoofing signals are aligned to within a small fraction of the $\approx 1\,\mu$s spreading code chip interval. Because the counterfeit and authentic signals in this test are so nearly matched in power, this stage manifests strong interaction between the two in the defender's complex-valued prompt correlator. Such interaction violates the either/or assumption of the SCER detection test. The detection statistic does exceed the threshold more than half the time, but instead of clustering within $p_{L|H_1}(\xi|H_1)$, it exhibits spreading driven by variations in the relative carrier phase of the interacting authentic and spoofing signals.

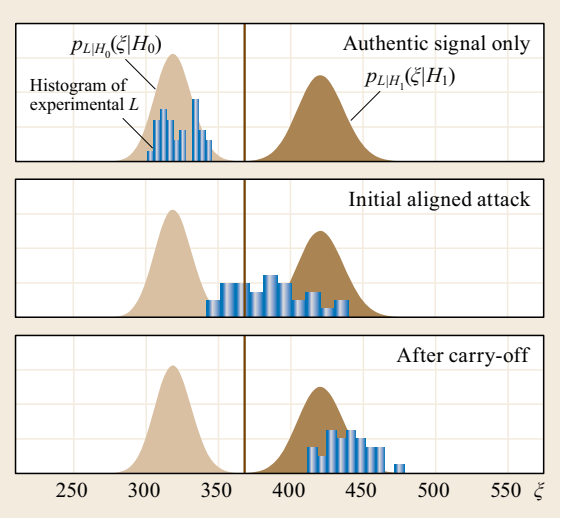

**Fig. 16.28** Histograms of experimentally generated detection statistics $L$ (*bar plots*) compared with the detection threshold (*thick vertical line*) and the theoretical distributions $p_{L|H_j}(\xi|H_j), j = 0, 1$ at various stages of a zero-delay SCER attack

After the spoofer has successfully carried off the defender's tracking points and the authentic and spoofed correlation peaks are separated by more than two spreading code chips, the SCER detector's attack model again becomes valid. The bottom panel of Fig. 16.28 shows that at this stage, the detection statistic clearly clusters beyond the detection threshold and roughly within the theoretical $p_{L|H_1}(\xi|H_1)$ distribution.

## 16.6.6 Antenna-Based Techniques

A GNSS receiver employing only a single, static antenna cannot measure the arrival direction of incoming signals, but a receiver with a moving antenna or multiple antenna elements can discern arrival direction and can use this information to detect interference. Antenna-based techniques are powerful for interference detection because an interference source commonly transmits from a single antenna whereas GNSS signals come from a spatially diverse set of overhead satellites. A spoofing detector based on a single moving antenna is developed in [16.73], and one based on a pair of static antennas is developed in [16.74]. The latter demonstrates nearly immediate spoofing detection with a low-cost system in a live spoofing attack.

## 16.6.7 Innovations-Based Techniques

A final opportunity for detecting spoofing interference arises in the PVT estimation algorithm that draws in the GNSS pseudorange and carrier-phase observables produced by the tracking loops, or, in the case of a vector tracking architecture, in the consolidated tracking and PVT estimation algorithm. The tracking block in Fig. 16.17 is intended as a generic reference to such tracking and estimation functions, and would be the application point for innovations-based spoofing detection techniques.

PVT estimation algorithms typically employ a model of the receiver dynamics – including clock dynamics – and may have access to non-GNSS aiding data such as from an inertial measurement unit (IMU), barometer, magnetometer, etc. Sequential estimators such as the Kalman filter are commonly used for this purpose, processing a regular cadence of observables and generating a regular output of PVT estimates.

Significant inconsistency between the estimator's predictions and GNSS observables can be detected by standard hypothesis testing applied to the estimator residuals, or innovations (Chap. 24). Reference [16.51] offers a framework for innovations analysis that is optimized for sensor deception, including GNSS spoofing. The framework applies an integrity risk performance

index to account for the fact that a sensor attack only causes harm when the target system exceeds its alert limit – when a ship leaves its assumed transit corridor or a timing system exceeds its required timing accuracy specification, for example. The framework adopts a minimax detection strategy for robustness to unknown spoofer actions. It is shown that an attacker can cause the target system to exceed its protection limits without detection whenever the attack-induced dynamics lie comfortably within the drift envelope of the PVT estimator's model-based propagation process. For example, PVT estimation based on pseudorange and Doppler observables and inertial sensors, a common combination, can be led astray by a spoofer whose induced error trajectory gradually departs from the true trajectory as if driven by the drift processes in the inertial sensors [16.50].

In response to this vulnerability, [16.75] proposes a powerful detection test for GNSS-guided vehicles that exploits high-frequency platform dynamics caused by environmental disturbances (e.g., wind gusts buffeting an aircraft). These dynamics are practically unpredictable to a would-be spoofer yet easily measured by both the inertial sensors and high-rate (e.g., 20 Hz) carrier-phase observables. An innovations test on the GNSS carrier-phase measurements that exploits such natural dithering, or even purposeful dithering if natural disturbances offer inadequate excitation, poses great difficulty for a spoofer unless the spoofer is physically attached to the target platform.

## 16.7 Interference Mitigation

GNSS interference detection is the key to avoiding hazardously misleading information in a GNSS-based PVT solution: Once interference has been detected, the user or larger system can make decisions with full knowledge that the trustworthiness of the PVT solution may be compromised. But mere detection does not ensure *continuity* of reliable PVT information, which is a requirement for many systems and users. PVT continuity may be achieved by human intervention: A ship's crew can fall back to visual, radar, or even celestial navigation once alerted to GNSS interference. But, increasingly, navigation and timing systems are expected to maintain PVT continuity *automatically* in the face of GNSS interference.

One design philosophy gaining traction in recent years views GNSS as so vulnerable to interference that it must be backstopped with an entirely GNSS-independent PVT source. According to this philosophy, the sensible response to detection of threatening GNSS interference is to abandon GNSS, at least temporarily, by failing over to a non-GNSS backup PVT system. But despite impressive advances in IMU and clock stability, in the use of non-GNSS signals of opportunity for PVT, in non-GNSS time distribution, in electro-optical navigation, and in dedicated terrestrial PVT systems, this approach has only proven useful for short intervals of time (a few minutes) or restricted areas of operation (a radius of a few tens of kilometers). So far, GNSS remains irreplaceable because no combination of non-GNSS PVT systems has yet to rival the essential suite of GNSS benefits: (1) global coverage, (2) high PVT accuracy over indefinitely long time intervals, and (3) low cost to users. Accordingly, this section focuses on GNSS interference mitigation techniques that ensure PVT resilience not by abandoning GNSS but by toughening and augmenting it.

### 16.7.1 Spectrally or Temporally Sparse Interference

Effective techniques exist for mitigating interference that is sparse in frequency (narrowband) or time (pulsed). Mitigation of spatially sparse interference, that is, interference with a small number of narrow directions of arrival, will be treated in Sect. 16.7.3.

Sparse interference mitigation techniques exploit time correlation in an interference signal's phase or amplitude to estimate and excise the interference signal, thereby, increasing the desired signal power to noise ratio. The more highly time correlated an interference signal's amplitude or phase, the more accurately it can be reconstructed and excised, sparing the downstream acquisition and tracking routines from harmful interference effects.

#### Filtering

Without proper early stage RF filtering, even interference far from GNSS frequency bands of interest can be problematic for a GNSS receiver when the interference is sufficiently strong: The out-of-band signal rejection of the receiving antenna and the first-stage LNA may not be sufficient to prevent a strong out-of-band signal from saturating the LNA. Thus, in mobile handsets and at cellular base stations, one finds GNSS receivers with stringent RF filtering before first-stage amplification despite the direct $C/N_0$ reduction (equivalent to the filter impedance loss) that such filtering entails.

Narrowband interference within the GNSS band is more challenging to mitigate than out-of-band interference. Selective (high quality factor) analog filtering within a GNSS band of interest requires large and expensive analog filters. Likewise, LNAs with a linear range wide enough to prevent saturation in the face of strong interference are expensive, as are antenna arrays capable of pointing a null toward the interference source. Thus, attenuation of the received signal before low-noise amplification may in some cases be the only economical recourse to prevent LNA saturation. Unfortunately, one pays the full measure of such attenuation in reduced $C/N_0$.

Assuming LNA saturation is avoided, properly configured multibit quantization can be a first defense against narrowband interference. As mentioned in Sect. 16.3.2, multibit quantization can yield a conversion gain (an increase in $C/N_0$ relative to the unquantized discrete-time samples) when the amplitude of the incoming interference is approximately constant. However, for the one-bit (two-level) quantization employed in many low-cost GNSS receivers, quantizer SNR is severely and irrecoverably degraded by the presence of strong narrowband interference. Even two-bit (four-level) quantization may be insufficient to prevent capture of the quantization process by a strong narrowband interferer, if the interference amplitude varies rapidly or if there are multiple narrowband interferers present.

Assuming sufficient quantization resolution, adaptive digital filtering in the precorrelation stage (point (2) in Fig. 16.17) is a low-cost and highly effective way to mitigate in-band narrowband interference. This technique, commonly referred to as adaptive notch filtering, exploits the time correlation of narrowband interference signals to distinguish them from thermal noise and from the desired spread-spectrum signal, both of which look uncorrelated at chip-length sampling intervals.

Adaptive notch filtering can be implemented either as a transversal filter in the time domain or as shaping in the frequency domain. In the time-domain approach, the weights of a transversal filter are adjusted to minimize the filter's output power [16.76]. Solution of the optimal tap weight vector has complexity $\mathcal{O}(n^2)$, where $n$ is the number of samples in the block used to determine the optimal weights. One may trade off performance for reduced computational demand by extending the interval between subsequent computation of the optimal weight vector. Straightforward implementation can yield highly effective interference suppression even for multiple narrowband interferers: *Dimos* et al. [16.77] show that three pure tone interference sources with a combined interference-to-thermal-noise power of 30 dB in the GPS L1 C/A band can be suppressed by 28 dB. For the same interference power and number of interferers, but with bandwidths of 25, 50, and 100 kHz, suppression performance reduces to 24.25, 20.75, and 16 dB, respectively, showing that time-domain notch filtering performance degrades as the interference bandwidth increases.

The frequency domain approach entails Fourier transformation of a block of $n$ precorrelation samples (possibly weighted by a windowing function), multiplication of the transform by some appropriate filter, and inverse Fourier transformation of the product. The interference suppression filter applied in the transform domain can be generated automatically to whiten the transformed samples. In the simplest approach, regions containing interference peaks exceeding a predefined threshold can be simply blanked out. The transform approach has complexity $\mathcal{O}(n\log(n))$ and so is less computationally burdensome than time-domain notch filtering with continuous updating of the filter tap weighting. Another benefit of the transform approach is that successive transforms can be averaged to produce a power spectrum estimate, which, as mentioned earlier, is a useful tool for general situational awareness of the interference environment.

The distinctive swept tone interference of PPDs can also be considered sparse given its high regularity [16.47]. A model-based technique is developed in [16.49] that effectively estimates the frequency sweep parameters of PPD signals, allowing the interference to be excised. Such model-based filtering is the logical extension of notch filtering for interference signals that are highly predictable and easily distinguished from the desired GNSS signals.

#### Blanking

Interference signals that are sparse in time, for example, pulsed interference, can be substantially suppressed by so-called pulse blanking [16.1]. Blanking degrades $C/N_0$ in proportion to the fraction of RF front-end samples that are discarded. A combined adaptive notch filtering and blanking technique is explored in [16.1] to mitigate DME/TACAN interference, which is sparse in both time and frequency.

### 16.7.2 Spectrally and Temporally Dense Interference

Interference that is both wideband and continuous is spectrally and temporally dense, unlike narrowband or pulsed interference. It may yet be spatially sparse, but a GNSS receiver with a single, static antenna is unable to exploit such sparseness for mitigation. In this section, dense interference will refer to interference

which is both spectrally and temporally dense regardless of its spatial characteristics. The focus will be on signal-processing-based interference mitigation techniques that do not rely on multiple or moving antennas. The next section treats mitigation of spatially sparse interference using multiple or moving antennas.

Dense interference has substantially time-uncorrelated amplitude and phase at the RF front-end sampling rate, making it appear as thermal noise or as a spread-spectrum GNSS signal to the receiver. Spoofing interference (including meaconing) is an example of interference that is especially difficult to mitigate, because by construction it is intended to masquerade as a legitimate GNSS signal. Faced with multiple identically shaped and sized autocorrelation peaks for the same pseudorandom number code, a receiver can easily recognize that a spoofing attack is underway but cannot mitigate the attack – that is, cannot identify and track only the authentic signal – unless the receiver's combined timing and positioning uncertainty is well within the inter-peak separation. For this reason, post-detection mitigation of a subtle spoofing attack is often only possible by exploiting multiple or moving antennas and will therefore be left to the next section.

It is convenient to treat dense nonspoofing interference such as continuous wideband Gaussian interference as if it were thermal noise for purposes of mitigation. Thus, the dense interference mitigation problem becomes identical to the problem of acquiring and tracking weak GNSS signals in an indoor environment except that the multipath effects in the indoor environment are likely to be more severe than in an outdoor interference environment. Mitigation is applied at the correlation and post-correlation stage, or point (3) in Fig. 16.17. Given a front-end bandwidth of $W_{FE}$ Hz and an in-band interference-to-signal power ratio of $P_I/P_S$, the resulting effective $C/N_0$ will be as in (16.8), which for strong interference becomes $C/N_{0,\text{eff}} = P_S W_{FE}/P_I$. Thus, to withstand interference exceeding $P_I/P_S = 50\,\text{dB}$ in a $W_{FE} = 10\,\text{MHz}$ bandwidth, a receiver would need to acquire and track GNSS signals below $C/N_{0,\text{eff}} = 10\log_{10}(10^7) - 50 = 20\,\text{dB Hz}$.

Consumer-grade GNSS receivers offer surprisingly good protection against dense interference despite their low cost, because they have been designed for operation at low $C/N_0$. Even without network aiding, a consumer-grade GNSS receiver can acquire signals from a cold start at −148 dBm, which corresponds to $C/N_0 = 26\,\text{dB Hz}$ for a typical $N_0 = -174\,\text{dBm/Hz}$. This amounts to resilience against $P_I/P_S$ up to 37 dB in a 2 MHz bandwidth. Tracking and performance can be substantially better than cold-start acquisition, achieving remarkable thresholds as low as −167 dBm, or $C/N_0 = 7\,\text{dB Hz}$ assuming $N_0 = -174\,\text{dBm/Hz}$ [16.78].

The receiver presented in [16.11] can be considered a benchmark for what is possible with a stand-alone scalar-tracking architecture when computational limitations are ignored. Its algorithms can acquire and maintain lock on signals down to $C/N_0 = 18\,\text{dB Hz}$ by assuming a low-cost TCXO and moderate acceleration uncertainty. Clearly, the superior tracking performance of the consumer-grade receiver in [16.78] implies a vectorized tracking architecture.

The current state-of-the art in low-$C/N_0$ acquisition and tracking is embodied in the DINGPOS high-sensitivity GNSS platform for deep indoor scenarios [16.79]. The platform records synchronized data from a micro-electromechanical system (MEMS) IMU, a barometer, a magnetometer, and a GNSS RF front-end driven by an OCXO-quality reference clock. The data are combined with known navigation data symbols in a software-defined GNSS receiver employing a vector tracking architecture to achieve coherent integration over 2 s intervals under pedestrian dynamics. In dynamic simulation scenarios, DINGPOS acquires down to $C/N_0 = 6\,\text{dB Hz}$ and tracks down to $C/N_0 = -1\,\text{dB Hz}$. This represents remarkable interference immunity: up to $P_I/P_S = 71\,\text{dB}$ in a $W_{FE} = 10\,\text{MHz}$ bandwidth for tracking. Even higher $P_I/P_S$ immunity can be achieved by combining DINGPOS-style signal processing with antenna array processing, the subject of the next section.

### 16.7.3 Antenna-Based Techniques

Though currently expensive, multielement antenna arrays are perhaps the most effective general tool for interference mitigation. Antenna array interference mitigation exploits spatial sparseness in the direction of arrival of interference sources and spatial diversity in the direction of arrival of desired GNSS signals from overhead satellites. Early array processing methods passed the RF signal from each array element through a variable phase shifter. The phase-shifted RF signals were then combined into a single RF stream that was directed to the RF front end for conditioning and digitization. In this approach, the GNSS receiver saw only a single antenna gain pattern (e.g., a pattern with a null directed toward an interference source) at any given instant.

The modern approach to array processing is much more flexible. The RF feed from each antenna is independently digitized, as shown in Fig. 16.17. A complex weight vector is applied across the individual digitized streams to achieve a desired gain pattern. Importantly, any number of weighted combinations of the digital

streams can be created simultaneously, with the unique combinations fed to a bank of separate GNSS processing channels. In this way, each channel sees an alternative antenna array gain pattern, which permits a beam to be steered toward the satellite whose signal the channel is intended to track, for example.

Continuously calculating the set of optimal weighting vectors is the primary computational challenge of array processing, with the primary practical challenge being the need to periodically calibrate the array as temperature and other environmental variations cause minute but significant changes in the phase shift through each antenna element.

A computationally efficient approach to weighting vector calculation is offered in [16.80], but this approach requires the direction of arrival of the desired signal to be known, which entails knowledge of the antenna array's attitude in global coordinates. Preferable are blind adaptive techniques such as the one proposed in [16.81], which automatically maximizes the ratio of power in the desired signal to power in the interference signal plus thermal noise in the correlation products. Better still, though more computationally demanding, are joint space–time interference mitigation techniques that exploit interference time correlation or spatial correlation, or both, in a joint space–time mitigation framework [16.82]. A single interferer is detected in this framework based on estimates of the spatial correlation matrix. A narrowband interferer is detected based on estimates of the time correlation matrix (or based on time correlation evident in the Fourier domain). Such space–time array processing thus combines the virtues of adaptive notch filtering with adaptive beam forming. The beamforming aspect of the approach works equally well whatever the nature of the interference source – intentional or not, GNSS-like or not – so long as the source presents a compact direction of arrival.

# 17. Antennas

Moazam Maqsood, Steven Gao, Oliver Montenbruck

The basic purpose of a global navigation satellite system (GNSS) user antenna is the reception of navigation signals from all visible GNSS satellites. Transmit antennas onboard the GNSS satellites, on the other hand, are quite different and employ large antenna arrays to create high-gain global beams illuminating the entire surface of the Earth.

This chapter presents different design options for GNSS antennas operating in the L-band of the radio frequency spectrum. It starts with a brief discussion of key requirements for the GNSS receiving antenna, where several design parameters are introduced and explained. Thereafter, antennas of different design technologies suitable to GNSS are explored and discussed in detail. Following the introduction of major antenna candidates, different variants for specialized requirements, such as the small form factor or multipath mitigation are presented. Complementary to receiving antennas, the design of antenna arrays for signal transmission on the GNSS satellites is presented next, along with a discussion on specific antennas employed on the Global Positioning System (GPS), Galileo, Global'naya Navigatsionnaya Sputnikova Sistema (GLONASS) and BeiDou satellites. Finally, a comprehensive discussion on antenna measurements and the performance evaluation is provided.

## 17.1 GNSS Antenna Characteristics

Antennas are basic elements of any radio frequency (RF) system, be it used for for audio and video broadcasting, communication, or radio navigation. An antenna serves as an interface between the electric circuitry of the RF system and free space [17.1, 2]. In a transmit antenna, electric currents are converted into electro-magnetic waves. On the contrast, a receiver antenna converts those radio waves back into electric currents. However, any antenna can, in principle, serve both purposes. The distinction is thus largely driven by the practical application, since specific antenna aspects may be optimized for either of the two functions.

Global navigation satellite systems (GNSSs) such as the US global positioning system (GPS), the Russian Global'naya Navigatsionnaya Sputnikova Sistema (GLONASS), the European Galileo, and the Chinese BeiDou transmit their signals in the so-called L-band of the RF spectrum. Within this band, which covers a total frequency range of 1–2 GHz, various types of communication services have been allocated by the International Telecommunications Union (ITU), but frequencies of 1164–1300 and 1559–1610 MHz have been specifically assigned to radio navigation satellite services (RNSSs). With the exception of the Indian regional navigation satellite system (IRNSS) and the third-generation BeiDou system, that expanded into the S-band and use a frequency near 2.2 GHz for selected navigation signals, all global and regional navigation systems as well as satellite-based augmentation systems (SBAS) are presently confined to the aforementioned L-band frequencies.

Figure 17.1 illustrates the frequency allocation chart for individual navigation satellite systems. The close (and in some cases overlapping) frequency allocation has both its advantages and disadvantages. The advantage is that all the designated frequencies for GNSS lie in a close vicinity, thereby making it possible for a single wide-band antenna to receive signals from several systems. Moreover, the use of re-configurable antennas and RF front ends becomes possible. On the other hand, the potential disadvantage of such an arrangement is possible interference from one system into another. The interesting fact is that all navigation satellite systems use different signal formatting and modulation forms, thereby providing natural immunity against the interference due to frequency overlapping (Chap. 4).

In order to understand the design and performance aspects of a GNSS antenna, we will start with the requirements of an ordinary GPS antenna [17.3]. This approach is realistic as the GPS is a widely used navigation system. However, the same discussion, with a few modifications, can be applied to other systems as well. Table 17.1 presents representative design requirements of a GPS antenna suitable for receiving all signals transmitted by this navigation system. An important point to note is that these are only basic requirements of a GNSS antenna design. Some applications may also put a set of particular requirements such as phase-center (PC) stability, cross-polarization isolation, axial ratio (AR), and and so on. A brief overview of these requirements is presented in the following sections for the reader to appreciate the challenges these requirements can put on the antenna engineer.

**Table 17.1** Example requirements of a triple-frequency GPS antenna for civil users

| Parameter | Value |
|---|---|
| Center frequency | L1: 1575.420<br>L2: 1227.600<br>L5: 1176.450 |
| Bandwidth | L1: $\approx 2 \times 10.023$ MHz<br>L2: $\approx 2 \times 10.23$ MHz<br>L5: $\approx 2 \times 10.23$ MHz |
| Radiation pattern | Semi-hemispherical |
| Gain | $\approx$ 3–5 dBiC |
| Polarization | Right-hand circular polarization |
| Return loss | $< -10$ dB |
| Impedance | 50 Ω |

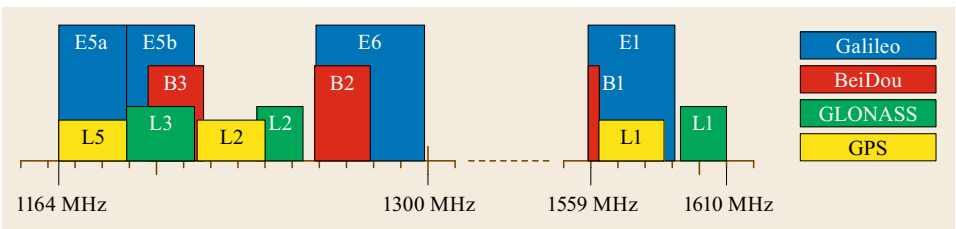

**Fig. 17.1** Frequency allocation for navigation satellite systems in the lower and upper L-band range assigned for radio navigation satellite services. Frequencies for BeiDou refer to the second generation system (BDS-2) which started its regional service in 2012

### 17.1.1 Center Frequency

Center frequency or the frequency of operation is the value at which the complete RF system including the antenna is designed. In the case of GPS, three center frequencies are mentioned (L1, L2, and L5). The L1 frequency (1.575 GHz) is the primary GPS frequency and has been designated for the open standard positioning service (SPS). The precise positioning service (PPS), in contrast, makes the joint use of both the L1 and L2 frequencies to enable ionospheric corrections, and similar options have become available for general users with the addition of the new civil L2C signal on the L2 frequency. Finally, a new L5 signal has been introduced, which is mainly targeted at aviation users. To support all related applications, a modern GPS antenna must, as a minimum, cover the L1, L2, and L5 frequencies. An even wider set of center frequencies must be covered by a generic multi-GNSS antenna.

### 17.1.2 Bandwidth

The bandwidth of an antenna is normally defined as the range of frequencies within which the antenna operates successfully (i. e., fulfilling the entire design requirements). The term bandwidth can be further classified into the impedance bandwidth and the gain bandwidth. In terms of a GNSS antenna, another important consideration is whether the antenna maintains the required right-hand circular polarization (RHCP) within the given bandwidth. A common bandwidth of $\pm 10.23$ MHz has been required in Table 17.1 to cover all signals transmitted by the GPS satellites at the respective center frequencies. Antennas designed to support only the C/A-code and L2C signals might, however, be confined to a $\pm 1.023$ MHz bandwidth in view of the 10-times lower chipping rate of these signals.

### 17.1.3 Radiation Pattern

The *radiation pattern* of an antenna is a representation of radiation properties such as the electric field or power as a function of spatial coordinates. These patterns can be represented in two- (2-D) and three-dimensional (3-D) coordinates, and are commonly presented as functions of observation angles around the antenna. A trace of the received electric field at a constant radius is called the amplitude field pattern, while a graph of the spatial variation of the power density along a constant radius is called an amplitude power pattern. Often the power pattern is plotted on a logarithmic scale or more commonly in decibels (dB). This is done to achieve a more detailed representation of areas with low power. In the case of a GNSS receiving antenna, the antenna should have a semi-hemispherical pattern (directed toward the transmitting satellite). On the other hand, the radiation pattern of a transmitting GNSS antenna is a sharp directional beam compensating for the notable free-space loss.

### 17.1.4 Antenna Gain

The gain $G$ of an antenna [17.2] describes, how well an antenna can receive power from or transmit into a specific direction in comparison to an idealized, lossless isotropic antenna. It is defined as the product $G = e\,D$ of the efficiency $e$ of energy conversion inside the antenna and the directivity

$$D = \frac{4\pi U}{P_{\mathrm{rad}}}\,, \tag{17.1}$$

where $U$ is the antenna's radiation intensity (power per solid angle) in a given direction and $P_{\mathrm{rad}}/(4\pi)$ is the corresponding value (ratio of radiated energy per solid angle of a sphere) for the isotropic radiator. The gain is commonly expressed in a logarithmic scale

$$G_{\mathrm{dBi}} = 10\,\log\left(\frac{G}{10}\right), \tag{17.2}$$

where dBi denotes decibels relative to an isotropic antenna. More specifically, dBiC is used for gain specifications when working with circular polarization. If no direction is specified, gain values are usually referred to the boresight direction (i. e., the main symmetry axis of the gain pattern). While GNSS receiving antennas are typically low-gain antennas enabling reception over a large range of angles, highly directive (high-gain) antennas are used for transmitting signals on the GNSS satellites.

### 17.1.5 3 dB Beam Width

The antenna beam width is normally used to define the area of maximum power concentration. Graphically, it is represented by the angular separation between two identical points around the antenna maximum. Two most common methods of representing an antenna beam width are the half-power beam width (HPBW) and the first-null beam width (FNBW). When plotted in decibels, the HPBW is also referred to as the 3 dB beam width. In the case of the GNSS receiving antenna, the required antenna beam should be as wide as possible. This ensures maximum satellite visibility. On the other hand, the transmitting satellite shall have a narrow beam width as it requires more focus into a particular direction. Figure 17.2 shows the radiation pattern of a GNSS

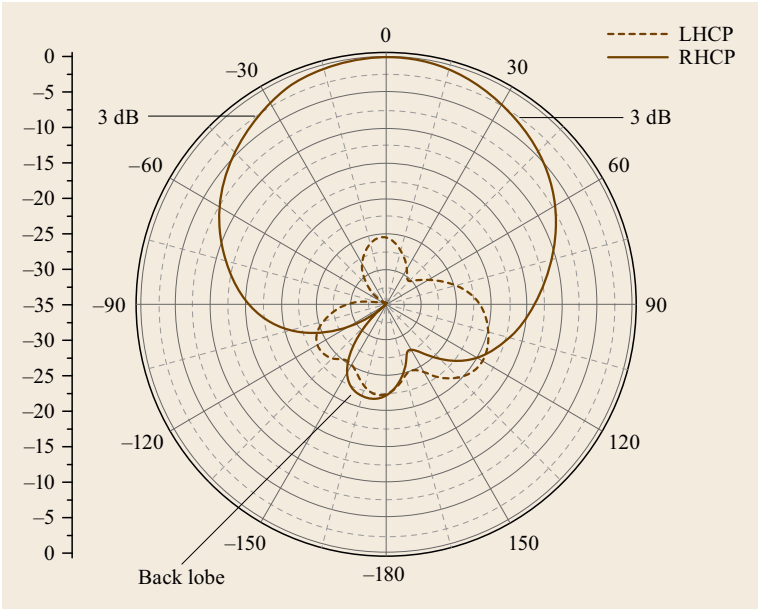

**Fig. 17.2** Simulated radiation pattern of a GNSS antenna. Values are normalized relative to the boresight direction

antenna, where a dominant semi-hemispherical pattern can be seen for the RHCP. The 3 dB beam width points have also been labeled.

### 17.1.6 Polarization

When an antenna emits electromagnetic waves, it has associated electric and magnetic field vectors. The polarization of any antenna is generally defined as the orientation of its electric (E)-field vector. If the E-field vector is aligned with the horizon, the antenna is said to be horizontally polarized, whereas for the E-field vector to be aligned perpendicular to the horizon, the antenna is said to be vertically polarized. In the case of GNSS, the conventional polarization is neither horizontal nor vertical, but RHCP. This means that the electric field of a GNSS signal is composed of two orthogonal waves of equal amplitude with a 90° phase shift. The resultant E-field then circulates in a clockwise direction. Upon reflection, the polarization may change, thus giving rise to left-hand circularly polarized (LHCP) waves. Ideally, such signal components should be fully suppressed by a GNSS receiving antenna.

### 17.1.7 Axial Ratio

The AR is the ratio of the magnitudes of the major and minor axes of the polarization ellipse. It is equal to 1 for purely circular polarization and grows with increasing ellipticity. For linear polarization, the AR is infinite, because one of the orthogonal components of the field is zero.

An ideal GNSS antenna would thus exhibit an AR of 0 dB, but a value of $< 3$ dB is generally acceptable. Since the AR tends to increase with increasing boresight angle, it is common to indicate the range of boresight angles for which this condition is met. The 3 dB AR beam width is a key parameter for advocating the performance of circularly polarized antennas. The wider this beam width, the greater the ability of the antenna to reject multipath signals.

### 17.1.8 Impedance Matching and Return Loss

Impedance matching and return loss are the two parameters that tell an antenna engineer, how well an antenna will accept the incoming power. Regardless of the antenna type and the frequency of operation, it is essential for the antenna to have a good impedance matching with the feed line and a high return loss. As mentioned in Table 17.1, the input impedance requirement for a GNSS antenna is 50 Ω, a common standard, which makes the antennas of different manufacturers compatible with the RF system. The return loss describes the ratio between the power fed into a transmit antenna and the power reflected back into the feed cable. It is usually required to be less than −10 dB, which ensures that at least 90% of the incoming power is transmitted to the antenna for radiation.

As an alternative to the return loss, the reflection coefficient $|s_{11}|$ and the voltage standing wave ratio (VSWR) are occasionally provided in antenna specifications. They relate to the ratio of the reflected and incoming field amplitude and can be converted to return

loss by the relations

$$\text{return loss} = -20\log|s_{11}| = -20\log\left|\frac{\text{VSWR}-1}{\text{VSWR}+1}\right| . \tag{17.3}$$

### 17.1.9 Front-to-Back and Multipath Ratio

The front-to-back ratio (FBR) relates the antenna energy directed in the boresight (main lobe) direction to that of the backlobes

$$\text{FBR} = \frac{G(\theta = 0^\circ)}{G(\theta = 180^\circ)} . \tag{17.4}$$

The ratio simultaneously highlights an antenna's directivity and resistance to multipath. Generally, a high FBR is required for a GNSS antenna, since it will allow the antenna to attenuate signals (e.g., ground reflections) coming from unwanted directions. The FBR is influenced by a combination of the antenna's backside shielding and the sensitivity to LHCP signals.

A related parameter, known as the multipath rejection ratio (MPR)

$$\text{MPR} = \frac{G_{\text{RHCP}}(\theta)}{G_{\text{LHCP}}(180^\circ-\theta) + G_{\text{RHCP}}(180^\circ-\theta)} , \tag{17.5}$$

directly compares the gain for RHCP signals from a given boresight angle $\theta$ with those for RHCP and LHCP radiation received from $180^\circ - \theta$ [17.4]. For a zenith-looking antenna, this angle corresponds to the incidence angle of ground-reflected signals. The MPR is thus an important indicator for characterizing the multipath mitigation performance of an antenna.

### 17.1.10 Phase-Center Stability

Conceptually, the antenna phase-center is a point within the antenna radiation pattern, where all the power emanates from (for a TX antenna) or converges to (for a RX antenna). This point is typically different from the geometric center of an antenna and also depends on the signal frequency. In practice, the wavefronts of an antenna will also deviate from the ideal case of the concentric spherical shell. These deviations give rise to direction-dependent delays in GNSS measurements, which are known as phase-center variations (PCVs). Accurate knowledge of the phase-center offset (PCO) and PCV from an established mechanical reference point is most important for precise positioning applications and requires proper calibration for both GNSS satellite (transmit) and user (receive) antennas. Ensuring a good PC stability is generally most challenging for wide- or multiband antennas.

## 17.2 Basic GNSS Antenna Types

GNSS antennas can be categorized in more than one ways: based on the associated design technology such as microstrip, helix, spiral, and so on, or according to the subject application such as navigation, surveying, remote sensing, and antijamming. This section takes the former approach and introduces the basic GNSS antenna candidates along with a discussion of their design methodology. It is complemented later by a dedicated section on application-specific GNSS antennas (Sect. 17.3), which presents several variants of the basic antenna types for specialized requirements.

The two most common and popular GNSS antenna configurations are the printed (microstrip patch) and helix antennas [17.5, 6]. Both of these antenna types can provide a reasonably small size and are widely used for single-frequency, mass market applications. Even though the concepts may be extended to dual- or even multiband antennas, a much simpler option is to use a wide-band antenna covering almost the entire L-band. However, such an antenna will require sharp filtering to isolate adjacent frequency bands and the associated receiver should have a mechanism in place to reject out-of-band interference coming, for example, from amateur radio and digital audio–video broadcast (DVB, DAB) services.

### 17.2.1 Microstrip Patch Antenna

The microstrip patch (or simply patch) is a simple antenna configuration, consisting of a metallic patch that is mounted above a conducting ground plane with a dielectric substrate separating both layers (Fig. 17.3, [17.7]). The top layer is designed so that it resonates at a particular frequency, thereby acting as a radiating antenna, whereas the bottom layer acts as a ground plane and is necessary for successful antenna operation. Microstrip antennas have the advantages of low profile, small form factor, surface conformability, and moderate gain performance, while its disadvantages include narrow bandwidth and emission of surface waves. Despite these disadvantages, the microstrip antenna is the most popular choice for GNSS antennas and is particularly attractive for mass market applications.

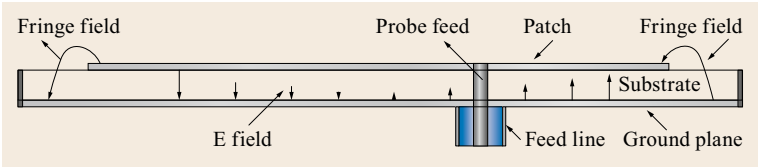

**Fig. 17.3** Side view of a patch antenna with fringing field

Even though different shapes may be considered for general patch antennas, a square patch is commonly employed for antennas for the reception or transmission of RF signals with circular polarization. Together, the patch and ground plane form a cavity with a resonant frequency $f_r$ that depends on the width $w$ of the patch element and the permittivity $\varepsilon_r$ of the substrate. As a rule of thumb, resonance is achieved if the patch dimension equals half the signal wavelength in the dielectric material, that is,

$$w = \frac{c}{2f_r\sqrt{\varepsilon_r}}\,, \tag{17.6}$$

with $c$ denoting the speed of light. While a substrate of low permittivity ($\varepsilon_r \approx 1$) would result in a GNSS antenna size of about 1 dm, substantially more compact patch antennas can be designed with ceramic materials offering a 10–100 times higher permittivity.

As illustrated in Fig. 17.3, the electric field lines connecting the patch and the ground plane pass through two different media (air and substrate). This creates a fringing effect, which increases the *electronic width* of the microstrip line. Even though the field lines are mostly concentrated under the patch itself, whenever the width of the patch is much larger than the substrate thickness $h$, the fringing affects the resonance frequency and must be compensated by a corresponding length correction. In order to achieve a resonance at the desired frequency $f_r$, a slightly smaller patch size

$$w' = w - 2\Delta w \tag{17.7}$$

is required due to the fringing than given by the simplified relation (17.6). Following [17.8], the correction can be approximated by the expression

$$\Delta w = 0.412\,h\,\frac{(\varepsilon_{\text{eff}}+0.3)\left(\frac{w}{h}+0.264\right)}{(\varepsilon_{\text{eff}}-0.258)\left(\frac{w}{h}+0.8\right)}\,, \tag{17.8}$$

where

$$\varepsilon_{\text{eff}} = \frac{\varepsilon_r+1}{2} + \frac{\varepsilon_r-1}{2}\left(1+10\frac{h}{w}\right)^{-\frac{1}{2}}\,, \tag{17.9}$$

denotes an effective permittivity.

One of the biggest advantages of a patch antenna is that it can be designed with more than one shape. Rectangular, circular, diamond, and ring are the few common shapes that can be employed for patches. However, with reference to GNSS, the shape of the patch needs to be symmetric (square or circular) as the achievement of circular polarization is only possible if the patch produces similar but orthogonal electric fields. This is achieved by feeding the patch antenna at two orthogonal points and then combining them by means of a quadrature hybrid coupler or a delay line mechanism (Fig. 17.4a). An alternative design approach is to use a single-feed square patch antenna with two truncated corners on opposite sides (Fig. 17.4b), where the position of the feed relative to the corners determines the rotation of the circular polarization. This approach is very simple, easy to implement, and results in an inexpensive antenna. However, the achievement of good polarization purity requires rigorous tuning of the corners.

Microstrip patch antennas can also be used for multiband operation by stacking more than one patch elements over one another [17.9, 10], where different stacked layers are fed together using proximity or aperture coupling.

### 17.2.2 Helix Antenna

Next to the microstrip patch antenna, the helix antenna [17.1, 9] represents another basic antenna type for GNSS applications. The antenna consists of a wire shaped in the form of a helix with the longitudinal axis perpendicular to the ground plane (Fig. 17.5).

The radiation pattern of the helix antenna can be controlled by varying geometrical parameters of the antenna. The same is true for the input impedance of the antenna, which primarily depends upon the pitch angle and size of the conducting wire. The general polariza-

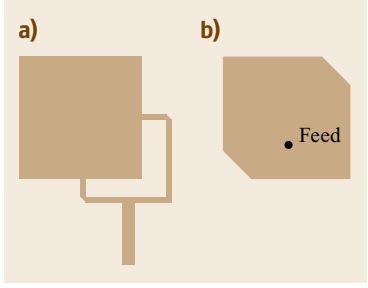

**Fig. 17.4a,b** Patch antenna with feed network for circular polarization **(a)** and patch antenna with truncated corners **(b)**

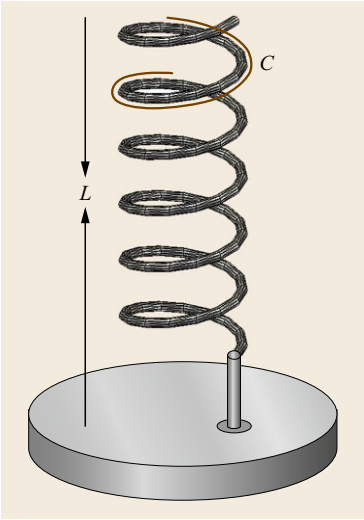

**Fig. 17.5** Geometrical parameters of a GNSS helix antenna

tion of the antenna is elliptical as it has both vertical and horizontal sections. While the antenna acts like a dipole with an almost omnidirectional gain pattern and linear polarization if its dimension is small compared to the wavelength (*broadside* or *normal* mode), it attains a high directivity (*axial* or *end-fire* mode) and circular polarization in the opposite case.

In reference to GNSS, the helix is normally operated in the axial (end-fire) mode to obtain a semi-hemispherical pattern. For circular polarization in the main lobe, the number of turns should be greater than 3, which implies that the antenna size may not be suitable for use in handheld devices. However, the helix antenna is a very popular candidate for GNSS satellites, where it is used for transmitting the navigation signals in a high-gain beam. The helix normally operates with a ground plane, whether flat or cupped in the shape of a cylindrical cavity. The typical diameter of the ground plane amounts to three quarters of the signal wavelength.

To operate the helix in the axial mode with circular polarization, the circumference ($C$), pitch angle ($\alpha$), and number of turns $N$ of the helix should remain within the following limits

$$\begin{aligned} &\frac{3}{4} < \frac{C}{\lambda} < \frac{4}{3}\,, \\ &12^\circ < \alpha < 14^\circ\,, \\ &3 < N\,. \end{aligned} \tag{17.10}$$

Once the above parameters are fixed, the spacing between the turns $S$ and the antenna length $L$ can be obtained as

$$S = C\tan\alpha\,, \quad L = NS\,. \tag{17.11}$$

With the above quantities, key parameters of the helix antenna such as the input resistance $R$, the directivity $D$, and the HPBW can be obtained from the approximate relations

$$\begin{aligned} R &= 140\frac{C}{\lambda}\,, \quad D = 15N\frac{C^2 S}{\lambda^3}\,, \\ \mathrm{HPBW} &= 52^\circ \frac{\lambda^{\frac{3}{2}}}{C\sqrt{NS}}\,, \end{aligned} \tag{17.12}$$

which are further discussed in [17.2].

### 17.2.3 Quadrifilar Helix Antenna

A popular variant of a helical antenna, which is not restricted by the number of turns for circular polarization and, therefore, suitable for handheld GNSS terminals, is the quadrifilar helical antenna (QHA) [17.11]. It offers a simple geometry and small size, and is able to produce a circularly polarized hemispherical radiation pattern, but also exhibits some backlobes.

Unlike a traditional monofilar (single-wire) helix antenna, a QHA consists of four standalone helices fed with progressive quadrature phase shifts (Fig. 17.6). The rotation of circular polarization is defined by the curling direction of the monofilars while the increasing or decreasing phase progression dictates the direction of the radiation pattern (forward- or back-fire). The resonant QHA can have variable lengths, such as $1/4\lambda$, $1/2\lambda$, $3/4\lambda$, or a full wavelength $\lambda$ [17.13]. Similarly, the number of turns can also vary from $1/4$ to 1. Moreover, for the volutes of an odd number of quarter wavelengths (i. e., $\lambda/4$ and $3\lambda/4$), the end of the helix element is open circuited, whilst for an even number of quarter wavelengths, the end of the helix element is bent

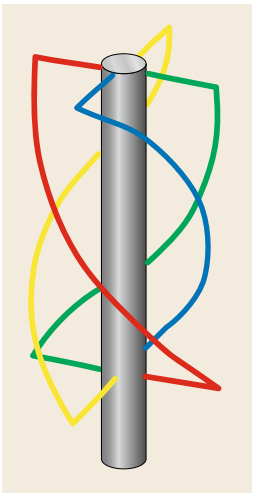

**Fig. 17.6** Schematic view of a half-turn quadrifilar helix antenna. For improved clarity, different colors are used for the individual wires (after [17.12])

toward the center and short circuited to the ends of the other helix elements [17.13].

Despite the suitability of QHA for GNSS applications, its manufacturing is complex. A planar quadrifilar helical antenna (PQHA) simplifies the antenna fabrication while maintaining the performance of the traditional QHA. Etching the PQHA on the thin layer of flexible substrate material allows for line meandering, looping, bending, and varying the pitch angle, thereby reducing the size and mass [17.2].

Similar to microstrip antennas, the quadrifilar helix antenna can also be modified for multiband operation. A dual-band QHA can be constructed by running parallel lengths of helix-wound wires where the length of each wire determines the resonant frequency. Alternatively, a trap circuit can be inserted into each of the four wires to shorten their effective length at the higher signal frequency [17.14]. A folded QHA covering the full range of GNSS frequency bands as well as the adjacent IRIDIUM communication frequencies has been developed by the MITRE Corporation [17.15]. A triband PQHA has also been demonstrated by integrating a dual-band and a single-band PQHA in a piggy back configuration [17.16]. Although these antennas demonstrate good GNSS performance, there is yet a long way to go when these antennas will be used commercially.

One of the main issues with the use of the QHA is the relatively complicated phase requirements for the feeding network. In order to produce the circular polarization in the desired axial direction, a progressive phase shift between the multiple arms is required to be produced. This can be achieved in two different ways. Either a 1-to-4 feed network consisting of a 180° and 90° hybrids, as shown in Fig. 17.7, can be used

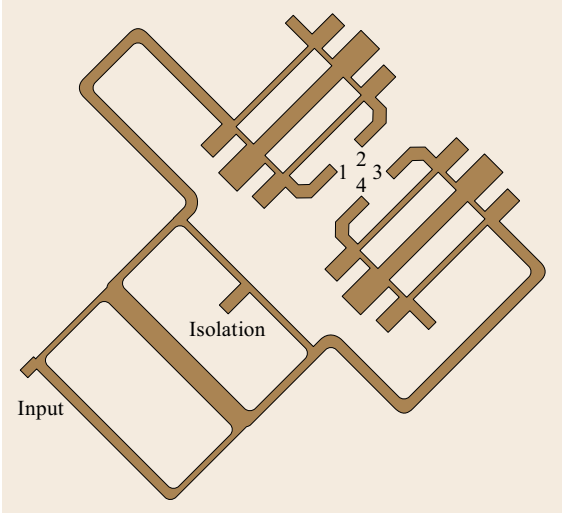

**Fig. 17.7** 1-to-4 hybrid coupler

or there is also an alternative solution. The quadrifilar antenna is considered to be made of two bifilars combined together. By making one bifilar slightly longer than the second bifilar, a ±45° phase shift can be created, allowing two adjacent arms of the QHA to be connected to the same balun terminal, and still achieve the phase quadrature relationship necessary for correct operation [17.2].

### 17.2.4 Spiral Antenna

Spiral antennas are popular for their wide-band circular polarization operation. The antennas actually belong to a category called frequency-independent antennas. Spiral antennas come in more than one configurations such as Archimedean spiral, logarithmic (log) spiral, and conical spiral [17.1, 2]. The Archimedean and the log spiral are 2-D planar configurations and can be considered as a dipole antenna twirled in a spiral fashion. The conical spiral, on the other hand, takes its inspiration from a helix antenna that is tapered to form a conical shape.

Both planar and conical spirals can be manufactured easily using printed circuit board (PCB) techniques. The conducting conical spiral surface can be constructed by forming conical arms on the dielectric cone. The feed cable can be bound within the metal arm and wrapped around the cone. The radiation pattern is toward the apex with its maximum along the axis. Similarly, a planar spiral can also be etched on a thin substrate layer.

In this section, we will stick to the design of the log spiral only. Similar to a dipole, a planar spiral antenna has an omnidirectional but circularly polarized radiation pattern. Therefore, in order to achieve a semihemispherical pattern, a requirement for GNSS, a spiral antenna backed with a decent reflector is usually employed.

The general shape of a logarithmic spiral antenna can be modeled by the relation

$$r = R_0 e^{a\phi} , \tag{17.13}$$

which describes an exponential growth of the radius of the two spiral arms with polar angle $\phi$ in the antenna plane (Fig. 17.8). $R_0$ is the initial radius of the spiral and matches 1/4 of the shortest wavelength that can be transmitted or received by the antenna. On the other hand, the outer circumference ($2\pi R_{max}$) matches the longest wavelength at which the antenna can be operated.

The factor $a$ defines the rate at which the spiral grows with the increasing angle $\phi$ and effectively controls the spacing between the spiral arms. A small value of $a$ will result in extremely small spacing between the spiral

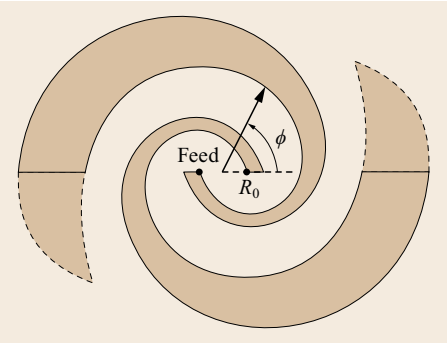

**Fig. 17.8** Center-fed log spiral antenna (after [17.2])

arms, making the antenna behave like a capacitor with very poor radiation. On the other hand, a large value of $a$ will make the spiral behave like a dipole losing its circular polarization capability. A commonly recommended value for a good spiral operation is $a = 0.22$ [17.2].

### 17.2.5 Wide-Band Bow-Tie Turnstile Antenna

Another type of antenna that can achieve a wide bandwidth is a bow-tie turnstile antenna. The antenna produces an omnidirectional radiation pattern and, therefore, requires a reflector ground plane to achieve a hemispherical radiation pattern. A bow-tie turnstile antenna, shown in Fig 17.9, has been used in [17.17]. The antenna is optimized to achieve 28% impedance bandwidth at the L-band.

It uses a differential feed and a 90° hybrid coupler to achieve circular polarization. Antenna measurement results show that the antenna achieves an average gain of 8 dBiC (i. e., 8 dB relative to a perfectly isotropic circularly polarized antenna) across the resonant bandwidth. The antenna has been tested by integrating it to a flat ground plane [17.17].

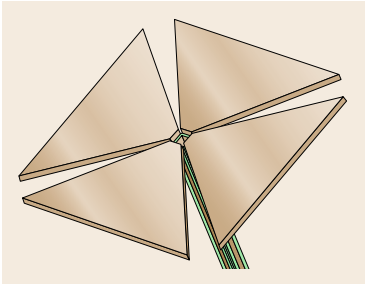

**Fig. 17.9** Bow-tie turnstile antenna

**Fig. 17.10** Modified NovAtel pinwheel antenna (after [17.18], courtesy of NovAtel)

### 17.2.6 Wide-Band Pinwheel Antenna

A wide-band pinwheel antenna designed by NovAtel, Inc. has been presented in [17.18, 19]. The antenna configuration consists of an array of coupled spiral slots arranged in a pinwheel of about 20 cm diameter backed by a microstrip-based multiple-turn spiral transmission line (Fig. 17.10). The overall antenna structure is compact, lightweight, and has multipath mitigation capability for almost the entire L-band. However, antenna measurement results presented in [17.18] show that the antenna performance is not uniform across the resonance bandwidth with better performance achieved at higher frequency. The antenna achieves a 6.8 dBiC gain at 1.575 GHz (L1) but only 2.8 dBiC at 1.227 GHz (L2).

## 17.3 Application-Specific GNSS Antennas

The overview of antenna concepts given in the previous section illustrates that any antenna type with a circularly polarized semihemispherical pattern can, in principle, be used for GNSS. However, it should be kept in mind that not all antennas are equally suitable for all types of GNSS applications [17.20]. As an example, antennas for handheld terminals will require a very low form factor, while superior (PC) stability is required for surveying and geodetic applications. Even more specialized requirements may apply for scientific applications such as GNSS remote sensing and atmospheric sounding. Table 17.2 presents an overview of common GNSS applications and related antenna requirements. Specific antenna solutions for some of these fields are discussed throughout this section.

### 17.3.1 Hand-Held Terminals

Hand-held terminals (such as mobile phones) require a high level of miniaturization. Two specific examples of microstrip patch and helix antennas are presented in

**Table 17.2** Application-specific GNSS antenna requirements (after [17.21])

the following sections. Even though both antenna concepts can offer a very small from factor, the microstrip antenna is often preferred since it can be etched using simple PCB technology and enables extremely thin designs. However, as the antenna needs to pick up all signals from above the horizon, the radiation pattern and the direction of the main lobe are likewise important criteria for the antenna selection.

#### Inverted-F Antenna

An antenna type very commonly used for GPS in mobile phones is an inverted-F antenna (IFA). The antenna produces an omnidirectional pattern covering all visible GNSS satellites. The antenna is linearly polarized and, therefore, able to receive both RHCP (direct line of sight) and LHCP (reflected) GNSS signals. This may be considered as a problem in the conventional GNSS as the reflected signals tend to degrade position accuracy. However, handheld terminals are normally operated near the ground, where the path difference between direct and reflected signals results in only a limited performance degradation. Moreover, most handheld terminals only require a moderate level of accuracy and can therefore tolerate such performance limitations. Figure 17.11 shows the inverted-F GNSS antenna for a Samsung Galaxy tablet.

#### Dielectric Loaded Quadrifilar Helical Antenna

A miniaturized GNSS antenna for handheld terminals presented in [17.22] is shown in Fig. 17.12. The antenna is a compact version of a PQHA, where the small size is achieved by wrapping the QHA around a high-permittivity material. The antenna gives a uniform semihemispherical pattern above the ground and uses a sleeve balun in order to balance the unbalanced current in the coaxial line. Since the antenna is tightly wrapped around a high-permittivity material, its gain is very less and therefore a low noise amplifier (LNA) is directly integrated to the antenna feed.

### 17.3.2 Surveying and Geodesy

Surveying (Chap. 35) and geodesy (Chap. 36) represent two high-end GNSS applications, which make use of advanced carrier-phase-based techniques to achieve mm-level relative or absolute positioning accuracies. In order to fully exploit the precision offered by GNSS carrier-phase measurements, adequate care must be taken in the choice and design of the antenna. Key requirements for geodetic-grade GNSS antennas include a high level of multipath rejection as well as phase center stability. Since dual-frequency observa-

**Fig. 17.12** GNSS antenna for handheld terminals. The printed quadrifilar helix (PQFA) has a diameter of about 10 mm and is integrated with a low-noise amplifier (LNA)

tions are required to eliminate ionospheric path delays in precise point positioning or long-baseline differential GNSS techniques, the employed antennas must maintain its high performance in multiple individual frequency bands or even the full range of GNSS frequencies.

Multipath errors arise whenever the direct signal received from a GNSS satellite is superimposed by reflected signals and affects the code and carrier tracking inside the receiver. As discussed in Chap. 15, multipath effects can partly be mitigated through advanced correlators and tracking techniques. However, a careful antenna design may help to avoid reflected signals from entering the antenna in the first place and thus offers one of the most efficient means of protection against multipath-induced GNSS measurement errors.

The use of a *choke ring* (Sect. 17.4) around the sensitive antenna element constitutes one of the most widely employed techniques to reduce the adverse impact of low-elevation, reflected signals, even though it is less convenient for nonstationary applications. An example of such a choke-ring antenna for geodetic reference stations is shown in Fig. 17.13. To protect against rain or snowfall, the antenna is typically covered by a radome as illustrated in the right part of the image. In view of their significance, choke rings and other concepts of multipath-mitigating antennas are further discussed in a subsequent section (Sect. 17.4) of this chapter,

Next to proper multipath reduction, a high stability of the antenna constitutes the second main criterion for antennas used in high-precision positioning applications. Common specifications for surveying antennas require PCVs of less than a few millimeter across the relevant range of elevations in each of the supported frequency bands. Even though it has become common

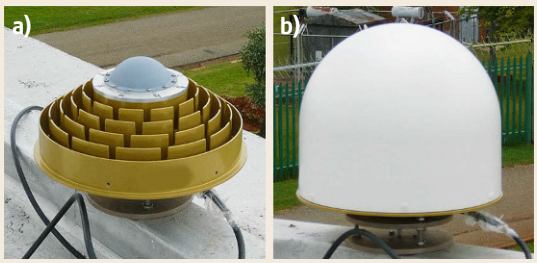

**Fig. 17.13a,b** Choke-ring antenna (Leica AR25) without **(a)** and with **(b)** protective radome (courtesy of O. Montenbruck/DLR)

practice to calibrate PCVs of geodetic-grade antennas for utmost positioning accuracy (see Fig. 17.14 and Sect. 17.6.2), the use of such calibration tables may not be convenient or feasible in all applications. Low PCV amplitude and good PCV repeatability among different units of a given antenna model therefore remain important antenna criteria for high-end GNSS positioning. For completeness, we note that these criteria also apply for the radome used to protect the actual antenna from environmental effects. Even though the radome is from nonconductive material such as plastic, it impacts the radiation pattern and care must be taken to minimize (and/or properly calibrate) associated PCOs shifts and PCVs.

### 17.3.3 Aviation

GNSS-based navigation for general aviation is so far limited to the use of the GPS SPS along with satellite- or ground-based augmentation systems (SBAS/GBAS) to enhance the integrity of the position information (Chap. 30). As such, aviation antennas are commonly confined to the L1 frequency, even though various types of dual-frequency antennas are available for military users. However, a growing need for dual-frequency aviation antennas will emerge along with the ongoing introduction of L5/E5 GPS, Galileo, and SBAS signals for safety critical aviation applications.

Compared to personal navigation antennas, miniaturization is not required for aviation use, but environmental robustness becomes a driving factor for the antenna design. In particular, the antenna should be able to operate at extreme vibration conditions and should be rugged enough to sustain a wide range of temperatures. Furthermore, the accommodation on the aircraft calls for a low profile or even conformal design to minimize drag and turbulences. Finally, aviation antennas must be tolerant to lightning to enable safe operation under severe weather conditions. Relevant standards for environmental robustness (DO-160 [17.24]) and mini-

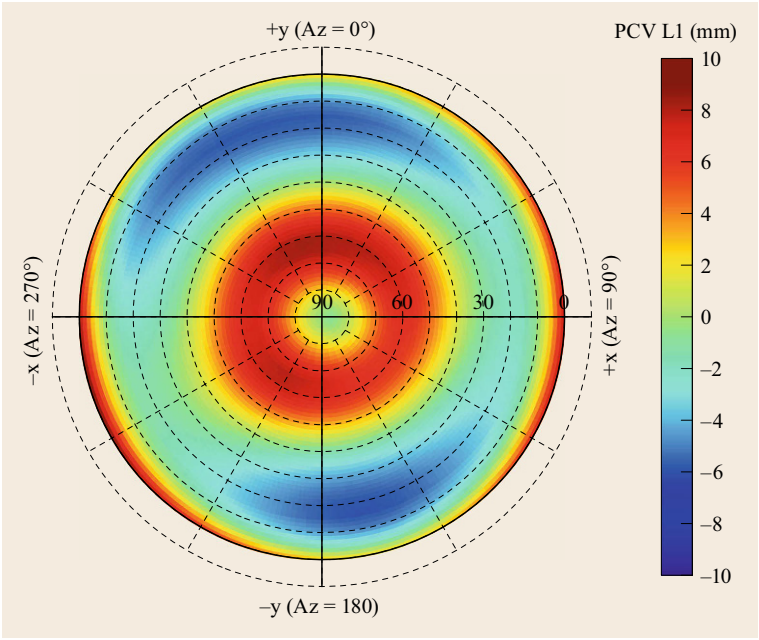

**Fig. 17.14** Phase-center variations of a geodetic-grade choke-ring antenna (Trimble TRM14532.00) on the L1 frequency as derived from robot calibrations (after [17.23], courtesy of igs08.atx antenna model)

mum performance (DO-208 [17.25]) of airborne GNSS equipment have, for example, been issued by the Radio Technical Commission for Aeronautics (RTCA). An example of an aviation GPS antenna with a standardized form factor and mounting holes is shown in Fig. 17.15.

### 17.3.4 Space Applications

GNSS receivers are nowadays widely used on spacecraft in the low Earth orbit as a means for onboard navigation and timing as well as precise orbit determination (Chap. 32). Similar to terrestrial antennas, the choice of an antenna for use onboard a spacecraft is largely dependent on application-specific needs and constraints such as the desired measurement quality and the available space for antenna accommodation.

Standard patch antennas encapsulated into an appropriate radome (Fig. 17.16a) are widely used for code-based single-frequency navigation that do not require the utmost precision of the resulting measurements. Even though many of these antennas have been specifically designed for use in space use, aviation antennas have also been found to be viable and cost-effective alternatives for many missions.

For precise orbit determination, dual-frequency antennas with well-calibrated phase centers and low multipath sensitivity are required. This is commonly accomplished by combining a patch or a cross-dipole antenna element with a choke ring. This choke ring is similar in function to those in geodetic reference sta-

**Fig. 17.15** L1 GPS/SBAS antenna for general aviation (courtesy of Sensor Systems, Inc.)

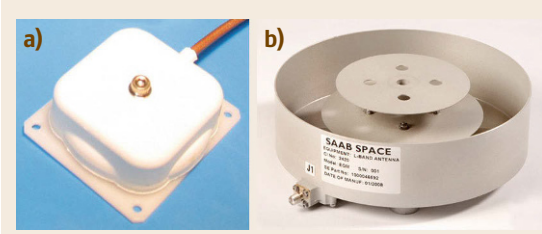

**Fig. 17.16a,b** Examples of GPS antennas for space use: **(a)** L1 patch antenna with radome (courtesy of SSTL), **(b)** dual-frequency patch excited cup antenna (courtesy of RUAG Space AB). Images not to scale

tions, but requires special effort in the manufacturing to meet the tight mass budgets and qualification standards of a space mission. Examples of such antennas as used on the Gravity Recovery And Climate Experiment (GRACE) and TerraSAR-X missions are given in [17.26] along with a discussion of ground and in-flight calibrations of their PCs.

An alternative dual-band, multipath mitigating antenna design has been proposed in [17.27]. The patch excited cup (PEC) antenna uses a stacked patch configuration mounted in a cup-shaped ground plane. It enables dual-band operation, while keeping the spacecraft interference to the antenna at a minimum. An example of a PEC antenna flown on the SWARM satellites is shown in Fig. 17.16b. A further enhancement of the multipath suppression capability can be achieved by adding a small number of choke rings inside the cup [17.28] as used for the Sentinel mission. Compared to traditional choke-ring antennas, the PEC design offers a high performance at a notably lower form factor.

Apart from its RF characteristics, a GNSS antenna for spaceborne applications needs to account for the specific environment in which it is operated [17.29]. This includes extreme temperatures, vacuum, and possibly space radiation. All materials for manufacturing the antenna should be space qualified and issues such as low outgassing need to be considered in the material selection. Where possible preference, should be given to materials that have previously been flown and tested in space. The antenna structure must be robust enough and the mounting of the antenna onto the satellite body has to be very rigid to survive shocks and vibration during the launch. Furthermore, the presence of other subsystems around the antenna and the mutual coupling between the antenna and the spacecraft body have to be taken into account. It is also important to avoid any suspended metallic layers within the antenna structure since charge deposition on the metallic structure of the antenna may cause harm to the LNA and other circuits.

### 17.3.5 Antijamming Antennas

Controlled reception pattern antennas (CRPA) represent a special type of beam-forming antenna, in which the shape of the beam pattern can be actively controlled and adapted during the operation [17.30]. While originally conceived for military users as a means to mitigate intentional jamming or spoofing of GNSS signals (Chap. 16), the use of CRPAs is getting of wider interest for civil users in the context of assuring position, navigation, and timing (PNT) services for critical infrastructure.

While fixed radiation pattern antennas (FRPAs) as used in various GNSS remote sensing applications mainly aim to maximize the antenna gain pattern in a given region of interest (e.g., toward the limb of the Earth; see Sect. 17.3.6), antijamming antennas adaptively steer selected pattern nulls in the directions of interference sources or adverse signal reflections. This helps the GNSS receiver to maintain the required signal-to-noise ratio, since the contribution of the interference signal is attenuated without affecting reception of the desired GNSS signals.

To achieve this goal, the signals of multiple antennas need to be phase coherently combined. This is illustrated in Fig. 17.17 for a simple set of two antennas with a PC separation of $\lambda/2$ and two delay elements that can be adjusted within the limits

$$0 \le \delta\phi_1 - \delta\phi_2 \le +\frac{\pi}{2} \,.$$

Using complex notation, the combined signal can be described as

$$\begin{aligned} S &= A\left(\mathrm{e}^{2\pi\mathrm{j}\left(\frac{\cos(E)}{2}+\delta\phi_1\right)} + \mathrm{e}^{2\pi\mathrm{j}(\delta\phi_2)}\right) \\ &= A\,\mathrm{e}^{2\pi\mathrm{j}\delta\phi_2}\left(1+\mathrm{e}^{2\pi\mathrm{j}\left(\frac{\cos(E)}{2}+\delta\phi_1-\delta\phi_2\right)}\right), \end{aligned} \qquad (17.14)$$

where $A$ denotes the single-antenna signal amplitude and $E$ is the elevation angle. For

$$\delta\phi_1 - \delta\phi_2 = \frac{1}{2}(1-\cos(E))$$

the total phase shift between both signals prior to combination amounts to half a wavelength, which results in a complete cancellation of signals received at this el-

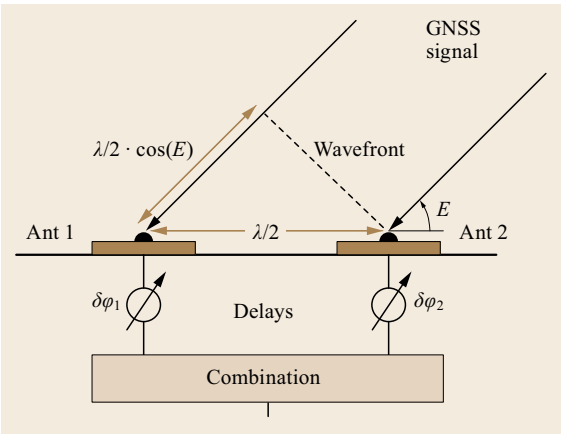

**Fig. 17.17** Schematic view of GNSS signal cancellation using two combined antennas

evation. For the given antenna geometry, exactly one null in the antenna diagram can be generated at a configurable direction in the plane of the illustration. This basic concept is easily extended to three dimensions using an array of $2 \times 2$ antenna elements, which then allows steering of the gain minimum throughout the entire hemisphere.

The common design strategy of the CRPAs is to put the individual antennas in the form of a circular array creating the nulls to be pointed in the direction of potential jammers. An important consideration in the design of a CRPA is the number of antenna elements as the number of nulls generated is usually one less than the number of individual elements [17.31]. However, this may come at the cost of reduced satellite visibility as increasing the number of antenna elements to introduce nulls reduces the antenna beam width [17.32]. Moreover, the large antenna array and complex electronics package increase the overall antenna mass and size. Compact arrays as described, for example, in [17.33, 34] offer better portability but are more challenging in terms of the required isolation between individual elements. An example of a seven-element antenna array for beamsteering and interference suppression is shown in Fig. 17.18.

Even though it is possible to build a CRPA as standalone unit that can be connected to arbitrary receivers like any other antenna, jamming-resistant GNSS terminals often involve a closely coupled design of the antenna elements and the receiver electronics. This is due to the fact that a phase-coherent combination of signals with variable delay from multiple input antenna elements can best be accomplished within the actual signal-processing chain. The use of software-defined radio techniques (SDR) and the ability to implement flexible signal-processing concepts in field programmable gate arrays (FPGAs) has enabled great progress in the design of jamming-tolerant GNSS receivers with multiantenna arrays for single- and dual-frequency applications.

The detailed design of CRPAs for GNSS antijamming applications and relevant beamforming algorithms exceed the scope of this chapter, but are readily covered in publications such as [17.30, 31, 35–37] along with practical examples and test results.

### 17.3.6 GNSS Remote Sensing

GNSS remote sensing [17.38] refers to a category of applications, where signals coming from the GNSS satellites are used to study diverse properties of the Earth's surface and atmosphere. While some of these applications do not require specific equipment, GNSS reflectometry, scatterometry, and radio occultation measurements are usually performed with specialized GNSS receivers as well as dedicated antennas.

GNSS reflectometry and scatterometry (Chap. 40) make use of GNSS signals reflected or scattered from oceans, land, or ice to retrieve information, such as wind speed, salinity, soil moisture, and ice-layer density, or even contribute to the detection of tsunami waves for disaster monitoring. The techniques resemble traditional radar and altimeter observations, but make the use of GNSS signals of opportunity and do not need an active illuminator as part of the instrumentation.

In the context of antenna design, a GNSS reflectometry antenna is usually a high-gain array antenna with an off-nadir pointing beam. A high-gain beam is required as the antenna needs to pick up weak reflected signals from a high-altitude (air- or spaceborne) platform, while the off-nadir pointing ensures a larger observation area. Since the polarization of the GNSS signals changes upon reflection, the reflectometry antenna is designed for LHCP signal reception.

**Fig. 17.18** Seven-element beamsteering antenna for multiband GPS, Galileo, and GLONASS reception (courtesy of DLR Institute of Communications and Navigation)

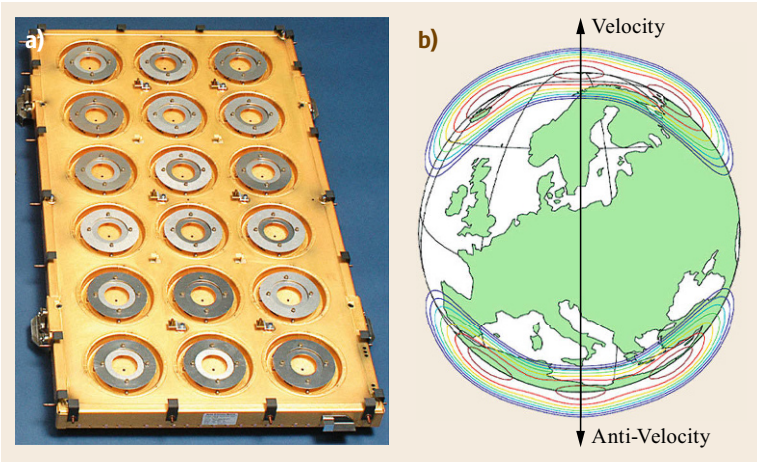

**Fig. 17.20a,b** Beam-forming array antenna for radio occultation measurements onboard the Metop satellites. **(a)** Separate antennas are used for the forward (velocity) and aftlooking (antivelocity) direction. The gain pattern of each antenna is adjusted to cover a narrow region close to the Earth's limb, where occultations from rising or setting GPS satellites can be observed **(b)** (courtesy of RUAG Space AB)

Figure 17.19 shows a three-element microstrip antenna array used as part of an early scatterometry experiment onboard the UK-DMC satellite [17.39]. The antenna works at the L1-band and follows a stacked configuration to achieve a greater than 12 dBiC gain. The design of a dual-frequency antenna array for spacebrone reflectometry applications is described in [17.40]. It has first been applied in combination with SSTL's SGR-ReSI (space GNSS receiver remote-sensing instrument) onboard the UK TechDemoSat-1 satellite [17.41].

Next to reflectometry, radio occultation measurements represent another GNSS remote sensing technique, which depends on specialized antenna designs for optimum performance. Radio occultations make use of signals propagating through the deep layers of the atmosphere between the transmitting GNSS satellite and a receiving satellite in low Earth orbit (Chap. 38). The GPS/Meteorology (GPS/MET) mission [17.42] has first shown that radio occultation can be used to predict accurate, all weather, global refractive index, pressure, density profiles in the troposphere, as well as electron density profiles and total electron content (TEC) of the ionosphere. Today, radio occultation measurements are routinely conducted by a variety of Earth orbiting satellites, which contribute directly to near-real-time weather prediction services.

Tropospheric radio occultation measurements are most challenging due to the pronounced attenuation experienced by the signals through the dense layers of the atmosphere. The situation is further complicated by severe losses experienced in the semi-codeless tracking of the GPS P(Y)-code signals that are still most widely used today, since a civil L2 signal is not yet available on the entire GPS constellation. Similar to reflectometry, the atmospheric sounding, therefore, benefits from array antennas, which provide a high gain in the direction of the horizon.

Figure 17.20 shows an 18-element array antenna for use with the global navigation satellite system receiver for atmospheric sounding (GRAS) onboard the metop satellites [17.43]. Each antenna element consists of RHCP concentric rings for dual-frequency (L1/L2) signal reception. The individual elements consist of a pair of concentric rings and are mounted in a cup in order to reduce mutual coupling and mitigate multipath interference. The ring elements are slot-fed, and an optimal performance for both frequency bands is obtained by using separate feed networks for each band [17.44]. Compared to smaller arrays used on other radio occultation missions, the large antenna array and sharp beamforming of the GRAS antenna contributes to a superior measurement quality achieved by the Metop satellites.

## 17.4 Multipath Mitigation

Multipath interference is one of the major error sources in GNSS, as it can severely degrade the accuracy of GNSS measurements. It arises when multiple copies of the same signal arrive at the receiver from more than one directions. This happens when the primary line-of-sight (LOS) signal suffers reflection or diffraction from the antenna surface or nearby objects. These attenuated and phase-shifted (delayed) signals are summed with the LOS signal in the receiver, which results in distortions of the correlation function and associated

errors in the range and carrier- phase measurements (Chap. 15).

A common multipath scenario is illustrated in Fig. 17.21 for a pole-mounted antenna. Here, the excess path difference

$$d = 2h \sin\theta \,, \tag{17.15}$$

between the direct signals and the signal reflected from the ground is usually much smaller than the GNSS code chip length. The receiver correlator may thus be unable to discriminate between the direct and reflected signals.

Multipath interference can be mitigated to a large extent by shaping the radiation pattern to have a sharp gain roll-off toward the horizon and by suppressing the sensitivity to signals received from the back of the antenna [17.45]. This helps in rejecting the reflected and diffracted signals coming from low- or even negative-elevation angles. Integration of external ground planes such as choke rings is amongst the popular methods for multipath mitigation at the antenna [17.28, 46, 47]. Alternatively, an antenna can be specifically designed to suppress the surface wave propagation [17.48–50], a stimulus for multipath interference, within the antenna structure. The present section discusses some of these techniques that are used to mitigate multipath in high-performance antennas. An overview of different multipath mitigation methods for GNSS antennas and an assessment of their performance are presented in [17.51].

### 17.4.1 Metallic Reflector Ground Plane

The simplest way to reduce the backlobe of an antenna is to put a metallic reflector underneath it. The metallic reflector will shield the antenna from the signals coming from below the horizon. A microstrip antenna can be directly mounted to a large reflector ground plane for performance improvement but generally most of the dual-frequency microstrip antenna designs have an integrated feed network at the most bottom. This makes the distance between the antenna base and the metallic reflector to be a critical parameter as putting it very close to the feed would generate higher order modes transforming the microstrip feed into a stripline configuration. Normally, the reflector is placed quarter of a wavelength ($\lambda/4$) away from the antenna base. Any electromagnetic energy coming toward the reflector would suffer a phase rotation of 180°, thereby forcing the antenna backlobes to be at minimum level.

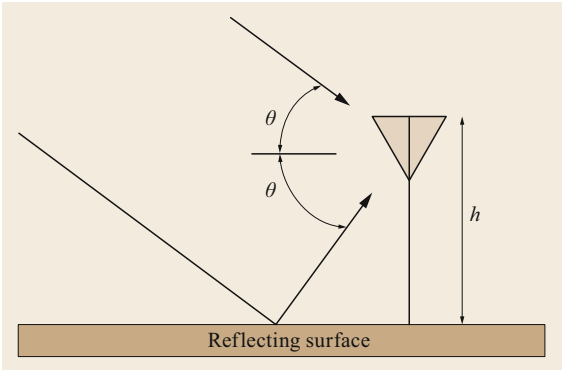

**Fig. 17.21** Typical multipath scenario for a ground-based GNSS antenna

### 17.4.2 Choke-Ring Ground Plane

Corrugated surfaces are widely used as ground planes (chokerings) to enhance the antenna performance. Their design is similar to corrugated horns, where metal corrugations are used to reduce the spill-over beyond a desired flare angle. Choke-ring ground planes help to sharpen the gain slope of the antenna radiation pattern, decrease side- and backlobe levels, thereby improving cross-polarization performance, and hence stabilize the antenna phase center. This is achieved by the cancelation of incoming waves after passing through successive corrugations as shown in Fig. 17.22.

Another interesting property of the corrugated surface is its high-surface impedance, which blocks the propagation of surface waves within the antenna substrate. Surface waves can occur on the interface between two dissimilar materials such as metal and air and travel along the boundary of the two surfaces. The high impedance of the choke ring is due to the quarter-wavelength deep corrugation which transforms the short-circuit boundary condition at the bottom of the corrugation to an open circuit at the top of the surface. Choke-ring ground planes are widely used with microstrip patch or Dorne–Margolin vertical dipole antenna elements for geodetic reference antennas with high PC stability and low multipath sensitivity.

The depth of individual groves needs to be larger than one-quarter and less than one-half of the signal

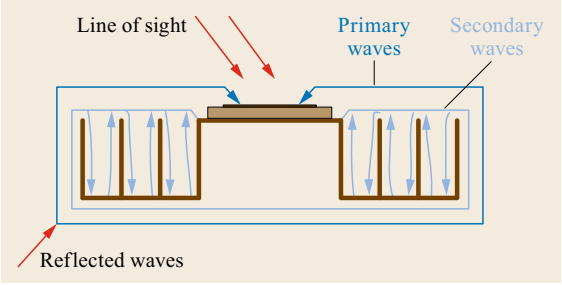

**Fig. 17.22** Field waves in a choke ring (after [17.46])

wavelength [17.17] for a *cut-off* choke ring that fully supresses the propagation of surface waves. Within this range, the lower value is preferred because of an optimum performance and smaller size of the resulting choke ring. To cover both the GPS L1 and L2 frequencies, traditional choke rings exhibit groves of about $\lambda_{L2} = 61$ mm and are thus best suited for the L2 signal. The implementation of a dedicated dual-frequency choke ring design that achieves different grove depths for L1 and L2 through the use of a frequency-dependent diaphragm is described in [17.46].

### 17.4.3 Noncutoff Corrugated Ground Plane

A corrugated ground plane with corrugation depth smaller than $\lambda/4$ is presented in [17.17] to achieve multipath mitigation at low-elevation angles. The ground plane, as shown in Fig. 17.23, achieves the surface wave suppression in a different manner than traditional choke-ring. Instead of creating a high-impedance region around the antenna, the shallow corrugations allow the surface waves to propagate toward the ground plane boundary, where they become out of phase with the line-of-sight signals and get canceled.

Although the simulation and measurement results presented in [17.17] show that the shallow corrugations can achieve respectable multipath mitigating performance, the ground plane requires a higher number of successive corrugations. This results in an increased diameter which partly compensates the benefit of the decreased choke-ring height.

### 17.4.4 Convex Impedance Ground Plane

The integration of the choke-ring ground plane with an antenna creates an impedance surface parallel to the antenna ground plane. Although this improves the multipath mitigation capability of the antenna, it also reduces the antenna gain at the grazing angles, thereby restricting the visibility of the low-elevation satellites. This happens as the grazing angles of an antenna with a flat ground plane coincide with the horizon. However, converting the flat ground plane to a convex one improves the antenna radiation pattern near the horizon while keeping the multipath mitigating capability.

A convex ground plane with pin structure has been presented in [17.52, 53] to achieve multipath capability over the GNSS band. The antenna design is shown in Fig. 17.24 where it uses an array of vertical convex dipoles capacitively coupled to the antenna feed. The overall antenna shows improved performance with regards to the visibility of low-elevation satellites.

### 17.4.5 3-D Choke-Ring Ground Plane

Despite the robust design and unique performance of the traditional choke-ring ground plane, it covers only a limited frequency range and provides poor sensitivity for satellites near the horizon. To cope with this limitation, a 3-D choke-ring ground plane has been proposed in [17.54]. Different from a conventional choke-ring ground plane, the 3-D choke ring has rings at multiple levels shaping it like a pyramid. The slots in the concentric rings allow the dissipation of unwanted RF energy. Similar to the convex impedance ground plane, a curved ground plane profile improves gain at grazing angles while keeping the PC stable.

The NovAtel GNSS-750 multi-GNSS reference station antenna shown in Fig. 17.25 integrates the 3-D choke-ring antenna with an ultra wide-band Dorne–Margolin antenna element. Test results for the build-identical Leica AR25 antenna [17.55, 56] confirm a notably improved low-elevation tracking along with a high PC stability over the entire frequency range, even though the forward–backward ratio is somewhat lower than that for a conventional 2-D choke-ring antennas.

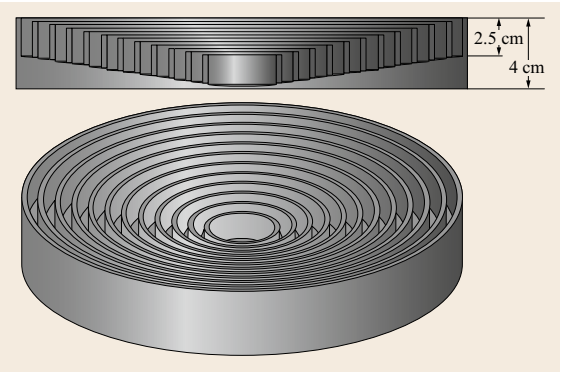

**Fig. 17.23** Noncutoff corrugated ground plane

**Fig. 17.25** Three-dimensional choke ring (courtesy of NovAtel)

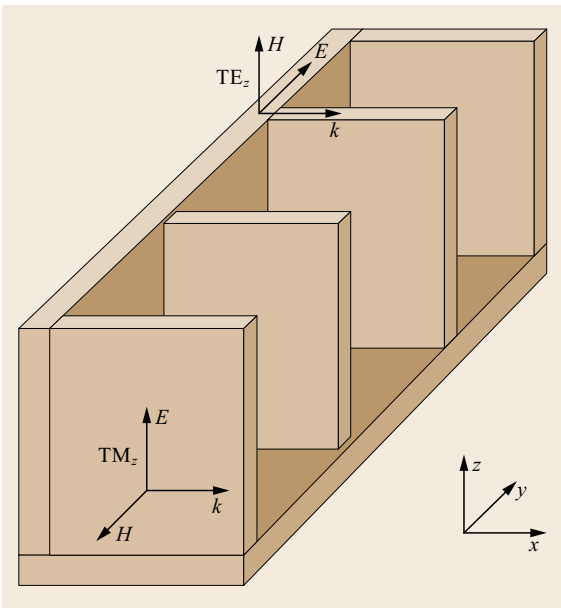

**Fig. 17.26** Vector representation of $TE_z$ and $TM_z$ waves on the cross-reflector ground plane surface (after [17.47])

### 17.4.6 Cross Plate Reflector Ground Plane

The design of a cross plate reflector ground plane (CPRGP) for multipath mitigation is discussed in [17.57]. Here, the antenna element is surrounded by a square of crossed sidewalls with a shape shown in Fig. 17.26.

Other than a flat perfect electric conductor, which only cancels the transversal electric ($TE_z$) waves, the cross plate reflector also cancels the transversal magnetic ($TM_z$) waves. This enables the reduction of the overall ground plane thickness to less than $\lambda/4$, that is, almost half that of a traditional choke ring. A prototype implementation of a dula-band CPRGP antenna using a shorted annular ring antenna element is presented in [17.47]. Tests confirm favorable multipath characteristics capabilities at a compact size of $19 \times 19 \times 3\,\text{cm}^3$.

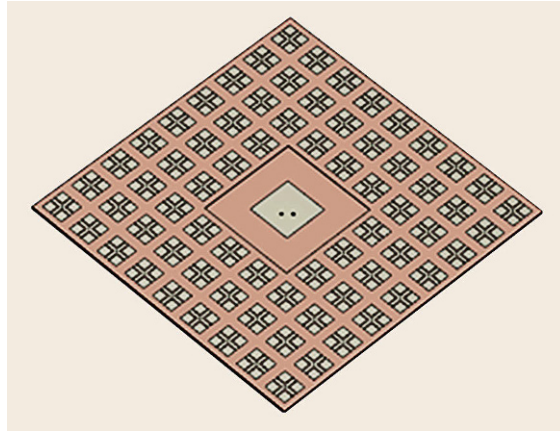

**Fig. 17.27** Dual-band patch integrated with EBG structure

### 17.4.7 Electromagnetic Band Gap (EBG) Substrate

Electromagnetic band gap (EBG) substrate [17.58] is a fairly new technique for surface wave suppression and has recently been used in GNSS for multipath interference mitigation. EBG surfaces are made by periodic structures producing very high surface impedance within a specified frequency band called the band gap where the high-impedance property is usually exploited for surface or lateral wave suppression [17.59].

An EBG substrate can be characterized by two properties, namely the employed material and the design of the EBG cells. A common EBG substrate design known as mushroom cell has properties similar to that of a corrugated metal surface. It blocks the propagation of surface waves by introducing a high-impedance region around the antenna. The high impedance is achieved by the two-dimensional distributed resonant circuit where capacitance is produced by the proximity coupling of periodic patch elements (mushroom hats in the mushroom unit cell) and the desired inductance is achieved by making loops of currents using via stems. A GNSS patch antenna integrated within an EBG surface is presented in Fig. 17.27.

## 17.5 Antennas for GNSS Satellites

Other than common GNSS receive antennas, which aim at a largely hemispherical gain pattern, the transmit antenna onboard a GNSS satellite needs to be highly directive to illuminate the Earth from a high altitude. While this could, in principal, be achieved with a narrow beam helix antenna pointed toward the nadir direction, such a solution poses two major disadvantages. Firstly, a notable fraction of the radiated energy would still pass by the Earth, if the gain variation across the visible surface of the Earth is kept small. Secondly, users in the nadir direction would always receive a higher flux than users near the rim of the Earth, since they benefit from both a smaller distance and a higher antenna gain.

Considering, as an example, the global positioning system with an orbital radius of $a = 26\,560$ km, the distance to the receiver varies between $r_{\min} = 20\,180$ km for a user (A) that sees the GPS satellite at zenith and $r_{\max} = 25\,780$ km for a user (B) that sees the GPS satellite near the horizon (Fig. 17.28). This corresponds to a factor of 1.6 or, equivalently, a 2.1 dB difference in the associated free-space loss.

### 17.5.1 Concentric Helix Antenna Arrays

To cope with this type of problem, shaped antenna patterns obtained by the combination of multiple antenna elements arranged in concentric rings have earlier been proposed for geostationary communication satellites [17.60]. They are based on the consideration that an M-shaped far-field antenna pattern with a local minimum along the boresight direction and a maximum near the apparent semidiameter of the Earth can be achieved by a specific choice of the illumination function across the antenna aperture. More specifically, the radial variation of the illumination function should be described by $J_1(x)/x$, where $J_1$ is the first-order Bessel function and $x = d/\lambda$ is the radial distance from the center of the aperture in units of the wavelength.

As discussed in [17.62], the ideal illumination function can be approximated by two concentric rings with suitably chosen radii that is populated with a total of 12 individual helix antenna elements (Fig. 17.29). The array comprises an inner ring of four antennas, which contributes the central peak of $J_1(x)/x$, while the outer antenna ring is placed at the first local minimum near $x = 4.6$. By feeding the outer antenna ring with a relative phase shift of 180° and using a reduced power for each antenna compared to the inner ring, a dip along the boresight direction is ultimately achieved in the far-field radiation pattern.

This concept was first implemented on the GPS Block I satellites [17.61] and successfully applied since then on all subsequent generations. It is also widely employed on other GNSS satellites as illustrated in Fig. 17.30 for selected GPS and Quasi-Zenith Satellite System (QZSS) satellites. The L-band antennas on the GPS Block IIR satellites comprise slim helices similar to the earlier Block I and II/IIA satellites, but are interleaved with an array of (shorter and thicker) ultra-high frequency (UHF) helix antennas on these satellites. A 4-plus-8 helix antenna array is also used by the GLONASS satellites. In the case of the latest K1 series, as shown in the figure, the free space between the inner and outer ringd is populated with retro-reflectors for satellite laser ranging. Finally, the figure shows the main L-band antenna of the QZS-1 satellite. It covers

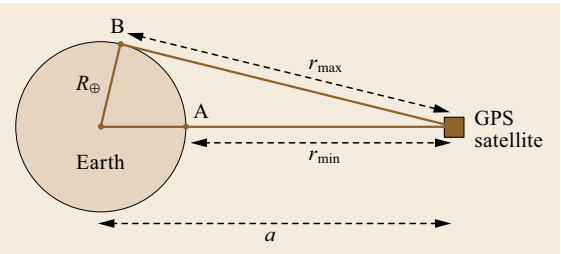

**Fig. 17.28** Geometric conditions for a GPS satellite transmitting navigation signals to the entire surface of the Earth. Points on the surface of the Earth with the minimum and maximum distance from the transmitting satellite are marked as A and B, respectively

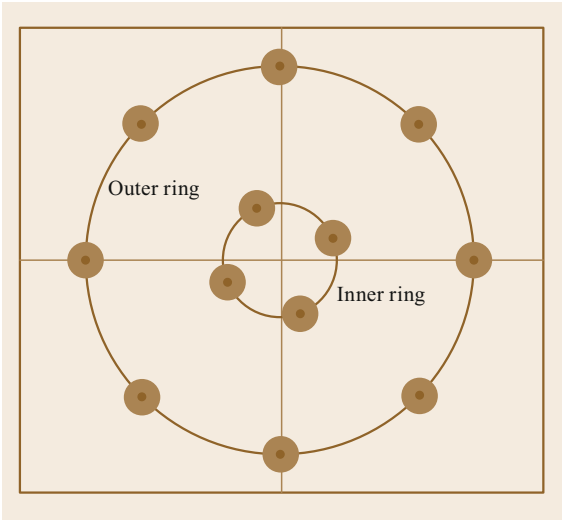

**Fig. 17.29** Arrangement of the 12 antenna elements on the GPS transmit antenna panel. The two rings have diameters of about 30 and 90 cm (after [17.61])

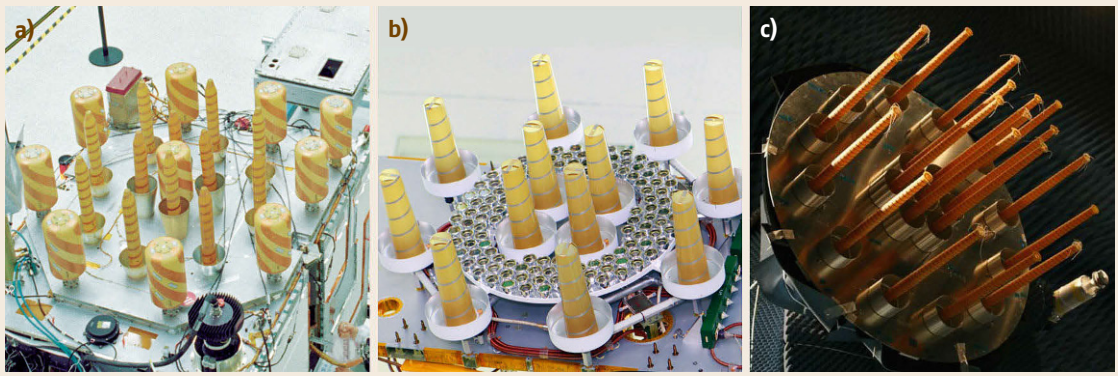

**Fig. 17.30a–c** Helix antenna arrays as used on the GPS Block IIR satellites (a), the GLONASS-K1 satellites (b) and the QZS-1 satellite (c) (courtesy of Lockheed Martin (a), ISS Reshetnev (b), and (JAXA) (c))

a total of four frequencies (L1, E6, L2, and L5) and is made up of a larger number of individual helix elements arranged in a central disk and an outer ring.

Measured antenna patterns are shown in Fig. 17.31 for two current types of GPS satellites (Block IIR and IIR-M) with slightly different antenna panels. A boresight angle of 0° refers to the nadir direction, while boresight angles of 14° mark the limb of the Earth as seen from the GPS satellite. The characteristic M-shape is most obvious for the L1 gain pattern of the Block IIR satellites, while an almost flat pattern over the entire surface of the Earth is obtained at the L2 frequency. Compared to the legacy IIR panel, the modernized panel of the IIR-M satellites uses new helix elements and a slightly modified arrangement, which results in the slightly modified overall gain pattern.

A diagram of the IIR-M gain pattern covering the entire hemisphere is shown in Fig. 17.32. Aside from the central main lobe, various sidelobes can be recognized at boresight angles near 30° and 55° at four distinct azimuth angles that reflect the four-quadrant symmetry of the antenna panel. The sidelobes point far off the Earth and are thus of no relevance for terrestrial and aeronautical navigation. However, their presence notably increases the availability of navigation signals for spaceborne users in high-altitude orbits around the Earth [17.63].

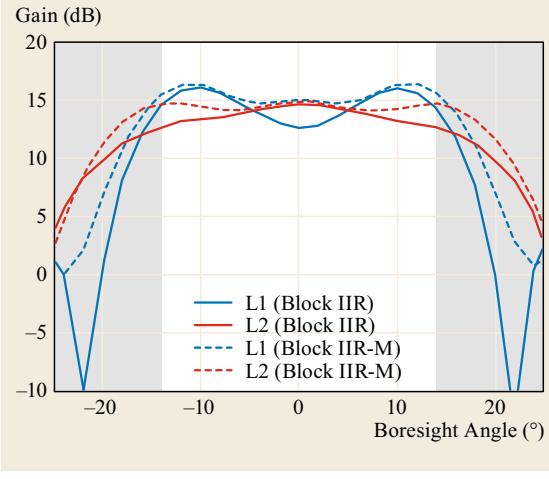

**Fig. 17.31** Gain pattern of GPS Block IIR and IIR-M satellites on the L1 and L2 frequencies (after [17.64]). *Shaded areas* mark regions outside the apparent Earth disk

## 17.5.2 Patch Antenna Arrays

As an alternative to the helix antenna arrays discussed above, the European Galileo system makes use of flat antenna arrays with a large number of individual patch elements to obtain the desired isoflux phase pattern over the E1, E6, and E5 frequency bands. Two different base designs are used on the individual satellites of the Galileo family. They include a hexagonal array of circular photo-printed patch elements developed by EADS CASA and used on Galileo in-orbit validation element (GIOVE)-B as well as the Galileo in-orbit validation (IOV) satellites as well as a near-circular array of four-layer stacked patches developed by Thales Alenia Space and used on the GIOVE-A and Galileo full operational capability (FOC) satellites (Fig. 17.33).

The Galileo IOV antenna consists of a densely populated array of photo-printed stacked patches generating a dual-band circular polarization. While 42 antenna elements were used on the GIOVE-B prototype, the number was later increased to 45 for the IOV satellites. The hexagonal array is formed by combining six sectors with six and nine elements, respectively, where some radiators in the outer periphery (three out of six sectors)

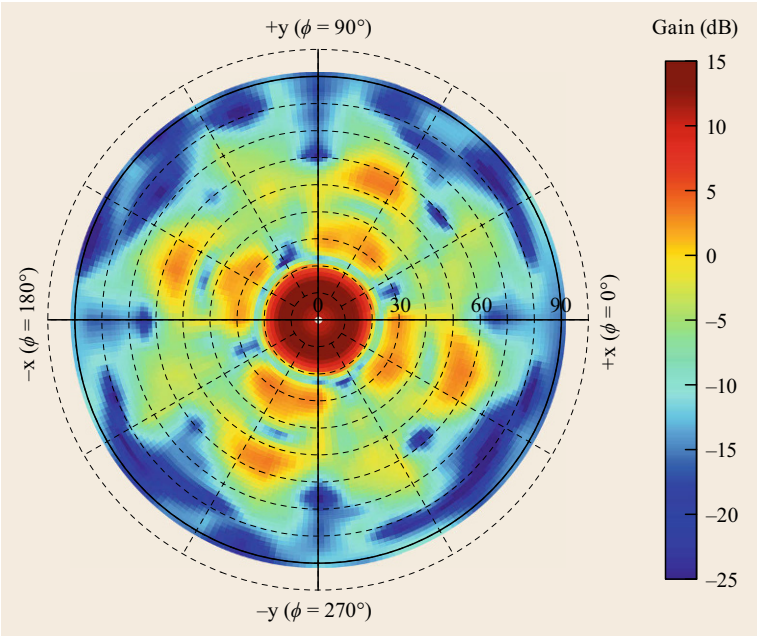

**Fig. 17.32** Color-coded representation of the L1 gain pattern for a Block IIR-M antenna as a function of azimuth ($\phi$) and boresight angle (after [17.64])

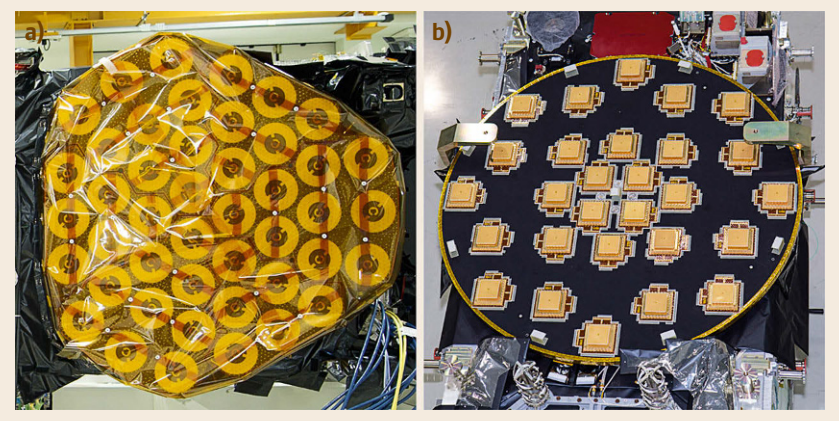

**Fig. 17.33a,b** Navigation antennas of the Galileo in-orbit validation (IOV) **(a)** and full operational capability (FOC) satellites **(b)** (courtesy of ESA and S. Corvaja **(a)** and OHB **(b)**)

of the antenna are slightly shifted in order to get the required field distribution across the antenna aperture. The M-shaped beam pattern is obtained by feeding the central and the external part of the array in phase opposition. Moreover, sequential rotation has been applied between consecutive sectors to improve the cross-polar performance.

The radiator is an arrangement of stacked microstrip patches fed by a coaxial pin. The smaller patch on the top is a circular ring microstrip and radiates at the E1 band, while a larger circular patch at the bottom radiates at the E5 and E6 frequencies. The RHCP at both bands is achieved differently. The top ring has two notches, while the bottom patch uses orthogonal feeds with 90° to obtain circular polarization [17.65]. A circular metallic wall surrounds the patches in order to shield the radiators in the array.

Key performance parameters of the IOV antenna are summarized in Table 17.3. Special care has also been taken to minimize passive intermodulation (PIM), that is, unwanted RF byproducts generated due to the nonlinear behavior of the transmitting system. Dedicated tests described in [17.66] confirm that PIM interference in the frequency bands of the near-by UHF search-and-rescue (SAR) antenna, the S-band telemetry, tracking and telecommand (TT&C) antenna as well as the C-band uplink receiver antenna are well below the noise and susceptibility level of those systems. Group delay variations in the individual frequency bands amount to $< 0.15$–$0.37$ ns (or 5–11 cm), while PCVs are confined

**Table 17.3** Galileo–IOV satellite antenna characteristics (after [17.65]) (LOC: limit-of-coverage, LB: low band, HB: high band)

| Parameter | Value |
|---|---|
| Orbital position | medium altitude Earth orbit (MEO) (23 616 km) |
| Frequency plan | 1145–1237 and 1259–1299 MHz (LB) 1555–1595 MHz (HB) |
| Polarization | RHCP both bands |
| Coverage and pattern | Isoflux corrected pattern (LOC: 12.67°) with 2 dB isoflux window |
| Minimum gain at LOC | 15.35 dBi (HB), 14.85 dBi (LB) |
| Maximum AR | 1.2 dB |
| Return loss and isolation | > 20 dB |
| Nominal power | 103 W (LB), 75 W (HB) |
| Mass | < 15 kg |
| Envelope | 1.38 m (diameter) 0.29 m (height) |

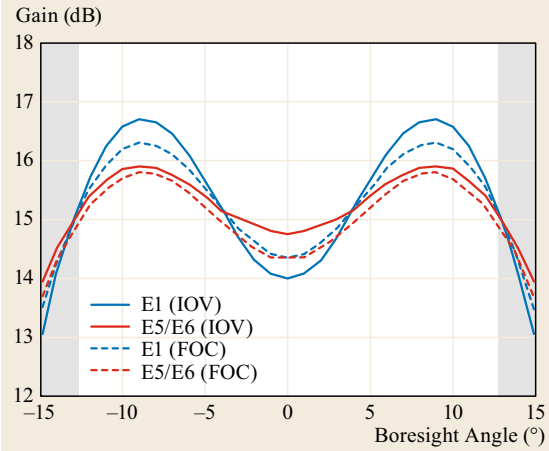

**Fig. 17.34** Gain pattern of Galileo IOV and FOC satellites in the upper and lower frequency bands based (after [17.67, 68]). *Shaded areas* mark regions outside the apparent Earth disk

to 4–7 mm over the 12.7° boresight angle range that covers the Earth from the orbital altitude of the Galileo satellites [17.67].

The Galileo FOC antenna (Fig. 17.33b) uses an array of stacked patch elements symmetrically arranged in four quadrants. It is inherited from the earlier GIOVE-A design but optimized to yield the desired performance with a lower number (28 versus 36) elements [17.68]. In addition, only the inner square of 12 elements covers the full set of three frequency bands (E1, E6, and E5), while the outer elements support either E1 and E6 (inner part of the outer ring) or E1 and E5 (outer part of outer ring). These design changes enabled a notably simplified feed network and helped to reduce the overall antenna mass to < 15 kg.

Compared to the fully populated IOV antenna, the arrangement of individual elements in the FOC antenna is similar to the helix antenna arrays discussed before and achieves the desired $J_1(x)/x$ intensity distribution in the aperture with a notably reduced number of patches. The M-shaped gain pattern of both Galileo antenna types is illustrated in Fig. 17.34 for the upper (1555–1595 MHz) and lower 1145–1299 MHz frequency bands. Both antennas closely approximate an ideal isoflux pattern with peak-to-peak gain variations of about 1.5–2.5 dB between nadir and the Earth's limb.

### 17.5.3 Reflector-Backed Monofilar Antenna

As an alternative to the helix and patch antennas discussed before, the use of a reflector-backed monofilar helix as GPS transmit antenna has been studied in [17.69]. In fact, a stepped parabolic reflector antenna had already been considered in the early design phase of the first GPS satellites. It offered a more uniform pattern than the helix array in use today but was discarded because of its notably higher sidelobes [17.61].

The design presented [17.69] uses a stack of two parabolic dishes with different diameter and focal length to achieve the desired M-shape gain pattern (Fig. 17.35). The monofilar helix is operated in backfire mode, sending most of the radiation from the feed point toward the reflector. At a diameter of only 6 cm, the helix itself causes only marginal obstruction. The reported antenna gain ranges from 12–15 dBiC for different GNSS frequencies and initial tests confirm a high

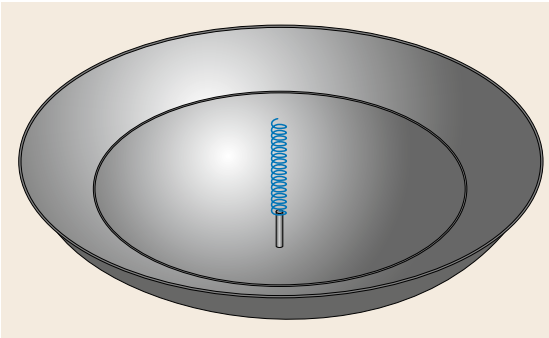

**Fig. 17.35** GNSS transmit antenna design based on a backfire monofilar helix element and a stacked reflector (after [17.69])

rotational symmetry of the achieved pattern. The simplicity of the overall design, which does not require an elaborate feed network, is claimed to result in notable cost savings compared to the traditional. However, reflector-based transmit antennas have not been adopted so far in actual GNSS satellites.

## 17.6 Antenna Measurement and Calibration

This final section discusses the testing and characterization of GNSS antennas. During the antenna design, the measurement of antenna parameters is of paramount importance to validate the desired function and performance. Although antenna simulation software gives the antenna engineer some idea of the expected behavior, human errors and manufacturing constraints may result in antennas which do not completely match the simulation results. Following a description of standard measurement techniques for the determination of basic antenna parameters, a dedicated subsection addresses the calibration of antenna phase patterns, which are of primary relevance for geodetic-grade user antennas as employed in all high-precision GNSS applications. Along with that, PC calibrations of GNSS transmit antennas are discussed.

### 17.6.1 Basic Antenna Testing

The testing of an antenna in general, and a GNSS antenna, in particular, requires sophisticated equipment for generating well-defined test signals and for measuring the overall system response. A typical setup for testing an antenna in receive mode comprises:

- A reference source antenna
- The transmit (TX) and receive (RX) system
- A positioning system
- The test facility (range).

These items are generic and are used for testing regardless of the antenna type or the subject application. Test setups for transmit antennas are similar to the above, except that the reference source antenna is replaced by a reference receive antenna. A sample facility for GNSS antenna testing is illustrated in Fig. 17.36.

The *reference source antenna* is the transmit antenna used to illuminate the antenna-under-test (AUT) and should have a stable PC and large bandwidth. Sectoral horns (linear polarized) and conical spirals (circularly polarized) are the few popular reference antennas. Since the GNSS antennas are designed to primarily receive or transmit RHCP signals, a conical spiral is usually the reference antenna of choice for the radiation pattern and gain measurements.

The *TX* and *RX systems* may comprise two distinct modules but can also be combined into a single unit. A vector network analyzer (VNA [17.71]) is a hybrid TX–RX test instrument very commonly used for the antenna gain and radiation pattern measurement. A VNA is used to measure four different *scattering parameters* (s-parameters) of a dual-port RF system such as a cable, filter, amplifier, or transmission line. With application

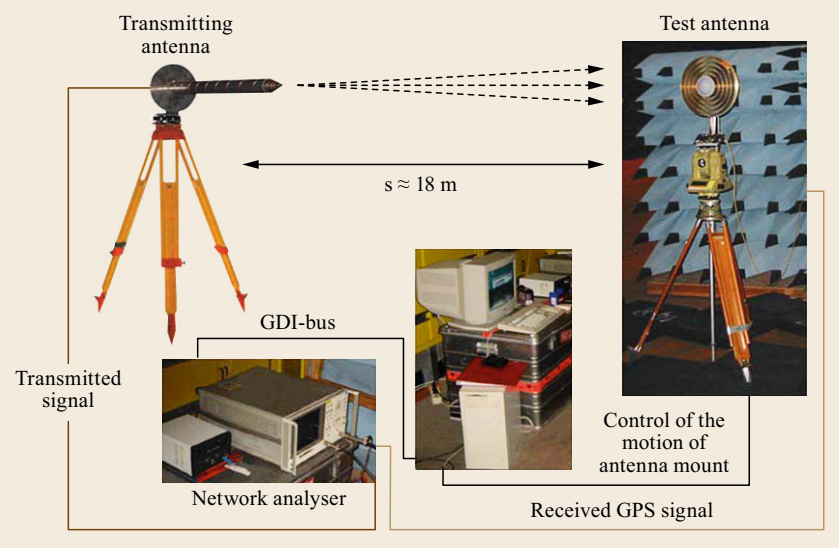

**Fig. 17.36** Anechoic chamber measurement setup for antenna testing (after [17.70])

to antenna testing, these parameters have the following meaning:

- $s_{11}$, the reflection coefficient of the antenna connected at port 1
- $s_{21}$, the transmission (from port 1 to port 2) between the two antennas connected at the ports
- $s_{12}$, the transmission (from port 2 to port 1) between the two antennas connected at these ports
- $s_{22}$, the reflection coefficient of the antenna connected at port 2.

Based on these measurements, the desired parameters of the test antenna can later be derived.

The *positioning system* enables controlled orientation changes of the test antenna to assess the variation of antenna parameters with incidence angle. It comprises a gimbal mount or robotic arm with at least two rotation axes, which can be computer controlled to change the orientation (and, optionally position) of the antenna relative to the incident radiation

The last and final element in the antenna testing is the identification of the antenna *test facility*. The primary prerequisite for accurate antenna testing is that both the antennas should lie in the far field. This implies that the angular dependence of the transmit antenna field no longer varies with the distance and that the wavefronts received at the test antenna are sufficiently flat in the vicinity of the AUT.

Given the moderate size of common GNSS receive antennas and the employed signal wavelengths, the testing is usually conducted in a *anechoic chamber*, that is, a room that is capable of absorbing electromagnetic radiation. This anechoic chamber is made by lining up the walls, ceilings, and floor with special electromagnetic wave-absorbing material. The material is often cut in pyramids of various sizes so that any remaining reflections tend to spread in random directions and to add incoherently which further suppresses their impact on the antenna measurements.

Using the equipment described above, diverse antenna tests can be conducted to ensure that it fulfills design requirements. Similar to any other antenna, a GNSS antenna is tested for common parameters such as impedance matching and gain. However, a few specialized parameters are also tested to ensure that the antenna performance is suitable for GNSS applications. The parameters commonly measured in practical GNSS antenna tests include:

- Reflection coefficient and impedance matching
- Frequency of operation and bandwidth
- Radiation pattern
- Gain and efficiency
- Antenna polarization and AR, as well as other values introduced in Sect. 17.1.

The reflection coefficient, frequency of operation, and the bandwidth of the antenna can be obtained from the $s_{11}$ reflection coefficient, when connecting the test antenna to the VNA and observing ($s_{11}$ or $s_{22}$). The typical outcome of such a test is presented in Fig. 17.37, which shows the reflection coefficient of a dual-band step-shorted GNSS antenna. The dual-frequency capability can clearly be recognized from the two frequency dips. The same curve can also be used to assess the impedance bandwidth of the antenna.

The antenna gain and radiation pattern are obtained from the measurements of the $s_{21}$ transmission coefficient across all incidence angles. However, appropriate calibration of the whole system is required in order to compensate for the transmission line as well as other losses. The gain pattern measurements can also be used to quantify the FBR as well as the multipath rejection ratio (Sect. 17.1) by comparing gains at different boresight angles.

Antenna polarization, finally, can be measured by testing the AUT against a reference antenna of known polarization. A receiving antenna will only have successful reception if the polarization matches that of the transmitting antenna. For quantitative AR measurements, the test antenna is measured successively against two linearly polarized antennas (vertical and horizontal).

### 17.6.2 Phase-Center Calibration

The performance achieved in carrier-phase-based positioning today (Chaps. 25 and 26) relies on high-accuracy observation models and a thorough character-

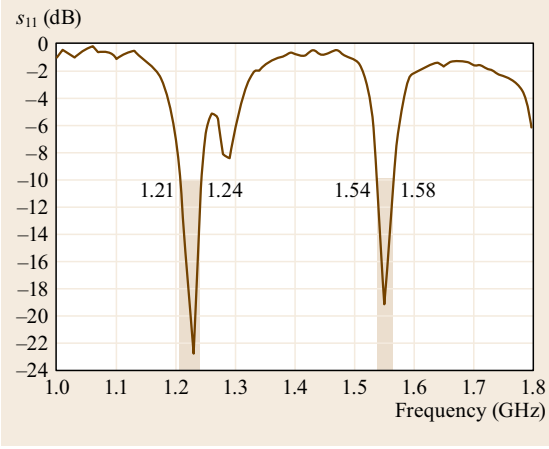

**Fig. 17.37** $s_{11}$ response of a dual-band GNSS antenna

ization of the measurement system. In order to exploit the (sub)millimeter precision of carrier-phase observations, a proper knowledge of the antenna PC is indispensable for both the receiver antenna and, in the case of absolute or long-baseline positioning, the transmit antennas onboard the GNSS satellites.

Driven by the needs of the geodetic community, dedicated antenna calibrations have, over many years, been conducted by various institutions in close cooperation with the international GNSS service (IGS; see Chap. 33). These calibrations presently cover a comprehensive set of geodetic-grade user antennas as well as the transmit antennas of GPS and GLONASS, which are sufficiently well observed by global GNSS monitoring stations [17.72].

### Concepts and Conventions

As already discussed before, the phase center is considered as the point from which all radiated energy appears to emerge. Given the finite dimension and specific design of an antenna, its PC is not necessarily identical to the geometrical center and may even fall outside the actual structure. It is, therefore, common to specify the PCO of the antenna with respect to a mechanical *antenna reference point* (ARP) that is well accessible and can be easily related to a physical marker of a given survey point (Fig. 17.38). For user antennas, the PCO is typically specified in a coordinate system aligned with the boresight–symmetry axis of the antenna ($z$-axis) and a fixed axis in the antenna plane ($y$-axis) identified by a north marker. Based on the assumption of a perfect antenna setup the $(x, y, z)$-axes of the antenna system are commonly equated to the east, north, and up direction when specifying antenna PCOs.

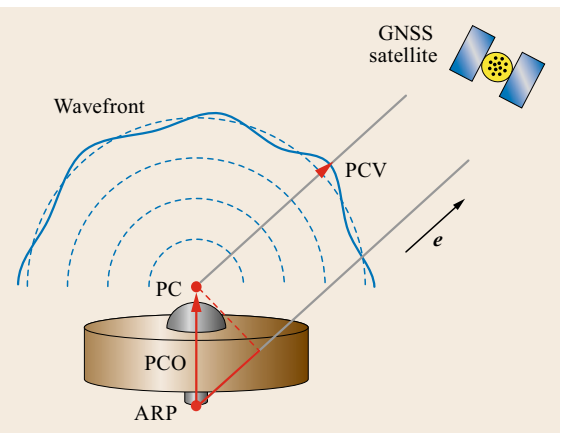

**Fig. 17.38** Schematic illustration of the antenna reference point (ARP), the phase center (PC) and phase center offset (PCO), as well as the PCVs for a receiver antenna. The *dotted lines* indicate idealized spherical wavefronts around the average PC

For GNSS satellite antennas, in contrast, a coordinate system aligned with the main body axes of the satellite is adapted, where the $z$-axis denotes again the (Earth-pointing) boresight direction, while the $y$-axis is aligned with the rotation axis of the solar panels. Details of the axes conventions adopted by the International GNSS service (IGS) for each constellation and type of satellites are documented in [17.73]. For practical reasons, GNSS antenna PCOs are commonly referred to the center of mass (CoM) of the spacecraft.

However, the concept of a unique PC is based on the idealized assumption of spherical wavefronts with a common center. In reality, the wavefront suffers various distortions induced by asymmetries of the antenna elements and the influence of the supporting structure on which the antenna is mounted (Fig. 17.38). The associated deviations from a point-like PC model are described by additional phase range corrections known as PCVs. Compared to the nominal range between the receiver ARP and the GNSS satellite CoM, the observed range differs by

$$\zeta_{\mathrm{PCO/PCV}} = \boldsymbol{e}^{\top}(\boldsymbol{r}_{\mathrm{PCO,sat}} - \boldsymbol{r}_{\mathrm{PCO,rcv}}) + (\zeta_{\mathrm{PCV,sat}}(-\boldsymbol{e}) + \zeta_{\mathrm{PCV,rcv}}(\boldsymbol{e}))\,, \qquad (17.16)$$

where $\boldsymbol{e}$ denotes the receiver-to-satellite unit vector, $\boldsymbol{r}_{\mathrm{PCO}}$ is the PCO vector (expressed in the same coordinate system), and $\zeta_{\mathrm{PCV}}$ describes the direction-dependent PCO for the satellite antenna (index *sat*) and the receiving antenna (index *rcv*), respectively. Equation (17.16) provides the basic observation model (Chap. 19) for the determination of PCO/PCV values from actual GNSS measurements as well as their application in precise positioning applications.

It may be recognized that (17.16) does not provide a unique distinction between PCOs and PCVs, since a change in the PCO value can always be compensated by a corresponding PCV change, a normalizing condition is required to separate both effects in an unambiguous manner. Common conventions include a zero-mean condition for the PCV over a given range of boresight angles or a zero PCV along the boresight axis.

Antenna calibration values recommended for geodetic processing and compatible with IGS orbit and clock products are distributed as part of the IGS antenna model [17.72], which is continuously updated to include new antennas and satellites. The respective PCO and PCV values are distributed in a standardized ANTenna EXchange format (ANTEX, see [17.74] and Annex A), which facilitates a consistent application in the positioning and orbit determination software.

### Receiver Antenna Calibration

Common techniques for the calibration of receiving antennas comprise of anechoic chamber measurements as well as relative and absolute field calibrations [17.75]. All of these can provide PC and pattern information for individual frequencies, but differ in a variety of practical aspects.

Anechoic chamber measurements, as described in the previous section, are among the earliest techniques employed for the PC characterization of geodetic antennas [17.70, 76]. Here, an artificial signal source – ideally a GNSS signal simulator – is used to provide navigation signals, and the phase response is measured while the test antenna is rotated around two independent axes. Anechoic chamber measurements, so far, provide the only means for PCO/PCV determination across all frequency bands utilized by current and emerging navigation satellite systems [17.77], but are so far limited in their availability.

Given this limitation and the complexity of anechoic chamber phase pattern measurements, relative field calibration has early-on been established as an alternative technique for antenna calibrations [17.78] and applied, among others, by the National Geodetic Survey (NGS) to characterize the phase patterns of most geodetic antennas. In this method, the receiver antenna is calibrated relative to a standard reference antenna. Both antennas are set up in close proximity on well-surveyed points and their relative position is determined from differential carrier-phase observations to obtain the PCO. Phase residuals with respect to the computed PC are then used to derive the PCVs.

To overcome the limitations of relative calibrations in the analysis of global geodetic networks, the IGS moved to an absolute antenna model in November 2006 [17.79]. It is based on field calibrations for the user antennas, which are obtained from GNSS measurements collected with a robot-mounted antenna (Fig. 17.39). Other than for a static antenna, the robot enables rapid changes of the boresight direction and the rotation angle. In this way, carrier-phase observations with a smooth hemispherical coverage of the antenna field of view can be collected in a short test campaign, based on which the PCO and PCVs can be inferred [17.80, 81]. Similar to chamber calibrations, the robotic measurements rely on the highly accurate knowledge of the translational motion of the ARP during antenna orientation changes.

In view of their availability for a comprehensive set of antennas as well as due to small differences between chamber and robot calibrations [17.70] that are a subject of ongoing research, only robot calibrations as well as converted relative field calibrations are currently incorporated into the IGS antenna model, which so far

**Fig. 17.39** Robotic test stand of Geo++, Hannover, for absolute field calibration of GNSS antennas (after [17.70])

(igs08.atx [17.72]) covers the L1 and L2 frequencies for GPS and GLONASS. An example PCV from robot calibrations of a geodetic antenna in the L1 frequency band is shown in Fig. 17.14. Benefits of the absolute PC model for the analysis of geodetic time series and the terrestrial reference frame are discussed in [17.79, 82].

### Satellite Antenna Calibration

Similar to receiver antennas, the aforementioned field and chamber calibration methods can likewise be applied to determine the PCO and/or PCVs of transmit antennas onboard the GNSS satellites. By way of example, relative field and robot calibration have been performed for the GPS Block II/IIA antenna array [17.83, 84], while PC/pattern calibrations using anechoic chambers or outdoor far-range test stands have, for example, been conducted for the antennas of the GPS Block IIR/IIR-M satellites [17.64, 85], selected antennas of the Galileo program [17.67, 86], as well as the two L-band antennas of the QZS-1 satellite. While these measurements can deliver PCO and/or PCV information for individual signals frequencies, they have neither been consistently applied to all GNSS satellites

nor can they fully account for the impact of the satellite body on the radiation field.

As part of the IGS antenna model, a different calibration technique is therefore employed, which estimates the antenna PCOs and, optionally, variations of all relevant GNSS satellites from observations collected with a global network of monitoring stations [17.87, 88]. Using the previously established absolute phase pattern corrections for the receiver antennas, the satellite PCOs (and PCVs) as defined in (17.15) can be obtained by adjusting these values along with other parameters, such as satellite orbits, station coordinates, and Earth orientation parameters from the observations (Chap. 34). The determination of PCOs for GPS and GLONASS satellites using this approach is discussed in [17.79, 89, 90] and a compilation of current values as used in the igs08.atx antenna model is given in [17.72]. For the BeiDou MEO and inclined geo-synchronous orbit (IGSO) satellites, initial PCO estimates have been reported in [17.91, 92], but further refinement will be required to establish a consolidated set of values for use in the IGS antenna model. For the Galileo FOC and IOV satellites, a first set of PCOs derived from observations of the IGS multi-GNSS network is reported in [17.93].

In various cases [17.89, 94, 95], azimuth-dependent PCVs have been obtained along with the PCOs of the GNSS transmit antennas. These patterns exhibit representative peak-to-peak amplitudes at the 10–30 mm level and typically reflect the symmetry properties of the respective antenna arrays. For practical purposes, only the boresight angle variation of the GNSS transmit antenna pattern is presently taken into account in the IGS antenna model. Even though the consideration of azimuth-dependent PCVs is likely to enable a further improvement in the GNSS data processing, they are not presently taken into account due to a lack of consistent PCV calibrations from multiple IGS analysis centers.

Other than chamber calibrations, the transmit antenna PCOs and PCVs cannot be determined for individual signal frequencies within the GNSS network processing but refer to a specific ionosphere-free linear combination of observations collected on two different frequencies (e.g., L1/L2 for GPS and GLONASS, E1/E5a for Galileo and B1/B2 for BeiDou). This constitutes an obvious limitation of the approach for future multifrequency applications and will need to be considered in the evolution of the IGS antenna models.

*Acknowledgments.* The authors of this chapter would like to thank the Editors of the book for their guidance during the development of this chapter. The authors would also like to thank Prof. Steffen Schön, Lori Winkler, and Prof. Dmitry Tatarnikov, who took time from their busy schedules and helped in getting the clearance for some of the key images required for this chapter.

# 18. Simulators and Test Equipment

Mark G. Petovello, James T. Curran

This chapter presents a review of a range of global navigation satellite system (GNSS) simulators and test equipment. Different types of systems are discussed, including radio frequency (RF) and intermediate frequency (IF) simulators; record and playback systems; and measurement simulators. The key features of each of these devices are examined, illustrating their various implementations, typical usage, and highlighting their individual benefits and drawbacks. The chapter concludes with an overview of considerations that should be borne in mind when selecting and using simulators and test equipment.

As a complement to previous chapters on receiver design and position estimation, this chapter looks at the role of global navigation satellite system (GNSS) signal simulators and related test equipment in the development of GNSS receivers.

Simulation plays many roles in various stages of a receiver's lifespan: initial component selection, algorithm development, fault-isolation and debugging, performance assessment, and final production-line quality-control, to name but a few. While all of these tasks could be performed using live GNSS signals, the use of a simulation resource can significantly simplify the task, increase efficiency, and provide higher test fidelity.

To generalize somewhat, one can consider that there are three types of testing that are conducted on receivers: known-response tests, performance tests, and exploratory tests.

Known-response testing is typical of quality control and fault-isolation, wherein the receiver is subject to a specific and well-defined scenario or stimulus, and its response is compared to a well-known reference response, representative of a properly functioning receiver. For quality control, a threshold is typically defined in terms of the difference between the reference and measured responses, and a pass or fail verdict can be ascribed. For fault-isolation or debugging tests, the particular stimulus may be carefully chosen to excite a specific feature or functionality of the receiver, thereby enabling a user to identify where the fault may lie.

Performance testing often takes a similar form, whereby a receiver may be subject to a well-defined

scenario or stimulus, and one or many of a set of typical receiver parameters may be examined. Common metrics describing receiver performance include, for example, time-to-first fix, acquisition or tracking thresholds, raw measurement accuracy, or position, velocity, and time (PVT) accuracy. These tests may be deterministic or statistical and may either be absolute measurements or may be relative to some reference data provided as input to, or generated by, the simulator. This kind of testing is often conducted, for example, during algorithm development, receiver prototyping or data-sheet generation.

Exploratory testing is the set of experiments or tests that an engineer may conduct to examine the behavior of a receiver or a system in a new or non-nominal scenario in order to evaluate new or different receiver algorithms or architectures. These tests are generally more qualitative than quantitative and seek to understand the behavior of the receiver, or to compare the behavior of multiple receivers under different scenarios.

Although these types of tests are quite different in nature and purpose, they have a number of common requirements: they require signals or stimuli that have the appearance of having originated from genuine GNSS transmissions and they require well-defined reference data. Genuine GNSS signals, of course, can be employed to excite or stimulate the receiver in the desired fashion, but may require a difficult, lengthy, and/or laborious test campaign. For example, inducing high-signal dynamics may require the use of a specialized vehicle, while inducing transmission channel effects may require dedicated test ranges. Moreover, attaining accurate reference data for the test can prove quite difficult. In these cases, the use of a simulator can greatly simplify and enhance the test procedure.

Unlike live testing, simulators generate highly controllable, configurable, and repeatable inputs to GNSS receivers. Moreover, depending on the part of the receiver that is to be tested, different types of simulators may be used. The most common type of simulator generates a radio frequency (RF) signal, but simulators can also be used to generate intermediate frequency (IF) samples, for injection behind the RF down-conversion stage. Simulators that generate receiver measurements can also be developed, which are useful for assessing navigation algorithms. All types of simulators allow users to choose from a range of constellation configurations, from a single, stationary satellite, to one or more systems (the U.S. Global Positioning System GPS, the Russian GLObal NAvigation Satellite System, GLONASS, the Eruopean Galileo, the Chinese BeiDou, etc.), at a single frequency or at multiple frequencies.

Depending on its purpose or format, a simulator may reproduce a version of a genuine scenario with varying degrees of fidelity. The simulated scenario need only reflect the genuine scenario with sufficient accuracy so as not to influence the results of a given test. Basic quality-control testing of a specific receiver component or function may only require a loosely modeled GNSS signal, perhaps as simple as a single-channel simulator producing a carrier modulated by the ranging codes and data. In contrast, to test the full navigation capabilities of a receiver, it may be necessary to employ a simulator producing a full constellation of satellite signals, including relevant errors and propagation phenomena. Testing receivers for mobile cellular handsets may require accurate modeling of a land-mobile satellite channel, whereas testing surveying receivers may place more emphasis on atmospheric errors. If only the baseband component of the receiver is to be tested, then a simulator may produce signals as they would appear at the entry to a baseband processor in a genuine GNSS receiver.

An interesting tradeoff between live testing and simulation is the use of record and playback systems. Unlike simulators, record and playback systems collect genuine GNSS data and allow the receiver developer to replay it as many times as necessary. These systems provide similar repeatability to that of traditional simulation tools, but make an interesting tradeoff between configurability and fidelity: capturing genuine GNSS signals ensures that all of the features of the genuine signals including all propagation phenomena are accurately captured. However, the exact properties of the signal that is captured may not be fully known and so acquiring accurate reference data may be difficult.

This chapter addresses all of the above aspects. It begins with an overview of GNSS and GNSS receivers and then discusses the basic requirements of a simulator. Different types of simulators and simulation techniques are introduced, discussed, and contrasted.

## 18.1 Background

This section provides an overview of GNSS and GNSS receivers from a simulation perspective. Equations are developed to describe the received signal as well as intermediate steps within a GNSS receiver. Based on this, different types of simulators are briefly defined, as are record and playback systems. The different types of simulators are then addressed in detail in later sections.

For the purpose of this chapter, Fig. 18.1 is a convenient high-level breakdown of GNSS and GNSS receivers. The left side of the figure represents the physical world and consists of two main parts. First, the physics and geometry component involves the position and velocity of the receiver and all satellites in view. This is used to compute the geometric range and range rate between the receiver and each satellite which is then contaminated by satellite and atmospheric errors. The second component represents the propagation channel which varies significantly between applications. In general, however, it accounts for effects such as free-space loss (geometric spreading), multipath, fading, shadowing, and antenna effects.

On the right side of Fig. 18.1 is a breakdown of a GNSS receiver under test. The first component is the front-end which is responsible for mixing the RF signal to near baseband, filtering, and sampling. This is also the first place where the receiver's oscillator is used. Second, the signal-processing component correlates the locally generated and incoming signals for use in signal acquisition and tracking. The outputs of this component are the pseudorange (code phase), carrier-phase, and carrier Doppler measurements that are passed to the third component of the receiver, namely the navigation solution. The navigation solution is responsible for generating the PVT estimates of the receiver.

### 18.1.1 Received RF Signal

This section presents a mathematical description of the RF signal at the output of a receiver's antenna (i. e., the left side of Fig. 18.1).

#### Physics and Geometry

The primary concern of the physics and geometry component is to describe the relationship between the receiver and a satellite, including all of the systematic errors related to propagation. In reality, satellites blindly broadcast signals toward the Earth, synchronized as closely as possible to their corresponding system time, and physics takes care of the rest. At the receiver, the satellite signals that are observed at any

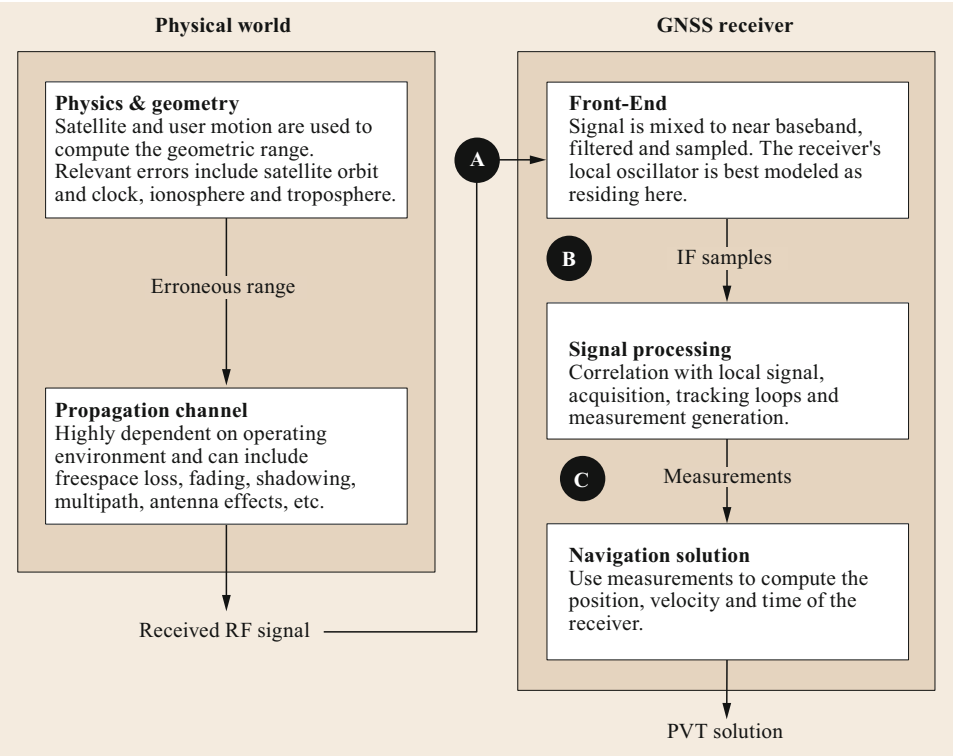

**Fig. 18.1** Breakdown of GNSS from a simulation perspective. The left side is a high-level description of what is taking place in the physical world that results in a signal observed at the receiver's antenna. The right side shows a high-level breakdown of a GNSS receiver; point A is the input for RF simulators, point B is the input for IF simulators, and point C is the input for measurement simulators

given point in time, say $t_R$, originated from some previous point in time, say $t_T$, from wherever the satellite was at $t_T$. Herein, $t_R$ is the time of reception or *receive time*, and $t_T$ is the time of transmission or *transmit time*. The time of flight, $\Delta t_{TOF}$, is thus the difference between the receive and transmit times

$$\Delta t_{TOF} = t_R - t_T \,. \tag{18.1}$$

For navigation, a receiver must compute the range between where the satellite *was* at $t_T$ and where the receiver *is* at $t_R$, all within the Earth-centered, Earth-fixed coordinate frame at the receive time. Since the receiver operates in its own time frame, $t_R$ is readily available even if it is nominally biased, and $t_T$ can be extracted from the satellite's navigation message. The pseudorange is then resolved as the difference between $t_R$ and $t_T$ scaled by the speed of light.

GNSS simulators are fundamentally different than what is described above because they are receiver-centric. That is, at a high level, input to a simulation consists of a series of positions and times of a *receiver* as well as a set of equations for the satellite positions over time (ephemerides), and it is the responsibility of the simulator to determine the transmit times for each satellite and, by extension, their corresponding position and velocity at that time.

Considering, for simplicity, the line-of-sight (LOS) case, the signal arriving at the receiver is effectively the same as the signal that left the satellite $\Delta t_{TOF}$ time ago. Thus, if $s_T(t)$ is the signal that left the satellite, then the signal that arrives at the receiver, $s_R(t)$, is approximately given by (a more detailed equation is given in (18.8))

$$s_R(t_R) \approx s_T(t_R - \Delta t_{TOF}) \,. \tag{18.2}$$

So the first task of a simulator is to calculate $\Delta t_{TOF}$ by examining how long it takes a signal to propagate from the satellite to the receiver. This is approximated here by the time needed to travel the geometric range at the speed of light in vacuum, plus some atmospheric-related delays

$$\Delta t_{TOF} = \frac{1}{c}\,||\boldsymbol{r}(t_R) - \boldsymbol{r}_{Sat}(t_T)|| + \frac{1}{c} L_{atm} \,, \tag{18.3}$$

where $\boldsymbol{r}(t_R)$ is the receiver position vector at time $t_R$, $\boldsymbol{r}_{Sat}(t_T)$ is the satellite position vector at time $t_T$, and $L_{atm}$ represents the delay induced by the atmosphere, in units of length, including the ionosphere and troposphere. Solving (18.1) for $t_T$ and substituting the result into (18.3) yields an expression for $\Delta t_{TOF}$ as an explicit function of $t_R$

$$\Delta t_{TOF}(t_R) = \frac{1}{c}\,||\boldsymbol{r}(t_R) - \boldsymbol{r}_{Sat}\,(t_R - \Delta t_{TOF}\,(t_R))|| + \frac{1}{c} L_{atm} \,. \tag{18.4}$$

Of interest is that the first term on the right side of this equation is only a function of the inputs to the simulator, namely receive time, receiver position, and satellite position (ephemeris). The second term needs to be modeled by the simulator.

Unfortunately, even if one ignores the atmospheric effects, (18.4) is somewhat difficult to handle as $\Delta t_{TOF}$ appears on both sides. Moreover, as has been discussed in Chap. 3, the function describing the satellite position is not simple since it must account for, amongst other things, the effect of Earth rotation during $\Delta t_{TOF}$ [18.1]. Fortunately, (18.4) is quite smooth and can be readily solved using recursion.

It is also noted that by changing $t_R$, (18.4) implicitly accounts for Doppler effects. Specifically, realizing that the numerator of the first term on the right-hand side of (18.4) is the geometric range, the derivative of $\Delta t_{TOF}$ with respect to $t_R$ is, to first order, given by

$$\frac{\mathrm{d}\Delta t_{TOF}}{\mathrm{d}t_R} = \frac{1}{c}\dot{\rho} + \frac{1}{c}\frac{\mathrm{d}L_{atm}}{\mathrm{d}t_R} \,, \tag{18.5}$$

where $\dot{\rho}$ is the geometric range rate which is related to the perceived Doppler shift by dividing by the carrier wavelength. The range rate can be expressed in terms of the satellite and receiver trajectories at any given instant by [18.2]

$$\dot{\rho} = \frac{(\boldsymbol{r}(t_R) - \boldsymbol{r}_{Sat}(t_T)) \cdot (\boldsymbol{v}(t_R) - \boldsymbol{v}_{Sat}(t_T))}{||\boldsymbol{r}(t_R) - \boldsymbol{r}_{Sat}(t_T)||} \,, \tag{18.6}$$

where $\boldsymbol{v}_{Sat}(t_T)$ is the satellite velocity at the time of transmission and $\boldsymbol{v}(t_R)$ is the receiver velocity at the time of reception. This expression is quite useful as $\dot{\rho}$ actually changes relatively slowly with time, and is approximately constant over a millisecond, that is, the smallest ranging code period used in GNSS (Chaps. 7–10). Simulators often exploit this fact and perform a linear approximation to the $\Delta t_{TOF}$ function with piece-wise sections of constant $\dot{\rho}$, effectively producing signals which step between short periods of constant Doppler.

Before writing the equation for the received signal, a simplified equation for the signal transmitted by the $i$-th satellite can be written as

$$s_{T,i}\,(t) = AC_i(t)D_i(t)\cos\,(2\pi f_{Nom} t) \,, \tag{18.7}$$

where $A$ is the amplitude of the transmitted signal which is assumed constant over time and across satellites, $C$ is the ranging code sequence, $D$ is the navigation data bit sequence, and $f_{\mathrm{Nom}}$ is the nominal RF carrier frequency (e.g., 1575.42 MHz for GPS L1 C/A). Equation (18.7) assumes that only a single signal on a single carrier is broadcast, but this can be easily generalized by adding additional terms. Similarly, different types of ranging codes and pilot signals can also be accommodated with additional terms. Then, the composite received signal can be expressed as the sum of the signals that left the satellites at their respective times of transmission

$$s_{\mathrm{R}}(t_{\mathrm{R}}) = \sum_{i}^{N_{\mathrm{SV}}} \alpha_i(t_{\mathrm{R}}) s_{\mathrm{T},i}(t_{\mathrm{R}} - \Delta t_{\mathrm{TOF},i} + \mathrm{d}t_{\mathrm{SV},i}) + n(t_{\mathrm{R}}) \ , \tag{18.8}$$

where $N_{\mathrm{SV}}$ is the number of satellites in view of the receiver, $\alpha$ is the attenuation of the received signal due to the propagation channel, and $n(t)$ is thermal noise. These latter two terms are expressed as a function of receive time because they are primarily a function of receiver location and/or hardware. An astute reader will have also noticed the inclusion of one extra term, $\mathrm{d}t_{\mathrm{SV},i}$ representing the satellite clock error. At the time the signal left the satellite, it was modulated according to the satellite's onboard clock. Although the true time may have been $t_{\mathrm{T}}$, according to the onboard clock, it is $\mathrm{d}t_{\mathrm{SV},i}$ seconds later/earlier, and so the signal parameters – code phase, carrier-phase, carrier Doppler, and data bit – will actually represent that at time $t_{\mathrm{T}} + \mathrm{d}t_{\mathrm{SV},i}$. Thus, satellite clock errors manifest themselves as range errors, just as receiver clock biases do, albeit at the *other* end of the signal.

Finally, it is noted that while the above model represents the LOS case only, a similar model can be readily constructed for the specular multipath case, provided a suitable equivalent for (18.3) can be found that represents the geometry of a reflected signal.

### Propagation Channel

The propagation channel nominally encompasses all of the effects on the signal between the satellite and the receiver. Having already discussed the factors influencing the time of flight, this section examines the factors affecting the signal quality. The key effects to be considered are briefly discussed below.

*Free-Space Loss.* Also called geometric spreading, this accounts for the loss of power intensity per unit area as the signal propagates away from the satellite. For Earth-based GNSS applications, the free-space loss differs by at most about 1 dB (depending on satellite elevation), but this variability is largely reduced [18.3] by proper shaping of the satellite's antenna gain pattern. In contrast, space-based applications may experience very different received powers due to the much wider range of distances to the satellites and the satellite antenna gain pattern (discussed below) [18.4–6].

*Shadowing.* This is the attenuation of signals resulting from propagation through natural or man-made obstructions such as trees, people, buildings, or vehicles [18.7, 8]. Depending on the receiver, shadowing may prohibit tracking of the signal.

*Antenna Effects.* With reference to Chap. 17, the most important antenna effects in the context of simulation are its gain pattern and axial ratio, which affect the received signal power. For Earth-based applications, the primary concern is for the receiver antenna, including phase variations that result from changing the orientation of the antenna relative to the satellites due to phase wind-up [18.9, 10] or phase-center variation, which, in turn, may depend on the assumed dynamics of the receiver (e.g., when a ship turns, the antenna also rolls). However, for space-based applications, the effect of the satellite's antenna gain pattern is critically important for correctly determining the received signal power [18.4–6].

High-accuracy positioning applications are also concerned with the phase-center variation/stability of the antenna which can introduce small (millimeter- to centimeter-level) systematic or randomly varying errors [18.11]. Some users may also be concerned with the antenna frequency response, perhaps wishing to investigate the rejection of out-of-band interference.

*Multipath and Fading.* As discussed in Chap. 15, multipath arises when a signal arrives at the receiver via multiple paths. Multipath is primarily a function of the reflectors in the vicinity of the receiver, but the large number of parameters needed to model the reflectors (i. e., their electrical characteristics, locations relative to the receiver, etc.) make it virtually impossible to predict in real time. A negative by-product of multipath is the decrease in received signal power that results from the destructive interference of two or more signals at the antenna. In extreme cases and/or when the signal is already attenuated, these *fades* may cause the receiver to temporarily lose lock on the signal [18.7, 8].

After the consideration of the propagation channel, the signal received via a single path still satisfies the general form of (18.8) with two differences. First, the amplitude term is the combination of several effects

$$\alpha(t_{\mathrm{R}}) = \alpha_{\mathrm{FSL}}(t_{\mathrm{R}}) \cdot \alpha_{\mathrm{Shdw}}(t_{\mathrm{R}}) \cdot \alpha_{\mathrm{Ant}}(t_{\mathrm{R}}), \tag{18.9}$$

where $\alpha_{FSL}$ is the attenuation due to free-space loss, $\alpha_{Shdw}$ is the attenuation due to shadowing, and $\alpha_{Ant}$ encapsulates antenna gain pattern effects (amplification or attenuation). Second, in the presence of multipath, all received paths need to be included in the summation in (18.8).

### 18.1.2 GNSS Receivers

This section provides a high-level description of what happens within different components of the receiver. In particular, features of the received signal that have a significant impact on different receiver components are highlighted. This will be used in Sect. 18.1.3 to motivate different types of simulators and their features.

#### Front-End

The front-end is generally the interface between the received RF signal (either real or simulated) and the remainder of the receiver. Its purpose is to accept an RF signal from the receive antenna or directly from the simulator, and produce digitized IF samples for the signal-processing stage. A receiver's front-end is generally comprised of a signal pre-amplification and filtering stage, one or more stages of down-conversion, anti-aliasing filters, gain control and, finally, analog-to-digital conversion (ADC; see Chap. 13).

The key factors that are of interest in measuring the performance of the front-end include: the oscillator quality as observed in the IF signal phase process; noise performance or noise figure; spectrum quality, including appropriate suppression/rejection of local oscillator harmonics; gain control, and digitizer performance. When available, direct analysis of the output of the front-end provides a useful means of assessing these factors.

#### Signal Processing

The receiver's signal processing is discussed in detail in Chap. 14. Here, it is noted that the basic task conducted in the signal-processing stage of a receiver is to process IF samples in order to produce pseudorange (code phase), carrier-phase, and carrier Doppler measurements for the navigation solution. Of particular interest are the parts of the received signal that stress the acquisition and tracking algorithms. For example, the received signal and noise levels are particularly significant in the acquisition stages; multipath and fading are generally most significant in the code-tracking algorithms; and, reference oscillator stability, scintillation, and LOS dynamics have the most impact on carrier-phase tracking [18.12–14].

In most cases, with the exception of vector or ultra-tightly (deeply) coupled receivers (Chaps. 13 and 18), the signal-processing stage operates on a signal-by-signal basis. From a tracking perspective, the loop bandwidths are generally wide enough such that slowly-varying errors due to atmospheric delays, orbital errors, and intersystem clock biases, to name but a few, are not observable here. Practically, this means that these errors pass through this part of the receiver unchanged and thus only manifest themselves in the measurements. More details on the outputs of the signal-processing stage are as described in Chap. 19.

#### Navigation Solution

The navigation solution accepts the pseudorange, carrier-phase and/or carrier Doppler measurements generated by the signal-processing step and uses them to compute the PVT solution of the receiver. The key challenge here is to remove as many of the systematic errors as possible prior to processing the measurements. Blunder detection (data snooping; see Chap. 24) should also be included in order to improve the overall reliability of the solution. Details for computing the PVT solution are included in later chapters.

### 18.1.3 GNSS Simulators

Having broken down GNSS and GNSS receivers in Fig. 18.1, this section introduces different types of simulators, their key requirements, and their purpose. Details of different simulators are given in Sects. 18.2–18.5.

#### Types of Simulators

Recalling Fig. 18.1, points labeled A, B, and C represent different locations within a receiver where simulated data can be injected. By extension, depending on what part of the receiver is being tested, points B and C, plus the PVT solution itself, can be interpreted as outputs that can be analyzed to assess performance. With this in mind, three types of simulators are identified:

- *RF-Level Simulators*: Using a combination of software and hardware, these simulators generate RF signals that can be fed directly into any commercial GNSS receiver. RF simulators allow for complete end-to-end testing of the receiver with the exception of the antenna, whose effects are usually modeled in the simulator itself such that the signal does not need to be broadcast over the air; this is called *conductive testing*. However, rebroadcasting the RF signal in an anechoic chamber would allow the antenna to be included in the testing chain;

this is called *rebroadcast testing*. Correspondingly, RF-level simulators are the most common types of simulator. Current manufacturers of such simulators, and sample current models, include: Spirent's GSS9000; Spectracom's GSG-6 Series; Rohde and Schwarz's SMBV100A Vector Signal Generator; and IFEN's NAVX-NCS product line.

- *IF-Level Simulators*: By generating a sequence of IF samples, IF simulators bypass the receiver's front-end and provide input directly to the signal-processing stage. Since most commercial receivers do not provide direct access to the signal-processing stage, IF simulators are typically reserved for research and in-house testing and/or used for testing software receivers – where all digital processing is performed using a reconfigurable architecture, be it pure-software, reconfigurable hardware such as field programmable gate array (FPGAs), digital signal processors (DSPs), or some combination thereof. IF simulators can, however, be coupled with a playback system (Sect. 18.1.4), to effect an RF simulator. A number of IF simulator products are currently available (most including playback capability as well), including: Averna's URT-5000; National Instruments' Global Navigation Satellite System Toolkits; M3 Systems' GNSS Test Platform; and RACELOGIC's LabSat 3 GPS Simulator.
- *Measurement-Level Simulators*: These simulators are used for testing a receiver's navigation solution, or an independent data-processing software. Assuming a receiver can properly track a signal without introducing any unexpected effects, measurement simulators are primarily concerned with modeling the systematic GNSS errors (e.g., orbit errors, atmospheric effects, etc.) as well as the stochastic errors arising from noise and multipath. Several different measurement-level simulators have been produced, many of them based on MATLAB®. Some of the more common simulators are the SATNAV Toolbox 3.0 from GPSoft LLC, the GPS Toolbox 5 from L3NAV Systems and the Galileo Service Volume Simulator from the European Space Agency (ESA) [18.15].

The type of simulator affects two things: the stages of the receiverthat can be tested and the phenomena that the simulator needs to simulate. Obviously, a simulator can only be used to test components of the receiver downstream of its entry point. By extension, for a given entry point, the simulator will usually simulate all of the *relevant* errors upstream from the entry point to adequately satisfy the testing requirements. For example, IF simulators can only test a receiver from its signal-processing stage and later, in which case the simulator must simulate the effects of the front-end and earlier.

The concept of *relevant* errors is critically important and can vary based on what is being evaluated. If the user intends to perform an *end-to-end* test starting from a given entry point through to the PVT solution, then indeed all effects above the entry point should be accounted for in the simulation. However, some tests may focus on a single stage of the receiver that may ease the simulation requirements. For example, consider testing only the signal-processing stage. As discussed in Sect. 18.1.2, low-frequency errors such as orbit error, atmospheric errors, and so on have no appreciable effect on this stage and thus would not need to be simulated. In contrast, tests of the navigation solution will almost certainly require simulating the low-frequency errors.

In general, simulating every effect is ideal, but this may be too costly and/or too time consuming, especially if a simulator is being developed in-house. In such cases, the user must decide if certain errors can be omitted from the simulation, or perhaps simulated with lower fidelity. This decision will depend on the type of simulator available and on the level of access to intermediate outputs within the receiver.

### Key Requirements

Regardless of the type of simulator considered and the tests being conducted, all simulators operate on the idea of simulating a particular *scenario*. Scenarios may differ for a variety of reasons including the location of the user, type of propagation channels considered, assumed receiver dynamics, level of atmospheric errors, etc. In all cases, however, simulators should provide scenarios that are:

- *High-Fidelity*: The simulator should be capable of producing a signal that is consistent with what the receiver is expecting and what, specifically, is being tested. This includes signal fidelity (structure, bandwidth, etc.), error fidelity, motion fidelity, etc. Some of these aspects, such as user motion, can be replicated with very high accuracy. Other errors, shadowing, for example, cannot be modeled easily or reliably; the model may be too smooth, not smooth enough, or may not exhibit the full range of values. Specifications for the fidelity of the simulation may vary considerably between application, receiver under test, and/or what part of the receiver is being tested.
- *Controllable*: The user should be able to modify/configure scenario parameters to excite the re-

ceiver in an appropriate manner. A simulator should be configurable to produce a sufficiently wide variety of scenarios so as to adequately evaluate receiver performance. The more variety that can be provided, the better the features and limitations of a receiver can be identified.

- *Repeatable*: A simulator should be capable of reproducing a scenario with sufficiently high repeatability that successive runs of an experiment produce equivalent results to within the expected level of accuracy. Repeatability is important when a user wishes to make precise measurements and requires that the test/retest variability is low. Otherwise, poor repeatability will result in high experiment variability and may mask the measurement being made. This can be particularly important when analyzing chaotic phenomena, such as carrier-phase cycle-slipping, receiver loss-of-lock and re-acquisition behavior, where small differences in the initial conditions can have a very large effect on the experiment outcome. The level of repeatability of a particular test will also have a direct impact on the precision with which quality control can be conducted.

### 18.1.4 Record and Playback Systems

Closely related to simulators is the concept of record and playback. Figure 18.2 shows a high-level view of a testing scenario involving a record and playback system. The *recording* phase accepts live RF signals as input, uses a front-end to shift the signal to IF, samples and digitizes the signal, and then writes the IF samples to a file.

Then, at some later point in time, the *playback* phase reads the IF samples and converts them to an analog signal at IF, shifts the signal back up to RF, and then outputs the RF signal.

The key difference of a record and playback system relative to a simulator is the loss of control over the input. This can be viewed as both a positive and negative characteristic. On the one hand, without special data-collection processes or equipment, it prevents the determination of the receiver's absolute position and the propagation/measurement errors that were present, thus limiting the ability to fully test the receiver. On the other hand, it allows for testing under *real* operating environments and, as such, circumvents any limitations that may exist in the simulator models.

In light of the above, record and playback systems can be viewed as hybrids of RF-level and IF-level simulators. Similar to an RF simulator, they generate an RF signal that can be used to test all aspects of the receiver. They even provide an additional advantage of including real antenna effects that were incurred during the recording phase. At the same time, the IF samples could be fed directly into a receiver, bypassing the RF portion altogether, thus mimicking an IF simulator. Conversely, if an IF simulator is available external to the record and playback system, the record and playback system could be used to convert those IF samples to RF (as discussed in Section 18.2, this is becoming the norm).

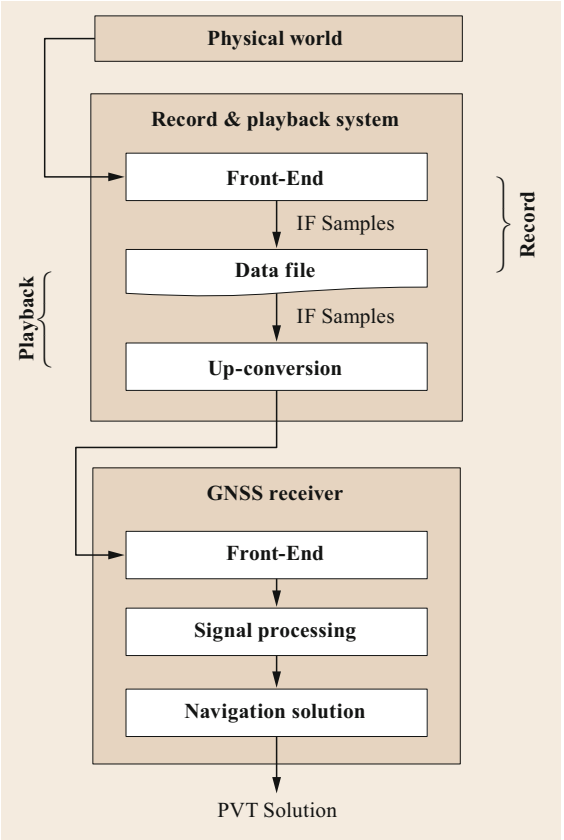

**Fig. 18.2** Flowchart for a record and playback system. Although drawn as a continuous process, the recording and replay are done as separate steps

Record and playback systems can also be used in innovative ways to improve or expand testing capabilities. For example, strong signals could be collected, but the replayed signal could be attenuated before passing the RF signal to the receiver. Similarly, interference-free data could be collected and different types of interferences could be added after the fact to assess its effect on the receiver [18.16, 17]. Or, since the recording phase is not limited to GNSS signals (except perhaps in terms of the center frequency and bandwidth), the system could be used to collect interference signals that occur in select locations and then replayed and combined with real or simulated GNSS signals.

Although relatively new to the GNSS community, several record and playback systems are commercially available. Examples include Averna's RP-3200 Wideband RF Record & Playback system, RACELOGIC's LabSat 3 GPS Simulator, and Spirent's GSS6400. Other systems, such as the National Instruments USRP-based (Universal Software Radio Peripheral) system, can also be used for GNSS with the added benefit of being able to also record and playback signals in other frequency bands.

### 18.1.5 Details

The rest of this chapter expands on each of the different GNSS simulators introduced above, including record and playback systems. Emphasis is placed upon implementation details, important considerations and, where appropriate, practical challenges and issues helpful for those with less experience with GNSS receiver testing. After each type of simulator is presented, the combination of real and simulated signals is discussed which can prove to be a powerful testing approach.

## 18.2 RF-Level Simulators

An RF GNSS simulator presents to the receiver an RF feed similar to what it would expect at the output of an antenna. In the case that the receiver has an enclosed or nonremovable antenna, it is possible to rebroadcast the simulated RF signal using a transmit antenna and a suitable anechoic chamber or enclosure to avoid multipath effects. Being the earliest entry point to the receiver flow, RF simulation maximizes the number of features of the receiver that can be examined.

The choice of simulator is generally constrained by the tests that are to be carried out, the features of the receiver the user wishes to examine, and by the accessibility of the receiver. For example, an RF simulator is appropriate when the user wishes to:

- Conduct an (almost; the antenna is usually omitted) end-to-end test of a receiver under predefined and repeatable scenarios, for example, when developing receiver specifications (acquisition and tracking) or in a quality-control procedure.
- Test the front-end in isolation, when IF samples are accessible to the tester, such that the performance of the filtering, down-conversion, and digitization stages can be examined.
- Examine the performance of the signal-processing and navigation solution algorithms when the only accessible input point to the receiver is the RF stage.
- Examine the coexistence or interoperability of other systems such as terrestrial communication networks with GNSS, or examine the effects of various interferences. In such cases, it may not be possible or practical to simulate these other systems/signals at the IF or measurement level.

An example of a bench-top RF simulator and accompanying shielding chamber is shown in Fig. 18.3. The simulator depicted may be used alone to perform conductive testing of entire receivers or receiver components. Alternatively, it can be coupled with the shielding chamber to perform either conductive tests, or broadcast testing of devices with integrated antennas. The chamber is designed to shield the device under test from external interferences, and absorb signals radiated within the chamber to minimize reflections.

**Fig. 18.3** An example of a bench-top simulator and accompanying RF shielding chamber suitable for conductive or rebroadcast testing of GNSS receivers or receiver components

In other cases, where it is desirable to perform a broadcast test, such that the effects of the antenna pattern are represented, it is necessary to place the system under test in the far-field of the broadcast antenna, which for GNSS requires a separation of some meters. For example, it may be of interest to observe receiver operation when the antenna observes GNSS signals from a high elevation and some interference signals from low or negative elevations. Such a configuration is illustrated in Fig. 18.4.

### 18.2.1 Implementation

RF GNSS simulators have changed quite significantly in the last decade. What were originally very large, expensive, and power-hungry devices are now available in a wide range of sizes and match a wide range of budgets. Such simulators exist as large cabinet-style installations, as bench-top units and even as hand-held devices, of course, with varying degrees of capability and accuracy. Although this technology is changing quite rapidly, RF simulators still, typically, fall into two main categories: those which dedicate a single hardware channel to each simulated signal, in some cases including one additional channel per multipath reflection; and those which synthesize all signals in the digital domain and perform a collective digital-to-analog conversion (DAC) and up-conversion to RF.

Those that dedicate a single channel to each simulated signal typically offer systems within the range of 16–64 channels per unit. Generally, the number of channels is extended further by combining/connecting more than one unit into a single simulator. Such simulators utilize essentially the same technology as the satellite transmitters themselves and have dominated the market until recently, as the technology to synthesize signals digitally in real time was unavailable or had limited capability. Examples of this kind of simulator include, for example, some units from IFEN and Spirent.

Recently, however, this has changed and modern simulation techniques begin with the digital synthesis of multiple signals, followed by collective DAC and up-conversion to RF. Examples of such, so-called, *software-defined* simulators include those from Rohde and Schwarz, Spirent and Spectracom. In fact, today, there are many real-time software-defined simulators available such as, for example, Averna's URT-5000, National Instruments' Global Navigation Satellite System Toolkits, M3 Systems' GNSS Test Platform, and RACELOGIC's LabSat systems. Software-defined digital synthesis has the distinct advantage that there is no intrinsic limitation to the number of signals that can be simulated (including multipath signals), an important consideration for those working with multi-frequency and/or multi-GNSS receivers. They also offer easier upgrading capabilities if additional features and/or systems need to be added later.

### 18.2.2 Important Considerations

It is important to consider that the first gain stage essentially defines the noise figure of the system. Therefore, when performing a rebroadcasting test on a receiver that has an integrated antenna or when an active antenna must be included in the test chain, it is preferable

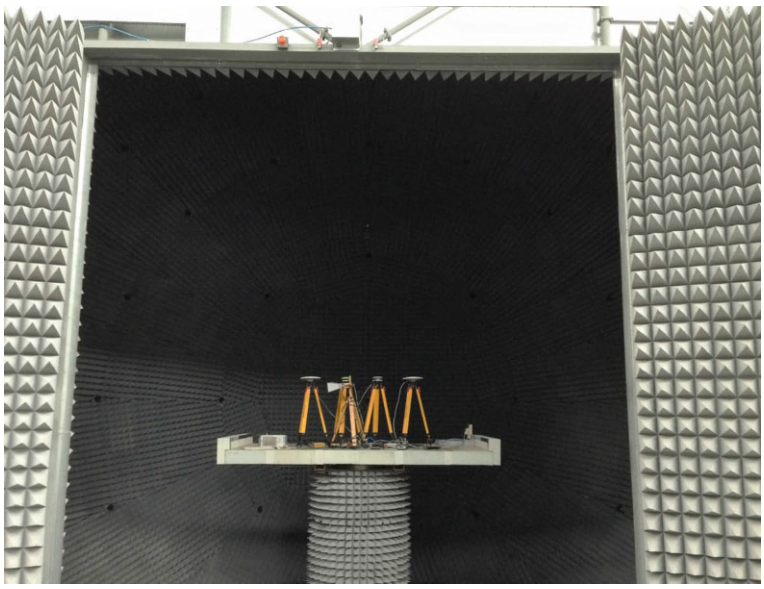

**Fig. 18.4** An anechoic chamber located at the Joint Research Center, Italy, during a GNSS interference test. The receivers and antennas under test are mounted on a central platform while simulated GNSS signals are broadcast from a fixed overhead antenna and a selection of interference signals are broadcast from a mobile antenna, from a variety of elevations

to simulate a well-calibrated signal without noise. In this way, the noise performance of the active receiver elements are reflected in the test results, with the carrier power being controlled by the simulator and the noise contribution being produced in the receiver itself. Accurately calibrating this broadcast power may not always be possible, however. When the broadcast signal cannot be accurately calibrated in absolute terms, it is better to broadcast both the signal and a simulated noise, such that a relative carrier-to-noise floor can be accurately synthesized, albeit at a noncalibrated absolute power level. This rebroadcast signal must be sufficiently higher than the true thermal noise floor of the receiver, so as to preserve the simulated carrier-to-noise ratio. Care must be taken, however, to keep the broadcast power within the levels expected by the receiver.

Similarly, when performing a conductive test, the receiver RF chain will have a specific noise temperature and will introduce into the system a certain level of nonrepeatable additive noise. As tests are repeated, this thermal noise will differ and will have a corresponding impact on the overall receiver performance. To reduce the effect of this issue to a certain extent, simulators can synthesize both simulated signals at a simulated thermal noise, having the appropriate relative power levels, but both at a higher power level than the true thermal noise floor of the receiver.

This issue of additive noise also plays into the repeatability of certain tests. RF simulators cannot provide an exactly repeatable test scenario. Repeatability of RF simulators is influenced, primarily, by three factors: thermal noise, reference oscillators, and start-time synchronization. By simulating both signal and noise, as mentioned previously, the contribution of the true thermal noise can be reduced, leaving only the repeatable simulated component.

The stability of the simulator's reference oscillator can also play a critical role. Any asynchronicity between the simulator and receiver timescales will appear as apparent receiver clock errors, regardless of which clock is more stable or better calibrated. To minimize this effect, it is important that the simulator clock be more stable than that of the receiver. The nature of GNSS navigation poses relatively strict requirements on the stability and turn-on bias of the oscillators used in receivers (at least relative to other telecommunication systems), and so RF simulators must be equipped with high-quality oscillators.

Nonetheless, the instability of the simulator's reference oscillator can influence the repeatability of tests. Crystal oscillators are affected by aging, temperature, physical orientation, and physical stress, all of which will influence the nominal frequency of the oscillator, and they also exhibit stochastic instability which produces a random variation in the oscillator output over time [18.18–20]. These effects are present on both the simulator and the receiver side and will lead to variability in the overall experiment. Variability arises due to the simulator and the receiver time frames moving relative to one another, and respectively relative to the true passage of time.

In the case that it is not necessary to include the receiver clock in the test path, the issue of oscillator instability can be partially circumvented by providing both the simulator and the receiver with a common clock or a common pulse per second (PPS), or by providing either the simulator or receiver with a clock or PPS from the other. Indeed, in many cases, an RF simulator will be capable of providing or accepting both a reference clock and a PPS signal, although it is not always the case that the receiver under test can accept or provide either of these. If it is the case that the quality of the receiver clock is the object of the test, then sharing a common clock or PPS is not an option and, therefore, it must be ensured that the simulator reference clock is at least an order of magnitude more stable that that of the receiver. This fact can impose real limitations on what level of testing can be conducted with a simulator. In practice, this problem is generally addressed by providing the simulators with a GNSS-disciplined reference clock exhibiting good short-term phase stability.

Start-time synchronization refers to the problem of aligning the beginning of the simulation scenario with the initialization of the receiver. This can be an issue when attempting to match a truth or reference dataset to measurements taken from the receiver in order to assess receiver performance. Although the timing information produced by the receiver's PVT solution is regularly used for synchronization, it may not always be available and it may not always be advisable to rely on the receiver in calibrating a test setup. It is also an issue when the receiver is excited by more than the GNSS simulator alone. For example, the simulation scenario may consist of a combination of simulated GNSS signals, other RF signals such as interferences, and/or simulated non-RF sensors such as inertial measurement units, magnetometers, barometers, wheel-speed sensors, etc. In this case, care must be taken to ensure that different sets of simulated data are precisely aligned.

Start-time synchronization also affects the repeatability of certain experiments. For example, it will vary the entry point into the received navigation message which, in turn, will affect receiver performance metrics such as the time to first fix, that is, the time needed for the receiver to compute and output its first PVT solution fix. In practice, such effects are averaged out in a well-executed experiment (it is common to

compute *mean*-time to first fix); nonetheless, for certain tests, a high degree of repeatability can be very useful. Many simulators provide a programmable *trigger* output or input to help tackle these issues. While this generally proves a satisfactory solution, it does require that the receiver can accept/produce a trigger input/output and that the user has the means to use it effectively.

Calibration is another significant issue for RF simulators, including an initial factory calibration, periodic maintenance, and experimental setup. In general, the precision of test equipment must be at least an order of magnitude greater than that of the device under test. For high-precision testing, simulation accuracy at the millimeter level for absolute and relative signal delay and less than 0.1 dB for signal power may be required. In such cases, the simulator may require careful calibration, in particular when more than one hardware channel is used. Many simulator manufacturers will correspondingly recommend and/or provide periodic maintenance for their products.

As mentioned previously, RF simulators are particularly useful for conducting coexistence or interoperability testing between GNSS signals or systems. When performing such tests, a user may be interested in assessing the receiver performance when it is processing: one or more GNSS systems simultaneously; one GNSS system in the presence of other GNSS systems broadcasting at the same frequency; or, one or more GNSS systems in the presence of non-GNSS systems, such as, for example, pseudolite or satellite telephony systems. Signals from these non-GNSS systems or interferences can be directly combined with the simulated RF signal ensuring that the relative power levels are suitably adjusted. The ease with which various signals can be combined with the simulated RF signal for testing purposes highlights one particular vulnerability of the technique: a user can never be completely sure that the receiver is not also receiving and processing other interferences (that are not intended to be part of the test plan) from the laboratory. In particular, in a well-stocked laboratory, it is not uncommon to have many other devices capable of generating signals in the GNSS band, for example, signal generators, arbitrary waveform generators, or programmable RF transceivers. Even nearby devices which operate some hundreds of MHz away from the GNSS bands can emit spurious signals or harmonics which can find their way into the receiver-under-test RF feed which can lead to unexpected results.

## 18.3 IF-Level Simulators

IF GNSS simulators share many commonalities with the software-defined RF simulators discussed in Sect. 18.2.1 – the obvious difference being the absence of DAC, and up-conversion to RF – but are a more specialized type of simulator and far less widely used than their RF counterparts. Nonetheless, in certain applications, typically research and development, they have many distinct advantages. IF simulators are invariably implemented in software (or another easily reconfigurable platform) and produce one or more streams of digitized IF samples, similar to what a receiver would produce at the output of a digitizing front-end. The simulator must not only model the signal as it appears at the output of the receiver antenna, but it must also model the receiver RF and IF chains including the effects of the local oscillator, filtering and digitization; this is the other key difference from software-based RF simulators.

Applications of IF simulators include testing of software-defined receivers, testing of various parts of receiver hardware, or cases where it is desirable to prototype an algorithm or system in software, and/or is necessary to have an absolutely repeatable test scenario. Generally speaking, IF simulation cannot be used for standard commercial-off-the-shelf receivers as their use necessitates access to an intermediate stage of the receiver and, for this reason, they are most commonly, if not solely, used for research, development, and educational purposes. As a result, they are most commonly encountered as in-house research tools, rather than as commercial products. The exception is the special case where the simulated IF signal is used in conjunction with other hardware, capable of up-converting and rebroadcasting at RF as with products from, for example, Averna, National Instruments, M3 Systems, and RACELOGIC. These record and playback systems are becoming increasingly popular and are discussed in Sect. 18.4.

One key benefit of IF simulators is flexibility. In general, the development cycle for software is much faster than that of hardware, so IF simulators are typically the easiest and fastest to be adapted to embody new signals, scenarios, and features than hardware-bound RF simulators (this is also a key motivator for the move toward software-based RF simulators discussed in Sect. 18.2.1). Moreover, the output of an IF simulator is itself quite easily manipulated by a user, thus allowing immense freedom to explore receiver performance.

This flexibility also allows a user to explore beyond the limitations of current technology, for example, synthesizing signals at arbitrary sample rates and/or arbitrary digitizer resolution.

Another important benefit of IF simulation is that the most basic and simple models for received GNSS signals are those of perfect signals. Indeed, all nonidealities must be consciously synthesized and applied to the synthetic signal. They can, therefore, be included or excluded at will and are absolutely repeatable, including noise. This enables a user to precisely investigate the impact of various signal and front-end features with relative ease, by including or excluding these features. Features such as receiver filters, reference oscillators, digitizers, gain-control algorithms, interference, atmospheric effects, and so on, can be excluded, included, and modified from experiment to experiment, while retaining the absolute repeatability of all other factors.

Being an entirely discrete-time simulated signal, when applied directly to the digital signal-processing stages of the receiver under test, IF simulators have the distinct advantage that they can operate faster than real time without sacrificing fidelity. This can happen because the IF simulator and receiver's digital processor need not wait for a full sample period to elapse, as is necessary in real operating conditions. Instead, with sufficient processing power, the IF signal samples can be generated and processed faster than if the signal were being sampled in real time (i. e., less than the sample period). For example, a sample stream that has been generated at a sythetic rate of 10 MHz might be processed at a rate of some tens or hundreds of megahertz. This capability can be an important consideration when a large range of tests must be conducted.

### 18.3.1 Implementation

If the IF samples are not to be upconverted to RF for rebroadcast, the IF simulator is required to model more than its RF counterpart as the effects of the receiver RF and IF stages must be included. Dominant amongst these effects are thermal noise in the amplification stages, the RF and IF filtering, the local reference clock, and frequency synthesizer, any on-board interference that may be introduced, the automatic gain-control unit, sampling, and digitization [18.21]. An IF simulator will generally create a baseband representation of the necessary signal modulation and, subsequently modulate it onto the appropriate IF, implement the appropriate filtering or conditioning, down-sample if necessary, and finally digitize [18.22].

The order in which these various effects are introduced into the signal throughout its generation is important as many of the effects are nonlinear. Nonlinear effects such as sampling, digitization, and gain-compression not only influence the amplitude of the signal, but also influence their spectral characteristics. For example, filtering an amplified signal, and amplifying a filtered signal, will produce different results if there are nonlinear elements in the amplifier [18.23]. In particular, the ordering of the sampling and digitization models is critical [18.22]. Of course, being a digital system, signals produced by an IF simulator are already discrete in time and so special attention must be paid to accurately modeling sampling effects. Under normal operating conditions, these effects would be negligible. However, in the case that the simulation must model some jamming or interference scenarios in which high power levels are present, these effects can become prominent.

In the case that the sampling model must exhibit/model some aliasing effects, it is likely that the IF data is synthesized at a much higher sample rate than is finally produced, such that intermediate filtering stages and the effects of aliasing can be appropriately incorporated. To consider a hypothetical example, if an IF dataset were to be created at a sample rate of 5 MHz complex, it may first be synthesized at upward of 20 MHz, filtered, digitized, and then down-sampled, such that the appropriate spectral folding would be more accurately modeled. In many cases, however, this level of fidelity may not be necessary, and direct synthesis at the final sample rate may be adequate.

Similarly, when synthesizing signal amplitude and phase, although the final IF signal may only exhibit 1 bit or 2 bit resolution, it will have been first synthesized with much higher precision, possibly even with floating-point precision. This can also be important when maintaining phase and time accumulators for various simulated parameters where the dynamic range of variables can be a limiting factor.

A basic flowchart of an IF signal simulator is shown in Fig. 18.5. In such simulators, the entire process is discrete time, although it is not uncommon that different components of the simulation operate at different rates. Firstly, the synthetic time process must be generated, whereby the transmit time corresponding to each sample epoch must be calculated – refer to (18.4). When simulating a perfect clock, these epochs are spaced evenly and according to the chosen sample rate, however, when simulating an unstable clock, these time increments will vary. When modeling a clock that is running slow, these increments will be larger, and when modeling a clock that is running fast, the increments will be smaller. In essence, this module must produce the inverse of the time process of an unstable clock or, more specifically, the projection of even time increments through this function [18.24–26].

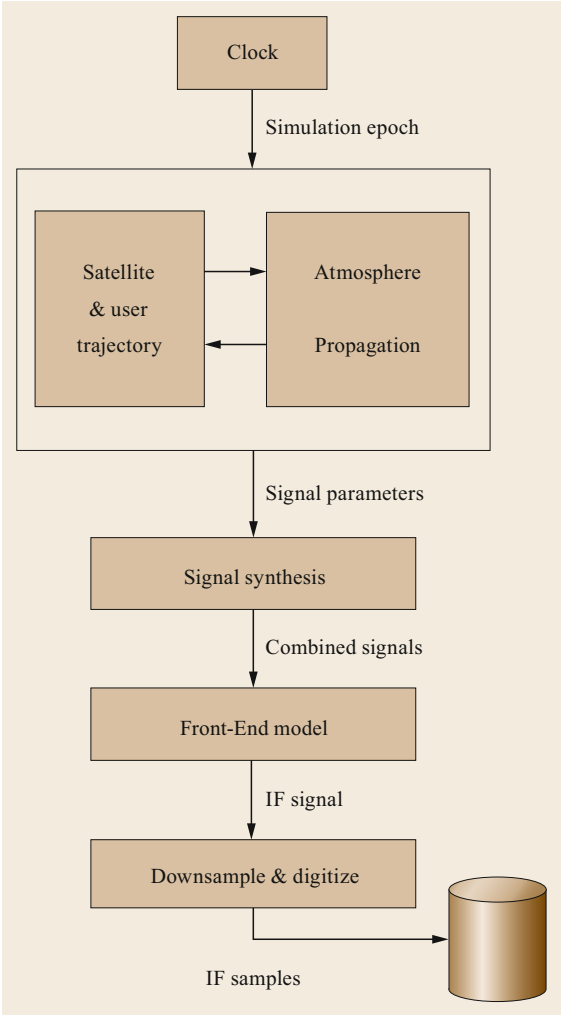

**Fig. 18.5** Flowchart for an IF signal simulator

For each sample epoch, the physical model must be resolved, including transmitter and receiver trajectories and the propagation channel in between. In comparison to the transmitted signals, this model is slow moving and is typically updated at a much lower rate, and interpolated as necessary, for example, at a rate of 1 kHz, or even as low as 50 Hz. Having resolved this process, a set of signal parameters including amplitude and code- and carrier-phases for the LOS and multipath signals and other interferences are generated, representing the signals as they arrive at the receive antenna. These signal parameters are then used to synthesize *infinite*-resolution, noise-free, discrete-time signals which are combined into one sample. In the case that the simulator is implementing multiple front-end channels, these signals may be grouped accordingly.

This combined signal sample is then applied to an equivalent IF front-end model wherein the thermal noise floor is applied. This model may include one or more filtering stages, interspersed with nonlinear receiver elements such as amplifier models or active filter models. Also, depending on the fidelity of the simulation, this stage may include a down-conversion from high IF to low IF. The final stage of the simulation is gain control, down-sampling, and digitization. If the simulator has produced a high sample rate model to better model some of the previous stages, then down-sampling to the final sample rate is conducted here. The signal is then scaled to reflect automatic gain control and quantized to the required resolution.

### 18.3.2 Important Considerations

Software IF simulators operate in a purely deterministic manner. This feature can, in some cases, be a distinct advantage; however, in other cases, this can pose some difficulties which must be handled with care.

In terms of simulation repeatability, scenarios can, if desired, be absolutely repeatable which can be a great enabler for empirical or brute-force tuning of systems or receiver comparison. Of course, if absolute repeatability is not desired, deliberate steps must be taken to vary or randomize the simulation. At first glance, this may seem like a trivial task, but in reality, producing high-fidelity random processes can be very difficult when a large volume of simulation is necessary [18.27].

Synthesizing stochastic processes in software can be very difficult and requires a number of key ingredients: a reliable source of random (or pseudo-random) data; an appropriate model for the stochastic process; and a deterministic algorithm which can impress this model upon the random data. If any one of these ingredients is missing, the stochastic process cannot be faithfully replicated. The first ingredient, a source of random data, is readily available on almost all software platforms in the form of pseudo-random number generators that generally provide uncorrelated data exhibiting a bounded uniform distribution. For example, the current International Organization for Standardization (ISO) C standard implements a linear congruential generator for its random function [18.28]. In reality, many simulation scenarios require more high-quality pseudo-randomness and implement a dedicated generator [18.27, 29]. As such, it is generally one of the two remaining ingredients, either the model or the deterministic algorithm, that limits the simulator.

The fidelity of synthesized data is directly related to the accuracy of the model from which it is derived. In many cases, the models available for real-word phe-

nomena are poor, either because the volume of data required to represent the phenomena is too large, the phenomena is too difficult to accurately measure, or because it is simply not cost-effective to launch a suitable data-collection campaign. In many cases, simulators either implement the generally accepted model in the field, or offer the user a choice of some of the more popular models. Indeed, even current simulators struggle to accurately model phenomena such as ionospheric scintillation due, primarily, to a lack of data upon which to base a simulation model.

The final limiting factor is the availability of a suitable deterministic algorithm which can convert the random data into the appropriate random process. This algorithm generally alters the distribution and the temporal correlation of the random data. In many cases, this involves the production of Gaussian variables that have a well-defined temporal correlation, for which simple linear algorithms exist [18.25, 30]. Other processes which occur widely in nature are not so easily dealt with; oscillator instability being a classic example, wherein the stochastic phase process exhibits, so-called, fractional or *flicker* noise, which is exceedingly difficult to reproduce in software [18.25, 31–33].

Finally, we note that IF simulation cannot be used to perform a full receiver test, as the front-end is omitted from the test path. To include the front-end the IF data must be up-converted to an analog RF feed and rebroadcast. It is worth mentioning also that IF simulation need not necessarily be restricted to purely synthetic data, as genuine GNSS signals that have been pre-recorded by a suitable front-end device can be applied to the receiver under test. These two topics will be discussed in the following section.

## 18.4 Record and Playback Systems

Record and playback systems have increased in popularity in recent years as an interesting alternative or compliment to both RF and IF simulation techniques. Record and playback systems consist of two tools: a recording tool which captures one or more specific RF bands that are down-converted to IF prior to sampling, digitization, and storage to a disk; and a playback tool which up-converts these samples to an analog RF signal for rebroadcast or direct feed to the receiver (Fig. 18.2). Used either in isolation or in combination, these tools offer a wide range of possibilities to a user.

Record and playback systems overcome many of the challenges faced by traditional simulation techniques. For example, they remove any limit to the number of satellite signals, interferences, multipath propagation effects that can be recorded, as well as the need to model real-world effects such as the atmosphere or propagation channels. Indeed, the fidelity of the signal is only limited by the quality of the unit itself.

Record units can be used to capture rare phenomena, such as ionospheric activity, or difficult to (re)produce scenarios, such as complicated interference/spoofing scenarios or fast-fading propagation channels. In general, the technique is useful whenever it is infeasible to synthesize the scenario either due to its rarity, sparsity, geographic isolation, chaotic nature, or because it is simply not fully understood.

A user may even blindly record the appropriate RF spectrum and, therefore, subject the receiver to a realistic scenario, even if the user is not fully aware of the scenario. Indeed, record units are not even restricted to capturing GNSS signals, and many record and playback systems facilitate the capture one or more RF bands, in the range of kilohertz to a few gigahertz.

Similarly, a user does not need to bring all of the devices on the test campaign; rather, the data can be played back at a later date to one or more devices. As a result, the use of record and playback systems has resulted in many laboratories compiling libraries of useful and/or interesting test scenarios, for future testing or research. These scenarios can then be distributed to third parties, for example, as in [18.16].

In cases where this data is used for performance assessment or calibration, and a truth or reference trajectory is required, record units are often used in combination with a GNSS reference receiver and/or high-quality inertial measurement units.

As mentioned previously, playback units are versatile and have been applied to the rebroadcast of IF samples collected from live GNSS signals, those collected from hardware RF simulators and, finally, to broadcast synthetic IF samples. As such, the combination of an IF simulator and a versatile replay unit constitutes a very practical and flexible RF simulator unit. In fact, this is the modus operandi of many modern RF simulators, as discussed in Sect. 18.2. Other examples of record and playback systems include Averna's RP-3200 Wideband RF Record & Playback system, RACELOGIC's LabSat 3 GPS Simulator, and Spirent's GSS6400.

### 18.4.1 Implementation

Unlike GNSS simulators, which are purpose-built and specialized tools, record and playback systems are often general-purpose devices. Historically, GNSS simulators have developed alongside GNSS receivers and have added or adapted functionality as testing demands and requirements necessitated. In contrast, record and playback systems, having their origins in the telecommunication industry, have been developed with a large and diverse user base. As a result, they offer a wealth of possibilities to a GNSS user, including the flexibility to capture far more than the GNSS band alone, and a digitization resolution far in excess of what is typically employed in GNSS systems; USRP-based systems are good examples of this, typically offering megahertz to gigahertz tuning range with 8 or 16 bit digitizer resolution.

Owing to their applications outside of GNSS, many record and playback systems are modular and can be manually configured to operate at various frequencies, typically between hundreds of kilohertz and 2–5 GHz. A typical unit will offer digitizer resolution ranging from 8 to 16 bit and will offer sample rates ranging from the low megahertz to some tens of megahertz. Units may vary in the number of channels they offer and, depending on the architecture, these channels may be either sample- or phase synchronized. For more portable solutions, however, many researchers opt for a GNSS dedicated solution, having a more restricted radio band and, typically, lower resolution digitizers.

Example record and playback systems are shown in Figs. 18.6 and 18.7, respectively. Both units are from National Instruments but differ greatly in terms of size and capability. The USRP units shown in Fig. 18.6 are highly portable but each is limited to recording a single band, and no more than two can be (synchronously) combined together. Furthermore, the data throughput is the same regardless of whether one or two units are recording data. The USRP unit can also be used to replay the data they recorded.

In contrast, the system shown in Fig. 18.7 is much larger and each chassis can be configured to log from multiple bands simultaneously, and multiple chassis can be time synchronized to collect even more data. Use of an array of hard drives allows for very high data recording rates across all bands (up to 40 Mb/s each).

The record stream generally consists of an antenna, amplification and down-conversion stages, digitization, and an optional signal conditioning and down-sampling stage. This digital data stream is either stored within the unit or streamed to a host computer. The replay channel essentially consists of the reverse: digital to analog, up-conversion in one or more stages and either power

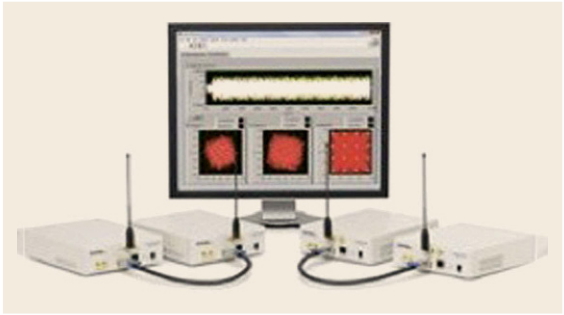

**Fig. 18.6** Four National Instruments USRP units, each capable of logging data from a particular band. Pairs of units can be time synchronized using special cables (*lower-left* and *right*) in order to log two bands at once (courtesy of National Instruments)

amplification or attenuation, depending on whether the signal is broadcast or fed directly to a receiver.

In most cases, the system operates in half-duplex mode, where data is first recorded and later rebroadcast, which generally meets the demands of receiver testing. Full-duplex mode, where the unit simultaneously receives and transmits, is offered by some units [18.34], and can facilitate some more complicated tests. A full-duplex system is capable of, for example: performing loop-back, where the received signal is simply rebroadcast as is; first modifying the received signal, as digital IF, prior to rebroadcasting; or creating a simulated signal based on the content of the received signal. These concepts are investigated further in Sect. 18.6.

### 18.4.2 Important Considerations

When using a record and playback system, there are a number of important factors that should be considered when designing an experimental setup.

Gain control and dynamic range are important factors. Firstly, it is important that the record unit has a significantly higher dynamic range than the receiver, both in the ADC and DAC stages, and, secondly, the converter gains should be held constant during the record and playback stages. Automatic gain control in the record unit is not advisable for receiver testing as, although the transmitted signal-to-noise ratios may remain constant, the receiver under test may perceive the variations in signal and noise floor separately, resulting in the appearance of signal-to-noise-ratio variations.

Ideally, the bandwidth of the record and playback system is greater than the bandwidth of the receiver under test, such that the playback system does not induce any ripple or roll-off the portion of the transmitted signal that lies within the receiver's passband. Further-

**Fig. 18.7** A record and playback system installed at the Joint Research Center, Italy, comprising of two national instruments chassis, one housing a vector signal transceiver and the other housing pairs of up- and down-converters and digitizers and analog-to-digital converters (ADCs). A single-reference oscillator is used to clock both chassis, and a calibrated set of trigger signals are generated to simultaneously launch record and playback. IF samples collected in four configurable bands are streamed to and from an array of magnetic hard drives (*bottom*)

more, when operating a record and playback system, there is no possibility to replay the GNSS signal alone, as it has been captured with thermal noise present. In this case, the noise figure observed in any subsequent testing has been limited by the noise figure of the record device. The properties of this noise are quite important. When thermal noise is simulated, it must appear white to the receiver, specifically, it should exhibit the same shape as the frequency response of an appropriate antenna which, from the perspective of most receivers, is flat. For simulators, this is generally not a problem. Record and playback systems, in contrast, may be bandwidth limited. Commercially available record and playback systems have configurable bandwidths ranging from 1 to 100 MHz. When performing a playback test using a broadcast bandwidth that is noticeably narrower than the receive bandwidth of the receiver under test, some problems may arise, for example, within the receiver automatic gain control, interference mitigation algorithms, or even in tracking.

One simple method of circumventing the problems of low playback bandwidth is to combine it with live thermal noise. The rebroadcast data can be passed through a variable attenuator to bring the playback spectrum close to the thermal noise floor. Subsequently, it can be passed through a broadband power amplifier to bring the narrowband playback signal plus thermal noise up to the power level that the receiver under test is expecting, similar to that of an active antenna.

Once again, the quality of the oscillator used is very important; however, unlike RF or IF simulator systems, frequency accuracy is less important as frequency offsets introduced in the record process will cancel in the up-conversion process, provided the oscillator is reasonably stable between the record and playback times. Short-term stability, on the other hand,

is amplified. White, flicker, and random-walk phase and frequency noise will be uncorrelated between record and playback times and so their effects will combine and manifest themselves as apparent errors in the *receiver* clock. It is important, therefore, to ensure that the reference clock used for the system is an order of magnitude more stable than that of the receiver under test.

Although record and playback systems do not impose a limit on the number of GNSS signals that can be reproduced, unlike traditional simulators, data transfer can impose limitations on the total bandwidth captured. Recording IF data can produce quite a lot of raw data that cannot be effectively compressed, as it is generally dominated by thermal noise. The task of transferring and storing this data is generally the limiting factor for these systems. The total data rate will be a linear function of the ADC/DAC resolution, the sample rate, and the number of frequencies recorded. For example, a single-frequency system sampling data at 20 MHz complex with 8 bit resolution per sample generates 40 Mb of data per second, or 2.4 Gb/min. Higher resolution, multifrequency systems will produce proportionally more. Even when the necessary recording rates are attained, tests with record and playback systems are generally limited to a few tens of minutes or a few hours for practical reasons, which has implications for experiment design.

Another factor that influences experiment design when using a record and playback system is the availability of accurate truth data. While with traditional simulators, a full set of truth data is available and receiver performance can be assessed in an absolute sense, record and playback systems offer no such feature. A user must either resign to assessing performance relative to a reference receiver, or to sourcing reference data elsewhere, for example, via precise ephemerides and a known trajectory or by including other sensors such as an inertial measurement unit (IMU). In either case, there is a limit to the degree of accuracy to which the truth data can be estimated because many variables, such as atmospheric and channel propagation parameters, are unknown. A user must therefore take care not to attempt to measure performance with greater precision than that of the truth data. Ideally, experiments conducted via record and playback should be designed to be as insensitive as possible to the accuracy of the truth data.

## 18.5 Measurement-Level Simulators

Measurement-level simulation aims at testing navigation solution calculations that are implemented internal to the receiver's firmware or external to the receiver in the form of third-party software. This differs from previously discussed simulators in three key ways.

First, whereas RF simulators generate a continuous signal feed and IF simulators need to generate millions of samples per second of simulation, measurement simulators are typically concerned with inputs on the order of 50 Hz or less. This is driven by the fact that, with a few exceptions, receivers simply do not need such high data rates. Correspondingly, allocating more processing resources to generate measurements at a higher rate is unjustified. This makes measurement simulation much less computationally strenuous.

Second, as mentioned above, the signal-processing stage of a receiver is insensitive to the low-frequency errors caused by orbital errors and the atmosphere, for example, and pass through this stage unaffected. These errors are therefore present in the pseudorange, carrier-phase, and carrier Doppler measurements, and need to be modeled with the level of fidelity needed for the type of testing being conducted. As with all simulations, the level of fidelity will vary greatly between applications.

The third difference is that measurement-level testing combines outputs from different channels within the receiver. Testing with RF and IF simulators is often focused on evaluating the signal-processing stages of a receiver and is thus concerned with channel-level information such as acquisition and tracking thresholds, $C/N_0$ estimation, time to first fix, etc. In contrast, testing the navigation solution combines information from all channels together. By extension, the fidelity of a single satellite's signal(s) is no longer sufficient and care must be exercised to ensure that measurements to different satellites adequately reflect the relative errors that are expected. The most obvious source of error variation arises from tracking satellites at different azimuth and elevation angles which induces different errors due to the atmosphere, but multipath errors are also critical in this context.

A fourth difference is also applicable in situations where differential processing between two or more receivers is being tested. In these cases, in addition to modeling the relative errors between satellites at a single location, the *spatial* variability of the errors is critical, as this ultimately dictates the accuracy of such systems. For carrier-phase processing in particular, the spatial variability of the errors is most important since

this will have the most profound impact on the ability to resolve the integer ambiguities.

In light of the above, measurement-level simulators are typically used as a means of testing a navigation solution's sensitivity to the magnitude and/or variability (temporal and/or spatial) of certain errors and, by extension, its ability to model or otherwise account for these errors [18.35, 36]. For applications where multipath is the largest effect (meaning the error cannot be practically modeled), the ability of the navigation solution to identify and reject large errors using fault detection and exclusion (FDE) is equally important, if not more so.

Measurement simulators are most commonly used for in-house development and testing of receiver firmware and/or separate data-processing software. They also play an important role in research and development and are thus commonly found in academia and research institutes.

Another motivation for using measurement simulators is to assess PVT performance as a function of the number of GNSS, the number and type of signals, and the number of frequencies used as input to the navigation solution. In turn, this can be used to decide how receiver resources are allocated for a particular application.

### 18.5.1 Implementation

In many instances, measurement simulation is *almost* a natural by-product of RF or IF simulators. Since the measurement errors need to be known in advance (18.3), they are usually logged to file by the simulator. Indeed, these measurements form the basis of a truth or reference dataset for RF or IF simulation. These files can then be read and used to form observations absent of noise and multipath effects.

Another form of measurement-level simulation can be found in the analysis of a GNSS constellation. For example, the early stages of the Galileo constellation design were assessed using service volume simulation, to reproduce the functional and performance behavior of the Galileo system. Generally used to conduct navigation and integrity performance analyses over long time periods and over large geographical areas, this tool computes figures of merit such as visibility, accuracy, integrity, continuity, and availability of service. However, it is also capable of generating raw Galileo and GPS observables for the validation of navigation and integrity processing facilities [18.6, 37].

Regardless of the implementation, the key challenge is to generate errors that exhibit the range of magnitudes, temporal variability, and spatial variability consistent with reality. This challenge is not to be taken lightly. Although many different models exist to correct for ionosphere and troposphere errors (Chaps. 38 and 39), these models are not perfect, meaning that some residual error remains in the measurements after the models are applied. Typically, models tend to produce overly smooth errors, both temporally and spatially. Using such models for simulation thus leads to overly optimistic performance because the simulator and receiver are using the same, or very similar models, thus limiting the amount of testing that can be reliably performed.

Inclusion of the effect of noise and multipath typically requires complete knowledge of how a particular receiver operates including: the length of coherent and/or noncoherent integration performed; the correlator spacing, and the types, order, and bandwidths of the tracking loops, etc. [18.38]. In many cases, these parameters are unknown to the user. Moreover, in some cases – when developing software to work with a variety of receivers, for example – specific parameters are less useful than covering a wide range of possible parameters. In light of this, noise and multipath models are usually based on some form of random process whose general statistical characteristics approximate those empirically obtained by a particular receiver in a particular environment as, for example, in [18.35, 39, 40].

In the case of benign environments (e.g., open sky), random noise can be added to match what is normally obtained for a particular receiver, usually scaled by the simulated $C/N_0$ of the signal. However, for high-sensitivity receivers, the effect of shadowing should be included, as per (18.9). In addition, the effect of fading also needs to be included explicitly.

Multipath errors can also be generated using a statistical model. A common approach is to model the errors as Gauss–Markov processes [18.40–43]. Alternatively, if a particular reflection geometry is assumed, the instantaneous effect of multipath on the code and carrier-phase discriminators may be used. Note, however, that this must assume the receiver response to the multipath signal, including filtering effects provided by the antenna and tracking loops, and any receiver-based multipath mitigation schemes.

### 18.5.2 Important Considerations

There are two main considerations when using measurement simulators. First, as mentioned above, proper simulation of noise and multipath normally requires the knowledge of how a particular receiver is implemented. If these parameters are unavailable, then assumptions are made based on empirical evidence.

The second consideration is how the type of processing undertaken compares with the errors being

simulated. In general, pseudorange processing is well suited to measurement simulation because noise and multipath are the dominant errors meaning that the fidelity of the ionosphere and troposphere errors is less of a concern. This is even more true for differential processing where the effect of ionosphere and troposphere is virtually zero (relative to pseudorange noise and multipath), except for over extremely long receiver separations.

Extra care must be exercised when using measurement simulation for high-sensitivity receivers. Whereas *standard* sensitivity receivers do a reasonably good job of only producing measurements containing errors within an acceptable range, high-sensitivity receivers may occasionally produce highly erroneous measurements. This occurs when the receiver is working at or near its tracking threshold. Correspondingly, accurately simulating a high-sensitivity receiver at the measurement level should also account for these *threshold effects*.

In contrast to pseudorange positioning, differential carrier-phase positioning algorithms are much more sensitive to the fidelity of the ionosphere and troposphere errors. The reason is that the reduced multipath errors on the carrier-phase means that these other errors can be significant – or even dominate – as the receiver separation increases. If the models are spatially and/or temporally too smooth, this could have significant impacts (positive or negative) on the ability to reliably resolve the integer carrier-phase ambiguities.

## 18.6 Combining Live and Simulated Data

One use of simulators that is noteworthy is the combination of live and simulated stimuli. Although this approach does not constitute a traditional simulator, and the style of testing is less well defined, it is becoming increasingly popular due, in part, to: the increasing number of GNSS satellites in view of a typical receiver; the increasing number of frequencies on which satellites transmit; the increasing use of other sensors in GNSS receivers; and the increasingly complicated scenarios a user wishes to examine.

A simulator tool may be limited in the number of signals/sensors it can synthesize and/or the number frequencies it can simulate. Fortunately, it is often the case that a user is only interested either in controlling, or examining receiver performance relative to a small subset of the signals in view. In such a case, it is possible to provide the GNSS receiver under test with both genuine signals, of which the user may or may not have complete knowledge, combined with a set of simulated signals, over which the user has full control and for which the user has good truth data.

Another common reason to augment both simulated and live data is when the user has no readily available means of simulating a particular signal, but has the means to record it live. Combining of genuine and simulated signals can either be done live, where the simulated component is produced in real time and fed directly to the receiver under test; or can be conducted in post-mission, where the genuine data is stored and reproduced (for example, via record and playback system) for combining with the simulated signals.

In some cases, this form of augmentation is simple and requires little or no calibration or synchronization, such as jamming or interference scenarios. In other cases, synchronization is critical, for example, when simulated GNSS signals are combined with live ones.

Augmentation of live GNSS signals with simulated signals or augmentation of a simulation with live signals is commonly employed to overcome either limited simulation resources or unavailability of live data including, for example:

- In the case that a user wishes to examine the performance of a multi-GNSS receiver on a GNSS system which is not yet fully deployed, for example, Galileo or BeiDou. A user may simulate only the satellites that are missing, providing the receiver with genuine signals for the remainder. This may either be done in real time or in post-mission via record and playback of the genuine signals. In practice, however, the post-mission case is far more straightforward.
- When an accurate model or simulation resource of non-GNSS signals is not readily available, for example, for compatibility/vulnerability analysis with devices such as jammers and pseudolites. In these cases, it may be necessary to have a repeatable GNSS component with an accurate truth dataset for performance evaluation. However, it may not be necessary to know exactly what the properties of the non-GNSS component are. Thus, the GNSS component might be simulated, while the non-GNSS component may be broadcast/conducted live [18.16, 17].
- In the case that a user wishes to add channel effects of the genuine received satellite signals to the RF feed of the receiver. A user may wish to add simulated multipath reflections to a scenario, in which

case the LOS signals are genuine and the simulator is used to add the reflections in a controlled and deterministic fashion.
- Similar to the multipath case, if a user wishes to simulate a spoofing attack. In this case, the simulator is used to produce the spoofed signals which are then either combined with the genuine LOS signals at the RF feed directly, or broadcast toward the target receiver from a local antenna.
- In the case when GNSS signals and other sensor data needs to be combined. In such a case, sensor data may be collected along some well-known reference trajectory. The GNSS signals corresponding to this reference trajectory can be subsequently simulated and combined with the sensor data. This might allow a user to examine integrated performance. Moreover, the quality and availability of the GNSS signals are readily controllable by the user. One example of this might be the combination of genuine inertial measurements with GNSS measurements for a tightly- or loosely-coupled solution.

### 18.6.1 Implementation

As mentioned above, the augmentation of simulated and live signals is conducted under exceptional circumstances. The requirements in such circumstances can vary widely, and this style of testing is conducted using a range of independent modules, rather than one bespoke unit.

Elements that may be employed include those required for simulation; sufficient equipment to observe or capture the genuine signals; and, where necessary, playback elements. Apart from these obvious elements, combining signals from different sources may also require some specialized tools for configuration and setup, including network/spectrum analyzers, timing, or synchronization tools and a reference receiver.

### 18.6.2 Important Considerations

As with pure simulation and record and playback methods, the effectiveness of augmenting simulation with genuine signals is limited by the quality of the combined signals. In this regard, the relative timing and relative power levels are amongst the most important. To make any high-precision measurements on the receiver under test, it is necessary that a user can distinguish between errors introduced by the user in the combining of the various signals, and those which relate to receiver performance. Moreover, it is important that the combined signals accurately reflect the desired test scenario.

For example, when combining simulated and genuine signals at RF, it may be beneficial to employ a network and/or spectrum analyzer to ensure appropriate matching of the network. In particular, combining live and simulated signals in a laboratory can necessitate long cabling and can be a significant source of error. Care must be taken to limit power loss, minimize interference emission, and signal reflection.

When injecting strong interference signals at RF, the reverse isolation of the network should be considered, both to ensure the quality of the test and to avoid unintentional broadcast. Matching power levels can also be a difficult task as the genuine signals and thermal noise will have been amplified at least once prior to combining. In general, ensuring that the simulated signals conform to the genuine signals involves scaling the power of the simulated signals relative to the thermal noise floor observed at the genuine signal feed.

When genuine GNSS data is combined with simulated GNSS data, timing becomes a crucial consideration. The passage of time must be consistent between the simulated and genuine data, and therefore biases in the reference oscillator used to drive the simulator must be bounded and the delay induced by the combining network must be accounted for in the generation of the simulated signals.

Firstly, the passage of time in the simulator must be reasonably consistent with the true passage of time. Unlike pure simulation or record and playback scenarios, where the simulator or the playback system *defines* system time, this style of augmentation necessitates consistency. To achieve this, the system should be equipped with either a GNSS-disciplined reference clock, or a complete reference receiver, which can serve to synchronize or discipline the simulator.

Secondly, the system time used by the simulator must lead the true system time by the difference in electrical length between the antenna–receiver path and the simulator–receiver path. This calibration is particularly important when the simulator is used to generate signals from a GNSS system that is also present in the set of genuine signals, for example, when performing multipath or spoofing testing. It is less crucial when simulating signals from a system not present in the set of genuine signals as this calibration error will simply appear as an intersystem bias.

Overall, this style of simulation can be very powerful and is an enabler for research and development; however, users should be cautioned that it is highly sensitive to calibration.

## 18.7 Other Considerations

The GNSS simulation and testing landscape is rapidly evolving to keep pace with the evolution and requirements of GNSS receiver manufacturers and GNSS system integrators. Correspondingly, there are many different features currently available, and more will likely become available in the future. This section briefly presents some considerations for deciding what type of simulator to use as well as what features might be of interest for a given type of simulator.

### 18.7.1 GNSS Systems Supported

The most obvious considerations revolve around the generation of the GNSS data including the GNSS systems that can be simulated, how many frequencies for each system, and how many signals/satellites can be simulated at a time. Also of importance might be the ability to simulate satellite- or ground-based augmentation system (SBAS or GBAS) signals. The number of outputs (e.g., RF feeds or IF sequences) that can be generated at a time is important for differential processing and testing of attitude determination systems, for example.

### 18.7.2 Interference and Spoofing

Both military and civilian systems are concerned with the effect of interference/jamming and spoofing (Chap. 16). Proper testing of a receiver in their presence requires the same level of control as testing a receiver in their absence. To this end, the types of interference that can be simulated (e.g., continuous wave, swept wave, pulsed, broadband, etc.) and their dynamic range are critical parameters that should be considered. Similarly, the types of spoofing scenarios that can be generated should also be taken into account.

However, interference/jamming need not be intentional and may arise from other RF signals/systems operating in adjacent frequency bands, either through insufficient filtering at the transmitter or via inadvertently re-radiating of interfering signals within the device. Possible signals may include mobile phones (e.g., LTE, 3G, GSM, etc.), short-range communications (e.g., Bluetooth, WiFi, etc.), or analog television broadcast [18.44]. A simulator's ability to generate these signals should therefore be evaluated.

### 18.7.3 Other Data

As GNSS continues to be integrated with other sensors or systems, the ability to test the fully integrated system, instead of just the GNSS receiver in isolation, becomes an important part of a testing program. Some simulators are already capable of generating additional outputs that can be used for navigation including inertial measurement unit (IMU) data, WiFi signals (for ranging and/or proximity sensing), and assistance data for testing aided GNSS receivers. As other sensors or systems become more commonly integrated with GNSS, the ability of a simulator to include them in the testing chain may be critical.

### 18.7.4 Configurability

The ease of configuring and running a simulation scenario can save considerable time and money and should be given requisite consideration. This may include the ability to control the simulator remotely or via scripts, thus allowing users to work from their own workstation and to perform testing 24 hours per day.

In terms of scenario setup, some simulators allow standard log files (e.g., National Marine Electronics Association (NMEA, see Annex A.1.1) or Receiver INdependent EXchange (RINEX, see Annex A.1.2) formats) recorded from a receiver in a real-world environment to be used as the basis of a simulation. In these cases, the logged data contains information about the user's position, what satellites were in view at every epoch and their measured power level. Such an approach saves time and arguably makes the simulation more realistic and this method of simulation implies that the user already holds a reference trajectory in a suitable format (Sect. 18.4.2).

Other simulators allow users to define a receiver's surroundings in terms of possible reflectors and then uses this to automatically determine what satellites are in view as well as when a particular satellite receives direct and/or reflected signals.

### 18.7.5 Expandability

All simulators have some software interface and processing capabilities and are, thus, theoretically, easily expandable. Similarly, adding additional hardware, for example, to simulate more signals is also generally possible. Nevertheless, understanding what changes/additions can be made after purchase should be an important consideration when purchasing a simulator or testing system.

## 18.8 Summary

This chapter has looked at using simulators for testing the performance of GNSS receivers and, to a lesser extent, complete positioning systems. With simulator options ranging from RF- to measurement-level or combinations thereof, system designers have a number of resources at their disposal that can be used for assessing various parts of a GNSS receiver or a GNSS-integrated system.

As the simulation and testing landscape continue to evolve, new features and capabilities will surely become available. Ultimately, however, proper selection of equipment and careful design of tests – taking into account key objectives – are still a key part of the testing process.

# 19. Basic Observation Equations

André Hauschild

This chapter introduces the fundamental observation equations for multiconstellation global navigation satellite systems (GNSSs). It starts with an introduction of the basic observation equations for pseudorange, carrier-phase, and Doppler measurements. In the remainder of the chapter, the parameters used in modeling the basic observation equations are discussed. The parameters covered in the discussion are relativistic effects, atmospheric delays, the carrier-phase wind-up effect, antenna phase-center offset and variation, pseudorange and carrier-phase biases, and finally multipath errors and receiver noise.

## 19.1 Observation Equations

This section develops generic basic observation equations for pseudorange, carrier-phase and Doppler measurements. All necessary modeling parameters will be identified and discussed in further detail in the following sections.

### 19.1.1 Pseudorange Measurements

For the generation of pseudorange observations, a GNSS receiver measures the apparent signal travel time of the signal from the navigation satellite to the user. The receiver's delay lock loop (DLL) generates a replica of the signal's code based on its internal frequency source and aligns it with the received signal. The necessary time shift is a measure of the apparent transit time modulo the code chip length. It is then combined with the number of complete code chips, complete code repeats, and additional information from the satellite's navigation data to obtain the unambiguous apparent signal travel time or, if multiplied with the speed of light, the apparent range or pseudorange. As shown in the following, the receiver's measurements differ from the true signal travel time or true range, since they are affected by the receiver's and the satellite's clock offsets with respect to the GNSS system time as well as other errors and signal delays.

The arrival time $t_A$ of the signal at the receiver depends on the time $t_E$, when the signal was emitted at the satellite, the signal travel time $\tau$ between the satellite $s$ and the receiver $r$, the relativistic effect due to

space-time curvature $\delta t^{\mathrm{rel}}_{\mathrm{stc}}$, the ionospheric delay $I$, and the tropospheric delay $T$ as follows

$$t_{\mathrm{A}} = t_{\mathrm{E}} + \tau(t_{\mathrm{A}}) + \delta t^{\mathrm{rel}}_{\mathrm{stc}}(t_{\mathrm{A}}) + \frac{1}{c}T(t_{\mathrm{A}}) + \frac{1}{c}I(t_{\mathrm{A}}) \,. \quad (19.1)$$

The signal travel time is equal to the geometric range between the satellite and the receiver divided by the speed of light $c$. More precisely, the range is the difference between the antenna phase centers of the emitting and receiving antennas. The following equation for the signal travel time $\tau$ therefore contains the geometric range $\rho^s_r$, which refers to the satellite's center of mass and the receiving antenna's reference point and the additional term $\xi^s_r$ contains the correction due to phase-center offsets of the transmitting and receiving antennas

$$\begin{aligned}\tau(t_{\mathrm{A}}) &= \frac{\rho^s_r(t_{\mathrm{A}}) + \xi^s_r(t_{\mathrm{E}}, t_{\mathrm{A}})}{c} \\ &= \frac{||\boldsymbol{r}^s(t_{\mathrm{E}}) - \boldsymbol{r}_r(t_{\mathrm{A}})|| + \xi^s_r(t_{\mathrm{E}}, t_{\mathrm{A}})}{c} \,, \end{aligned} \quad (19.2)$$

where $\boldsymbol{r}_r(t_{\mathrm{A}})$ is the receiving antenna's reference point at signal arrival time, and $\boldsymbol{r}^s(t_{\mathrm{E}})$ is the satellite's center of mass position at signal emission time. It should be noted that the term $\xi^s_r$ also contains the contribution of code-phase patterns. These variable pseudorange delays are caused by the radiation pattern of the transmitting and receiving antennas, and thus depend on direction of signal transmission or reception as well as on frequency. Note that they are often referred to as group-delay variations in other literature [19.1, 2].

Since the local oscillator of the receiver is not synchronized with the GNSS time, the measured arrival time $\tilde{t}_{\mathrm{A}}$ as measured by the receiver deviates from the true arrival time due to the receiver clock offset $dt_r(t_{\mathrm{A}})$, instrumental delays $d_r$, and other errors like receiver noise and multipath $e^s_r(t_{\mathrm{A}})$

$$\tilde{t}_{\mathrm{A}} = t_{\mathrm{A}} + dt_r(t_{\mathrm{A}}) + d_r + \frac{1}{c}e^s_r(t_{\mathrm{A}}) \,. \quad (19.3)$$

The signal emitted by the satellite is affected by the clock offset of the onboard clock $dt^s$, the instrumental delays $d^s$, and the relativistic effect $\delta t^{\mathrm{rel}}_{\mathrm{clk}}$. Summarizing these terms leads to the following expression for the apparent emission time $\tilde{t}_{\mathrm{E}}$

$$\tilde{t}_{\mathrm{E}} = t_{\mathrm{E}} + \left(dt^s(t_{\mathrm{E}}) + \delta t^{\mathrm{rel}}_{\mathrm{clk}}(t_{\mathrm{E}})\right) + d^s \,. \quad (19.4)$$

The receiver measures the difference between the apparent arrival and emission time, which is converted with the speed of light to a pseudorange measurement

$$p^s_r(t_{\mathrm{A}}) = c\,(\tilde{t}_{\mathrm{A}} - \tilde{t}_{\mathrm{E}}) \,. \quad (19.5)$$

Substituting (19.1)–(19.4) into (19.5) and introducing the signal identifier $j$ to distinguish between different signals from the same satellite yields the expression for the pseudorange measurement

$$\begin{aligned} p^s_{r,j}(t) = {} & \rho^s_r(t) + \xi^s_{r,j}(t) + c\left(d_{r,j} - d^s_j\right) \\ & + c\left(dt_r(t) - dt^s(t) + \delta t^{\mathrm{rel}}(t)\right) \\ & + I^s_{r,j}(t) + T^s_r(t) + e^s_{r,j}(t) \,. \end{aligned} \quad (19.6)$$

Equation (19.6) is the generic measurement equation for the pseudorange. The relativistic clock correction and the relativistic signal delay due to space-time curvature have been summarized in the single correction term $\delta t^{\mathrm{rel}} = \delta t^{\mathrm{rel}}_{\mathrm{stc}} - \delta t^{\mathrm{rel}}_{\mathrm{clk}}$. The dependency on the frequency for the ionospheric delay and the dependency on the signal for the instrumental delays and multipath are indicated by the additional signal index $j$. Note that the indices for arrival and emission time have been dropped for brevity [19.3, p. 410], [19.4, p. 148].

However, it must be kept in mind that the difference between $t_{\mathrm{A}}$ and $t_{\mathrm{E}}$ is crucial to yield to correct geometric range. The observations are usually available with time tags referring to the measured arrival time. However, for the computation of the geometric range, the satellite position at true emission time $t_{\mathrm{E}}$ is required (19.2). In practice, the emission time can be approximated from $t_{\mathrm{E}} = t_{\mathrm{A}} - \tau$, where $\tau$ is computed from $\tau = ||\boldsymbol{r}^s(t_{\mathrm{A}}) - \boldsymbol{r}_r(t_{\mathrm{A}})||/c$ based on an initial guess for the receiver position. With an updated receiver position from a positioning solution, a more refined value for $\tau$ can be calculated in further iterations (Chap. 21).

Another important effect to remember in the modeling of the geometric term $\rho^s_r$ is the rotation of the Earth-Centered Earth-Fixed reference frame during signal propagation. This effect must be accounted for if the receiver and satellite positions are computed in a noninertial reference frame. It is referred to as Earth rotation correction or Sagnac correction. One possibility to correct for this rotation is to rotate the satellites' positions backwards around the Earth rotation axis by an angle of $\tau \cdot \omega_{\oplus}$, where $\omega_{\oplus}$ is the rotation rate of the Earth [19.4]. Equivalently, the Sagnac correction can be applied as a correction

$$\Delta\rho^s_r = \frac{1}{c}\left(\boldsymbol{r}_r(t_{\mathrm{A}}) - \boldsymbol{r}^s(t_{\mathrm{E}})\right) \cdot \left(\boldsymbol{\omega}_{\oplus} \times \boldsymbol{r}_r(t_{\mathrm{A}})\right) \quad (19.7)$$

to the range between user and satellite, where $\boldsymbol{\omega}_{\oplus}$ is the Earth's rotation vector, the operator $\cdot$ denotes the inner product, and the operator $\times$ denotes the vector product. Introducing the vector $\boldsymbol{S} = \frac{1}{2}\left(\boldsymbol{r}^s(t_{\mathrm{E}}) \times \boldsymbol{r}_r(t_{\mathrm{A}})\right)$ perpendicular to the user and satellite position vectors, the correction can also be expressed as [19.5]

$$\Delta\rho^s_r = \frac{2}{c}\boldsymbol{S} \cdot \boldsymbol{\omega}_{\oplus} \,. \quad (19.8)$$

The different parameters in observation equation (19.6) may either be estimated, corrected for based on models, elimated by combining obervations (cf. Chap. 20), or even neglected depending on the application and the desired accuracy. For pseudorange-based positioning applications, the user may simply only estimate the receiver position $\boldsymbol{r}_r$, which is hidden inside the term $\rho_r^s$, and the receiver clock offset $dt_r$. Satellite clock offsets and positions, relativistic corrections, atmospheric delays and biases will instead be corrected for by external data or models. A GNSS service provider, on the other hand, will need to estimate the satellite's orbits, clock offsets, and biases based on a receiver network in order to be able to provide these values to users for positioning. Other applications may require precise estimates of the ionospheric or tropospheric delays, and these parameters may be estimated then based on GNSS data from a receiver network with known station positions. These examples for the use of GNSS data demonstrate that the decision of which parameters in (19.6) to model and which to estimate strongly depends on the desired application.

### 19.1.2 Carrier-Phase Measurements

A receiver does not only provide measurements of the pseudorange, but also of the signal's carrier phase from its phase lock loop (PLL). The receiver generates a replica of the carrier signal, aligns it with the incoming carrier from the satellite, and measures the fractional phase shift of both signals. When the range between user and satellite changes by more than one cycle, the receiver counts the full cycles and thus provides a continuous measurement. Due to the short wavelength of the carrier phase of approximately 19–25 cm, depending on the frequency, the carrier-phase measurement is much more precise than the pseudorange measurement. This advantage comes at the expense that this observable cannot provide an unambiguous measurement of the apparent satellite-receiver range like the pseudorange. Contrary to the pseudorange, where the navigation data modulated onto the signal is utilized to obtain an unambiguous measurement, the integer number of cycles between the satellite and the receiver at the start of carrier-phase tracking remains unknown. The observation equation for the carrier-phase measurement $\varphi_{r,j}^s$ in units of length is

$$\begin{aligned}\varphi_{r,j}^s(t) = {} & \rho_r^s(t) + \zeta_{r,j}^s(t) + c\left(\delta_{r,j} - \delta_j^s\right) \\ & + c\left(dt_r(t) - dt^s(t) + \delta t^{\mathrm{rel}}(t)\right) \\ & - I_{r,j}^s(t) + T_r^s(t) \\ & + \lambda_j\left(\omega_r^s(t) + N_{r,j}^s\right) + \epsilon_{r,j}^s(t)\,. \end{aligned} \tag{19.9}$$

The carrier-phase measurement is subject to clock offsets and instrumental delays in the receiver and satellite as well as atmospheric delays, receiver noise, and multipath similar to the pseudorange. The terms for geometric range, clock offsets, and tropospheric correction in this equation are identical to (19.6). Similar to the pseudorange, the carrier-phase observation is affected by phase-center offset and variations, which depend on the antenna phase-pattern and the frequency. To emphasize that the correction terms differ for both observables, the symbol $\zeta_{r,j}^s$ has been used to denote the corresponding correction in (19.9). In addition to that, the instrumental delays of receiver $\delta_{r,j}$ and satellite $\delta_j^s$ are different. The sign of the ionospheric correction is negative for the carrier-phase measurements, which will be explained in depth in the corresponding section.

Two additional terms have appeared in (19.9): the phase wind-up correction $\omega_r^s$, which accounts for a change in the measured phase in case of rotations of the antennas. Finally, an unknown integer number of cycles $N_{r,j}^s$ is present in the measurement equation and converted to units of length using the wavelength $\lambda_j$ of the corresponding frequency. The combined effect due to receiver carrier-phase tracking noise and multipath is summarized in the residual error term $\epsilon_{r,j}^s$ [19.4, p. 141].

### 19.1.3 Doppler Measurements

The observed frequency of a signal from a navigation satellite differs from its nominal frequency due to the Doppler shift caused by the relative motion of receiver and satellite. Additionally, the receiver's or satellite's clocks may be affected by a frequency offset or drift. In the receiver's PLL, the phase discriminator drives the numerically controlled oscillator (NCO) to match the frequency and phase of a local carrier-phase replica and the received signal. To compensate for the Doppler effect caused by relative motion of receiver and satellite or frequency deviations in the receiver or satellite clock, the NCO's frequency must be adjusted to keep both phases synchronized. This frequency adjustment in the PLL is reported by the receiver as the Doppler measurement [19.3, p. 411], [19.4, p. 467].

For the derivation of the Doppler observation equation, only the geometric Doppler effect is considered and atmospheric propagation delay, clock frequency deviations, and relativistic effects are neglected for now. Assuming that a receiver and a satellite are moving with velocities $\boldsymbol{v}_r$ and $\boldsymbol{v}^s$ respectively, the relation

$$f_r = f^s \left( \frac{1 + \left( \dfrac{\boldsymbol{e} \cdot \boldsymbol{v}_r}{c} \right)}{1 + \left( \dfrac{\boldsymbol{e} \cdot \boldsymbol{v}^s}{c} \right)} \right) \tag{19.10}$$

between the received frequency $f_r$ and the transmitted frequency $f^s$ can be found, where $\boldsymbol{e}$ is the unit line-of-sight vector from the user to the GNSS satellite. Assuming that $v_r \ll c$ and $v^s \ll c$, (19.10) is expanded in terms of the quantity $\boldsymbol{v}^s/c$. Neglecting all terms involving $\boldsymbol{v}_r$ and $\boldsymbol{v}^s$ in higher order than two yields the following expression for the relation of received and transmitted frequency [19.6, p. 9]

$$f_r = f^s \left[1 + \left(\frac{\boldsymbol{v}^s}{c} - \boldsymbol{e}\right) \cdot \frac{(\boldsymbol{v}^s - \boldsymbol{v}_r)}{c}\right] . \tag{19.11}$$

For the following derivations, the clocks' frequency deviations are now introduced. The frequency deviation of the receiver clock is denoted $df_r$. The transmitted frequency is also subject to a deviation $\delta f^{\text{rel}}_{\text{clk}}$ from its nominal value caused by relativistic effects as well as a frequency deviation $df^s$ due to imperfections of the frequency standard itself. As a result, the following expression for the measured frequency $\tilde{f}_r$ and the transmitted frequency $\tilde{f}^s$ can be found

$$\begin{aligned} \tilde{f}_r &= f_r + df_r \\ \tilde{f}^s &= f^s + df^s - f^s \delta f^{\text{rel}}_{\text{clk}} . \end{aligned} \tag{19.12}$$

Introducing the expression for the observed Doppler shift $D^s_r = \tilde{f}_r - \tilde{f}^s$ and substituting (19.11) and (19.12) leads to

$$\begin{aligned} D^s_{r,j} = {} & \frac{1}{\lambda_j}\left(\frac{\boldsymbol{v}^s}{c} - \boldsymbol{e}\right) \cdot (\boldsymbol{v}^s - \boldsymbol{v}_r) \\ & + (df_r - df^s) + \frac{c}{\lambda_j} \delta f^{\text{rel}}_{\text{clk}} . \end{aligned} \tag{19.13}$$

The term $\boldsymbol{v}^s/c$ is a line-of-sight correction due to satellite motion. Note that the Doppler is positive if satellite and receiver approach each other, i. e., when the range rate $\dot{\rho} = \boldsymbol{e} \cdot (\boldsymbol{v}^s - \boldsymbol{v}_r)$ is negative.

## 19.2 Relativistic Effects

The relativistic effects in GNSS can be split into two different categories: delays affecting the signal path due the Earth's gravitational potential, and deviations of the satellite clock frequency due to relativistic effects. Both of these are discussed in more detail in Sect. 5.4.

The Shapiro effect is a delay of the satellite signal due to the presence of the Earth's gravitational field, which causes a propagation delay due to space-time curvature. The corresponding delay correction $\delta t^{\text{rel}}_{\text{stc}}$ is computed from

$$\delta t^{\text{rel}}_{\text{stc}} = \frac{2\mu}{c^3} \ln\left(\frac{||\boldsymbol{r}^s|| + ||\boldsymbol{r}_r|| + \rho^s_r}{||\boldsymbol{r}^s|| + ||\boldsymbol{r}_r|| - \rho^s_r}\right) , \tag{19.14}$$

where $\mu$ is the Earth's gravitational constant [19.7, 8]. Assuming a user on the surface of the Earth, the maximum Shapiro effect is approximately 60 ps or 2 cm for medium Earth orbit (MEO) satellites of GPS, GLONASS, Galileo, and BeiDou. For BeiDou satellites on inclined geosynchronous orbits (IGSO), it is on the order of 70 ps.

The onboard clock will be affected by a relativistic clock correction term $\delta t^{\text{rel}}_{\text{clk}}$ caused by the motion of the satellite as well as the change in the gravitational potential. These effects caused by special and general relativity lead to a frequency offset of the onboard clock with respect to a ground-based clock. To mitigate this effect, the satellite's clock frequencies are actually offset from their nominal values. However, noncircular satellite orbits cause deviations from the mean frequency offset. The effect due to the orbit eccentricity can be computed from

$$\delta t^{\text{rel}}_{\text{clk}} = -\frac{2}{c^2}\sqrt{a\mu}\, e \sin E , \tag{19.15}$$

where $a$ is the semimajor axis, $e$ is the orbit eccentricity of the satellite orbit, and $E$ the eccentric anomaly of the satellite, an angle related to the position of the satellite on its orbit [19.9]. The same correction can also be formulated using the satellite's position and velocity vector $\boldsymbol{r}^s$ and $\boldsymbol{v}^s$ [19.8, 10]

$$\delta t^{\text{rel}}_{\text{clk}} = -\frac{2}{c^2}(\boldsymbol{r}^s \cdot \boldsymbol{v}^s) . \tag{19.16}$$

The time derivative of (19.16) is the frequency deviation due to the orbit eccentricity, which is required for the Doppler observation (19.13). It can be found from

$$\delta f^{\text{rel}}_{\text{clk}} = \frac{2\mu}{c^2}\left(\frac{1}{a} - \frac{1}{||\boldsymbol{r}^s||}\right) . \tag{19.17}$$

It becomes immediately obvious from (19.17) that the correction is zero if the orbit radius is equal to the semimajor axis [19.11].

The typical order of magnitude for the relativistic clock offset correction is on the order of nanosec-

onds. Assuming the maximum tolerated eccentricity of 0.02 for GPS, the maximum value for $\delta t_{\mathrm{clk}}^{\mathrm{rel}}$ is approximately 45.0 ns, which corresponds to about 13.5 m. The maximum frequency deviation $\delta f_{\mathrm{clk}}^{\mathrm{rel}}$ in this case amounts to about 6.0 ps/s or approximately 2.0 mm/s. For GLONASS satellites, which have smaller orbit eccentricities, $\delta t_{\mathrm{clk}}^{\mathrm{rel}}$ and $\delta f_{\mathrm{clk}}^{\mathrm{rel}}$ are on the order of 8.0 ns and 1.2 ps/s. It becomes obvious that for GNSS satellites on near-circular orbits, the relativistic frequency offset deviation can be safely neglected in modeling Doppler observations. Even for satellites of the Quasi-Zenith Satellite System (QZSS) on their elliptical inclined geosynchronous orbits, this correction does not exceed 20 ps/s or 6 mm/s.

Even on a circular orbit the satellite clock would travel through a varying gravitational potential, since the Earth is not a perfect sphere with homogeneous mass distribution. The most prominent effect at the height of GNSS satellites is caused by the Earth's oblateness, described by the term $J_{20}$ of the gravitation field expansion series. Often referred to as $J_2$-correction, the periodical part of this correction can be found from

$$\delta t_{\mathrm{clk},J_2}^{\mathrm{rel}} = -J_2 \frac{3}{2} \frac{r_{\oplus}^2}{c^2} \sqrt{\frac{\mu}{a^3}} \sin^2 i \sin 2u \,, \tag{19.18}$$

where $R_{\oplus}$ is the equatorial radius of the Earth, $J_2 = 1.083 \cdot 10^{-3}$, the orbit inclination $i$, and the argument of latitude $u$, which is defined as $u = \omega + f$, the sum of argument of perigee $\omega$ and true anomaly $f$. It should be noted that the $J_2$-correction as formulated in (19.18) is an additional correction term to the conventional eccentricity correction of (19.16) [19.8, 10].

Obviously, the magnitude of the $J_2$-correction is proportional to the inclination and inversely proportional to the semimajor axis of the satellite orbit. For MEO satellites, the correction varies between ±62 ps for Galileo satellites, which have the largest semimajor axis, and ±100 ps for GLONASS satellites, which have the lowest orbit altitude and the largest orbit inclination. For BeiDou IGSO satellites, the $J_2$-correction decreases down to only ±36 ps. Depending on the satellite system, this correction varies between approximately 1–3 cm and may therefore become relevant for the modeling of observations, especially for characterization of the high-precision rubidium atomic frequency standards of the GPS Block-IIF satellites and the Galileo passive hydrogen maser.

Finally, it will be emphasized that all relativistic clock corrections discussed here so far have only considered the satellite clock. Of course, for a receiver moving through the Earth's gravitational potential, relativistic effects also apply to the receiver clock. For example, a space-borne receiver on an eccentric orbit would be subject to a similar relativistic clock correction as described by (19.16). The receiver relativistic clock corrections affect all observations in the same way. Therefore, considering them in the observation model can safely be neglected since they are entirely compensated in the receiver clock offset estimation. Modeling only becomes relevant, for example, when the true behavior of the receiver clock is to be characterized, a rather special application, which has not been regarded here.

## 19.3 Atmospheric Signal Delays

On its way to users on or close to the surface of the Earth, GNSS signals have to traverse the atmosphere. At a height of approximately 1000 km the signals encounter the ionosphere, a layer of charged particles, which extends down to an altitude of about 50 km. Underneath, the troposphere, a layer of electrically neutral gases, is predominant. Both layers change the speed as well as the direction of travel of the signal. This effect is referred to as refraction, and it is characterized using the refractive index $n$, which is the ratio of the speed of light and the speed in the medium $v$

$$n = \frac{c}{v} \,. \tag{19.19}$$

Since the atmosphere is not a uniform layer, the refractive index changes along the signal path. This change of $n$ causes the signal to be bent in accordance with Snell's law. However, the travel time on the curved path is shorter than for the straight-line path according to Fermat's principle of least time. The travel time of the signal can be found from the integral of the refractive index along the signal-path $n(l)$ from satellite to receiver

$$\tau = \frac{1}{c} \int_s^r n(l) \mathrm{d}l \,. \tag{19.20}$$

The delay with respect to a signal path in a vacuum is then found from

$$\Delta\tau = \frac{1}{c} \int_s^r (n(l) - 1) \, \mathrm{d}l \,. \tag{19.21}$$

If the refractivity index depends on the frequency, the associated media is called *dispersive*. In dispersive media, signals on different frequencies are subject to different delays. Furthermore, the carrier of the signal and its modulation travel at different velocities, which is referred to as code-carrier divergence. Therefore, phase refractive index $n_p$ for the carrier and a group refractive index $n_g$ for the code are defined as

$$n_p = \frac{c}{v_p}$$
$$n_g = \frac{c}{v_g}\,, \tag{19.22}$$

where $v_p$ and $v_g$ are the phase and group velocities respectively. Both indices are related via

$$n_g = n_p + f\frac{dn_p}{df}\,. \tag{19.23}$$

These expressions will become relevant for the derivation of the signal delays for pseudorange and carrier phase in the dispersive ionosphere [19.4, 12].

In the following sections, the different GNSS signal delays caused by ionosphere and troposphere are briefly described. Simple models for the range delays are introduced. For a detailed discussion of tropospheric and ionospheric delays the reader may refer to Chap. 6 as well as Chaps. 38–39.

### 19.3.1 Ionosphere

The ionosphere is a layer of the atmosphere that contains electrically charged particles. The Sun's ultraviolet radiation causes gas molecules to break up into free electrons and ions. The delay of the signal depends on the number of free electrons along its path. The total electron content (TEC) is defined as the number of electrons in a tube with a cross section of 1 m$^2$

$$\mathrm{TEC} = \int_s^r n_e(l)\mathrm{d}l\,, \tag{19.24}$$

where $n_e(l)$ is the electron density along the signal path integrated from the satellite to the receiver. The electron density is not uniformly distributed along the signal path in the ionosphere. The ionization process affects the various layers of the ionosphere in different ways. As a result, the electron density changes along the signal path. The maximum density of charged particles can be found in altitudes between 250–400 km, which coincides with the so called F2 region of the ionosphere [19.13].

In addition to the spatial variability, there is also a temporal variation of the number of free electrons caused by the different amount of solar radiation during day and night. In the illuminated parts of the ionosphere, ionization takes place and the electron density reaches a peak value at 14:00h local time. With decreasing sunlight the recombination of electrons and ions prevails, and the number of free electrons is reduced again. In addition to this diurnal effect, the number of electrons undergoes a seasonal variation due to different amounts of solar radiation received in summer and winter as well as a long-term variation depending on the eleven-year solar cycle. However, there are also unpredictable short-term effects due to irregular changes in solar activity and traveling ionospheric disturbances. The latter can cause rapid changes in the electron density in a geometrically confined area. An active ionosphere can cause scintillation effects, which are rapid fluctuations in the carrier phase, as well as signal fading and may cause a threat to GNSS tracking especially in polar and equatorial regions [19.4].

As mentioned earlier, the ionosphere is a dispersive medium in which the signal delay depends on frequency and phase and code of the same signal travel at different velocities. The refractive index for the carrier phase $n_p$ can be approximated to first order as

$$n_p \approx 1 - \frac{40.3 n_e}{f^2}\,, \tag{19.25}$$

where $n_e$ is the electron density and $f$ is the frequency of the signal. The signal delay of the carrier-phase measurements can then be found from

$$\Delta\tau_p = \frac{1}{c}\int \left(n_p(l) - 1\right)\mathrm{d}l$$
$$= -\frac{40.3\cdot \mathrm{TEC}}{cf^2}\,. \tag{19.26}$$

The group refractive index $n_g$ is found by substituting (19.25) into (19.23)

$$n_g \approx 1 + \frac{40.3 n_e}{f^2}\,. \tag{19.27}$$

Similar to the carrier-phase delay, the pseudorange delay can be found by integrating the electron density along the signal path

$$\Delta\tau_g = \frac{1}{c}\int \left(n_g(l) - 1\right)\mathrm{d}l$$
$$= \frac{40.3\cdot \mathrm{TEC}}{cf^2}\,. \tag{19.28}$$

Multiplication with the speed of light converts the delays $\Delta\tau_p$ and $\Delta\tau_g$ to units of length

$$I = -I_p = \frac{40.3 \cdot \mathrm{TEC}}{f^2} \,. \tag{19.29}$$

It becomes obvious that the pseudorange delay $I$ has an opposite sign compared to the phase delay $I_p$, which has already been noted in (19.6) and (19.9). Furthermore, the pseudorange delay decreases with increasing frequency and depends, to first order, linearly on the total electron content along the signal path, also referred to as slant TEC (STEC). The TEC is measured in TEC units (TECU) which are defined as $10^{16}$ electrons/m$^2$. On the GPS L1 frequency, one TEC unit accounts for an approximately 16.2 cm delay.

A simple model for the ionospheric delay can be derived from the assumption that the ionosphere is a thin shell surrounding the Earth with evenly distributed electron density. In this case, the total electron content can be modeled as the TEC in the vertical direction (VTEC) scaled by an obliquity factor to account for the increase of ionospheric path length for lower elevation angles. Figure 19.1 depicts the geometry between user, satellite, and the ionospheric pierce point (IP), where the line-of-sight vector penetrates the ionospheric shell at the mean ionospheric height $h_I$. The total ionospheric pseudorange delay in terms of VTEC and zenith angle $z'$ at the IP can be found as

$$I = \frac{1}{\cos z'} \frac{40.3 \cdot \mathrm{VTEC}}{f^2} \,. \tag{19.30}$$

The zenith angle at the IP is related to the zenith angle $z$ at the user position through

$$\sin z' = \frac{R_\oplus}{R_\oplus + h_I} \sin z \,. \tag{19.31}$$

where $R_\oplus$ is the radius of the Earth. This leads to the final expression

$$I = \frac{1}{\sqrt{1 - \left(\frac{R_\oplus}{R_\oplus + h_I} \sin z\right)^2}} \frac{40.3 \cdot \mathrm{VTEC}}{f^2} \,. \tag{19.32}$$

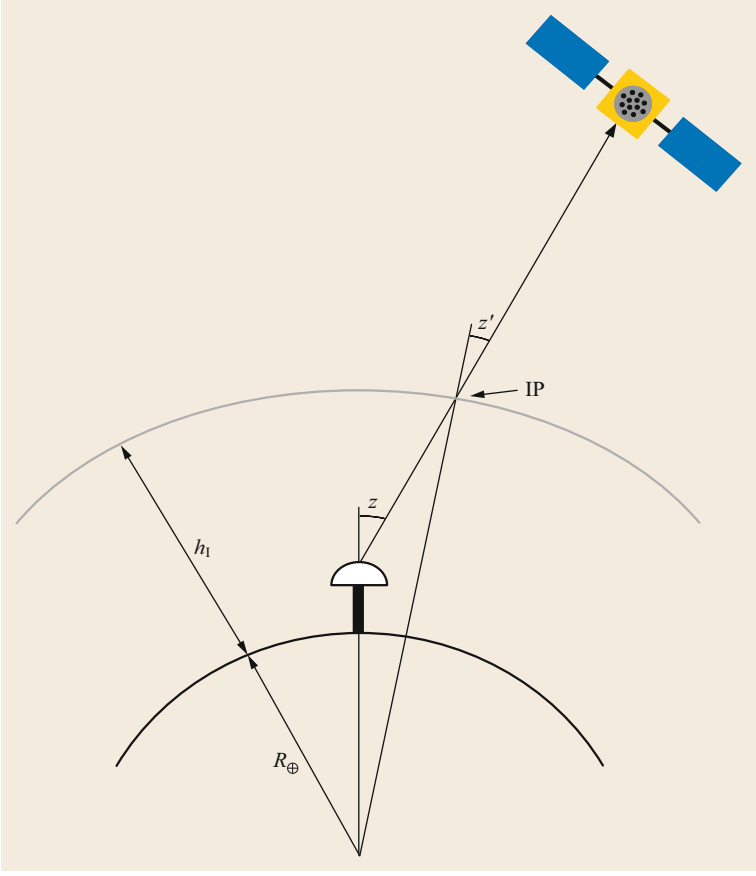

**Fig. 19.1** Geometric relations between zenith angles $z$ and $z'$ at user position and ionospheric pierce point (IP) for the thin-shell ionospheric model (after [19.12])

The values for the obliquity factor vary between 1 and 3 for satellites at zenith and close to the horizon. Vertical TEC varies typically between a few TECU at local nighttime and several tens of TECU at local daytime. In the case of very high ionospheric activity, the peak value of VTEC can reach more than 200 TECU [19.4, 13].

The simple model introduced here can be utilized in different ways. With a correction value for the VTEC available, for example from a global or regional ionospheric map (GIM or RIM), users can apply (19.32) as a correction of the ionospheric delay in the observation model. In the case of single-frequency GPS, this method has been found to yield improved results compared to the broadcast ionospheric model [19.14, 15]. In the case of multifrequency receivers, the delay based on (19.32) can serve as an a priori correction, which allows a constrained estimation of a residual slant delay [19.16]. Attempts to model and estimate VTEC based on (19.32) have also been made [19.17].

### 19.3.2 Troposphere

The troposphere and the stratosphere together form the neutral atmosphere. This layer is nondispersive for signals in the L-band, which has a frequency range of 1–2 GHz. The L-band GNSS signals are therefore affected by the same delay in this part of the atmosphere irrespective of their center frequency, and the delay is also identical for pseudorange and carrier-phase measurements. The majority of the water vapor and moist gases are concentrated in the troposphere, the lower part of the neutral atmosphere. The stratosphere begins above the troposphere and extends up to a height of approximately 50 km. It contains mostly dry gases [19.12]. Both layers are usually referred to as troposphere in the GNSS nomenclature, and the same will be adopted for the remainder of this section.

The tropospheric path delay $\Delta\tau_\mathrm{T}$ in units of time depends on the refractive index $n$ integrated along the signal propagation path $l$

$$\Delta\tau_\mathrm{T} = \frac{1}{c}\int_s^r (n-1)\mathrm{d}l\,. \tag{19.33}$$

Note the similarity of this expression to (19.26) and (19.28). Using the tropospheric refractivity $N_\mathrm{T} = 10^6\,(n-1)$ in (19.33) and converting the expression to units of length yields the total path delay

$$T_r^s = 10^{-6}\int_s^r N_\mathrm{T}\mathrm{d}l\,. \tag{19.34}$$

The total tropospheric refractivity $N_\mathrm{T}$ of air containing water vapor can be written as

$$N_\mathrm{T} = k_1\frac{p}{T}Z_\mathrm{d}^{-1} + k_2\frac{e}{T}Z_\mathrm{w}^{-1} + k_3\frac{e}{T^2}Z_\mathrm{w}^{-1}\,, \tag{19.35}$$

where $T$ is temperature, $p$ and $e$ are the partial pressures of the dry and wet constituents respectively, and $Z_\mathrm{d}$ and $Z_\mathrm{w}$ are the compressibility for dry and wet air respectively. The three constants are given as $k_1 = 77.6$, $k_2 = 64.8$ and $k_3 = 3.776\cdot 10^5$ [19.18].

According to *Saastamoinen* [19.19] and *Davis* et al. [19.20], the total tropospheric delay can be separated into a hydrostatic (i. e., dry) part, which only depends on the pressure, and a nonhydrostatic part, which depends on the water vapor pressure profile and is also referred to as the wet part. The hydrostatic part is responsible for the majority of the delay. The nonhydrostatic part only accounts for a minor part of the total delay, however it is more difficult to model, since the water vapor content in the atmosphere can change rapidly.

If the atmospheric parameters, which determine the refractivity, were known for the entire signal path, the tropospheric delay could be obtained by integration of (19.34). In practice, however, $p$, $T$, and $e$ may only be available with some effort from in situ measurements at the user position. A number of models have been developed, which relate the state of the atmosphere at an arbitrary height to the atmospheric parameters at the user height and thus allow the integration of (19.34) into zenith direction.

The resulting zenith tropospheric delay (ZTD) is then multiplied with a mapping function to yield the total delay along the signal path. The mapping function $m(E)$ may be different for the dry and wet delay, and depends on the satellite's elevation angle $E$ as seen from the user. In its most general from, the delay can be written as

$$T_r^s = \mathrm{ZTD_d}\,m_\mathrm{d}(E) + \mathrm{ZTD_w}\,m_\mathrm{w}(E)\,, \tag{19.36}$$

where $\mathrm{ZTD_d}$ and $\mathrm{ZTD_w}$ are the dry and the wet ZTDs, and $m_\mathrm{d}$ and $m_\mathrm{w}$ are the corresponding mapping functions.

One of the most fundamental models has been developed by Hopfield. It relates the hydrostatic and nonhydrostatic refractivities at the surface position to the refractivities at a given height above the user through a fourth-order function of height based on the assumption of a constant temperature lapse rate. The model also provides the corresponding mapping functions to compute the total slant delay. Atmospheric parameters are required as input [19.21].

Another fundamental model has been developed by *Saastamoinen* [19.19]. Based on his work, an expression for the hydrostatic delay has been derived that only depends on pressure, latitude and height above the geoid of the user position [19.20]. A consistent expression for the nonhydrostatic delay has been derived in [19.22], which depends on temperature, water vapor partial pressure, user location, and time.

Most of the mapping functions currently used to scale the zenith delay to a slant delay at satellite elevation angle $E$ are based on a continued fraction expansion of $1/\sin(E)$, as defined by *Herring* [19.23] based on the suggestion of *Marini* [19.24]. This continued fraction expansion has the general form of

$$m(E) = \frac{1 + \left( \dfrac{a}{1 + \dfrac{b}{(1+c)}} \right)}{\sin(E) + \left( \dfrac{a}{\sin(E) + \dfrac{b}{(\sin(E)+c)}} \right)} \,. \tag{19.37}$$

The mapping functions for wet and dry delay have identical form but differ in their values for coefficients $a$, $b$, and $c$. The coefficients for the wet mapping function according to Herring depend on latitude and height of the observation site as well as on local temperature. The dry mapping function only depends on latitude and temperature [19.23].

The Niell mapping functions (NMF) are also based on (19.37). The coefficients are obtained from a fit through radiosonde data from the Northern Hemisphere and are site- and time-dependent but do not require meteorological data [19.25]. Later, the accuracy of the NMF has been improved by deriving the coefficients of the mapping functions based on data of a numerical weather model. The resulting isobaric mapping function (IMF) is more challenging to evaluate, since it depends on meteorological data at the epoch of the observations. This information is available from meteorological data centers for a global grid of reference points that are updated several times per day [19.26]. A similar approach has been done for the Vienna mapping function 1 (VMF1) [19.27].

To overcome the dependency on actual in situ atmospheric measurements, research has been conducted into developing globally valid models to provide the meteorological data for the tropospheric modeling. One of these models has been developed at the University of New Brunswick (UNB). The UNB3 model and the refined version UNB3m provide tabulated data to compute the temperature, pressure, and water vapor partial pressure based on latitude and time. These values are then used to compute the zenith delay based on the Saastamoinen model and mapped to a slant delay using the Niell mapping functions [19.28, 29]. In an alternative integrated model, the meteorological parameters provided by the global pressure and temperature model (GPT) [19.30] are used to compute wet and dry zenith delays, which are then mapped using the global mapping functions (GMF) [19.31] to the slant delay.

The UNB3m model yields a hydrostatic zenith delay of 2.3 m for a user on the meridian at the equator on day-of-year 120. The corresponding nonhydrostatic delay amounts to 0.27 m. Tropospheric mapping functions typically increase gradually from unity at zenith to values of about 2 at 30° and about 5 at 10° elevation angle. Below, the mapping function increases steeply to approximately 14–16 at 3°.

For high-precision applications, however, it may not be sufficient to only model the meteorological parameters with empirical data due to the temporal variation of water vapor in the atmosphere. It is common practice in geodetic processing to apply a priori corrections of the tropospheric delay in the modeling of the observations and include an additional zenith delay correction in the estimation parameters [19.12].

## 19.4 Carrier-Phase Wind-Up

This section describes the physical background of the wind-up effect of circular polarized waves, and presents the mathematical model for describing the effect as a function of the relative attitude of transmitter and receiver antennas. Since knowledge about the satellite's orientation is crucial for the computation of the wind-up effect, different satellite attitude models are presented.

### 19.4.1 Wind-Up Effect for Radio Waves

Navigation satellites typically emit right-hand circularly polarized (RHCP) waves (Chap. 4). The polarization of the wave determines how the electrical field vector changes, when the wave propagates from the emitter to the receiver. Circularly polarized waves consist of two signal components created by two crossed

dipoles $\boldsymbol{x}$ and $\boldsymbol{y}$, which are perpendicular to each other, and create a sine wave with a relative phase shift of 90°. The resulting electrical field of the electromagnetic wave rotates in the $x/y$-plane.

Rotating the receiving antenna about its boresight direction, perpendicular to the two dipoles, changes the relative orientation to the electrical field, and thus the measured phase angle. Similarly, rotating the transmitting antenna changes the orientation of the instantaneous electrical field at the receiving antenna. This effect is referred to as phase wind-up or phase wrap-up. A full rotation of either the receiving or the transmitting antenna around its boresight vector causes a change in the measured carrier phase by one cycle for all frequencies. The corresponding range error is approximately 19 cm for L1 and about 25 cm for the L5 frequency [19.32].

Assuming that $\boldsymbol{k}$ is a unit vector pointing from the transmitter to the receiver, an effective dipole vector $\boldsymbol{D}$ can be defined in terms of the dipole unit vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ as well as $\boldsymbol{k}$ as

$$\boldsymbol{D} = \boldsymbol{x} - \boldsymbol{k}\,(\boldsymbol{k}\cdot\boldsymbol{x}) + \boldsymbol{k}\times\boldsymbol{y}\ . \tag{19.38}$$

A similar expression for the effective dipole vector $\boldsymbol{D}'$ of the transmitting antenna can also be found

$$\boldsymbol{D}' = \boldsymbol{x}' - \boldsymbol{k}\,(\boldsymbol{k}\cdot\boldsymbol{x}') - \boldsymbol{k}\times\boldsymbol{y}'\ , \tag{19.39}$$

where $\boldsymbol{x}'$ and $\boldsymbol{y}'$ are the corresponding dipole unit vectors of the transmitting antenna. These properties are illustrated in Fig. 19.2. The phase wind-up $\omega$ in terms of cycles can then be found from

$$\omega = \text{sign}\,(\gamma)\arccos\left(\frac{\boldsymbol{D}'\cdot\boldsymbol{D}}{||\boldsymbol{D}'||\,||\boldsymbol{D}||}\right), \tag{19.40}$$

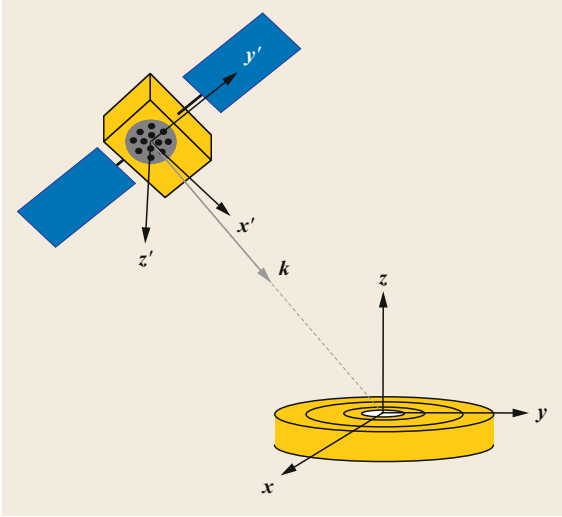

**Fig. 19.2** Carrier-phase wind-up

with the term $\gamma$ defined as

$$\gamma = \boldsymbol{k}\cdot(\boldsymbol{D}'\times\boldsymbol{D})\ . \tag{19.41}$$

Note that continuity of the phase correction in (19.40) has to be maintained if the relative rotation exceeds 360°.

The two different contributions due to satellite or receiver antenna rotation manifest themselves differently in the observations. The phase wind-up effect due to rotation of the receiving antenna is identical for all received signals. If uncorrected, it will therefore be compensated by an epoch-wise estimation parameter, which is common for all carrier-phase observations, for example a receiver clock estimate. On the other hand, this effect may also be exploited for spin-rate estimation of the receiving antenna [19.33]. The phase wind-up contribution from the transmitting antenna is different for each satellite, however, and is typically included in the modeling of undifferenced observations. For differential processing, the residual contribution is on the order of a few millimeters for short baselines of several hundreds of kilometers or less. However, residual errors of a quarter of a wavelength can occur in double differences of observations for baseline lengths of thousands of kilometers [19.34].

The previous discussion has assumed the ideal case, in which only right-hand circularly polarized (RHCP) signals have been considered. In reality, a fraction of the transmitted signal is also left-hand circularly polarized. However, this effect can generally be neglected for users on or close to the Earth, including satellites on low-Earth orbits within a cone of 16° of the transmitting boresight [19.34].

### 19.4.2 GNSS Satellite Attitude Modeling

Knowledge of the navigation satellite's attitude is obviously crucial for the computation of the phase wind-up effect due to rotation of the transmit antenna. The orientation of a navigation satellite is determined by two requirements. Firstly, the boresight vector of the transmit antenna must be pointed towards the Earth. Secondly, the solar panels have to be oriented to the Sun in order to provide sufficient power for the spacecraft. To fulfill the first requirement, the satellite's body-fixed $z$-axis, which points parallel to the antenna boresight vector, is always oriented towards the center of the Earth. The second requirement is achieved by rotating the satellite around its $z$-axis in order to keep the solar panel axis perpendicular to the Sun's direction. This continuous change in orientation during the orbital period is referred to as yaw steering (Sect. 3.4). The

rotation matrix $\mathbf{R}_{\mathrm{YS}}$ from the satellite body-fixed coordinate frame to the Earth-Centered Earth-Fixed (ECEF) is then [19.35]

$$\begin{aligned} \boldsymbol{e}_z &= -\frac{\boldsymbol{r}}{||\boldsymbol{r}||} \\ \boldsymbol{e}_y &= \boldsymbol{e}_z \times \boldsymbol{e}_\odot \\ \boldsymbol{e}_x &= \boldsymbol{e}_z \times \boldsymbol{e}_y \\ \mathbf{R}_{\mathrm{YS}} &= [\,\boldsymbol{e}_x\ \boldsymbol{e}_y\ \boldsymbol{e}_z\,]\,. \end{aligned} \tag{19.42}$$

Here, $\boldsymbol{r}$ is the satellite position vector, $\boldsymbol{e}_\odot$ is the unit vector pointing from the satellite to the Sun, and $\boldsymbol{e}_x$, $\boldsymbol{e}_y$, and $\boldsymbol{e}_z$ are the body-fixed unit vectors as depicted in Fig. 19.3.

The yaw angle $\Psi$ is the angle between the body-fixed $x$-vector and the along-track vector pointing towards the general direction of the satellite's velocity vector. The yaw angle $\Psi$ and the yaw rate $\dot{\Psi}$ can be found from

$$\begin{aligned} \Psi_{\mathrm{YS}} &= \arctan\left(\frac{-\tan\beta}{\sin\mu}\right) \\ \dot{\Psi}_{\mathrm{YS}} &= \dot{\mu}\frac{\tan\beta\cos\mu}{\sin^2\mu+\tan^2\beta}\,, \end{aligned} \tag{19.43}$$

where $\mu$ is the orbit angle measured from orbit midnight and $\beta$ is the elevation of the Sun above the orbital plane [19.35].

However, this attitude law is subject to a singularity that occurs if the Sun incident angle $\beta$ is zero. The yaw angle is therefore undefined twice along the spacecraft orbit in this case: when the satellite is closest to the Sun at orbit noon or furthest away from the Sun at orbit midnight. Furthermore, this attitude law requires the satellite to perform an instantaneous rotation by 180° after crossing the orbit midnight or noon position [19.35]. In reality, the maximum possible yaw rate of the spacecraft is already exceeded for small $\beta$-angles due to hardware limitations of the satellite's attitude control system and will cause the actual yaw angle to differ from the attitude law in (19.43). The resulting yaw attitude profiles differ between miscellaneous constellations, and even between different satellite types within the same constellation.

The Block II/IIA satellites of the GPS constellation cannot follow the nominal yaw rate defined by (19.43) close to orbit noon if $|\beta|$ is less than 3.6–4.9°. The satellite rotates with the maximum yaw rate of 0.10–0.13 °/s during these phases and the actual yaw attitude lags the required yaw angle. When the satellite proceeds on its orbit after crossing the orbit's noon position, the required yaw rate decreases and the satellite can catch up again and reaches nominal attitude. If a Block II/IIA spacecraft enters the Earth's shadow close to orbit midnight, its attitude control system cannot determine the yaw orientation anymore, since it solely relies on the Sun sensors for this task. The satellite starts a yaw motion with the maximal rate in this case until it leaves the eclipse again. It then recovers its nominal attitude. The direction of the yaw motion in the eclipse phase is

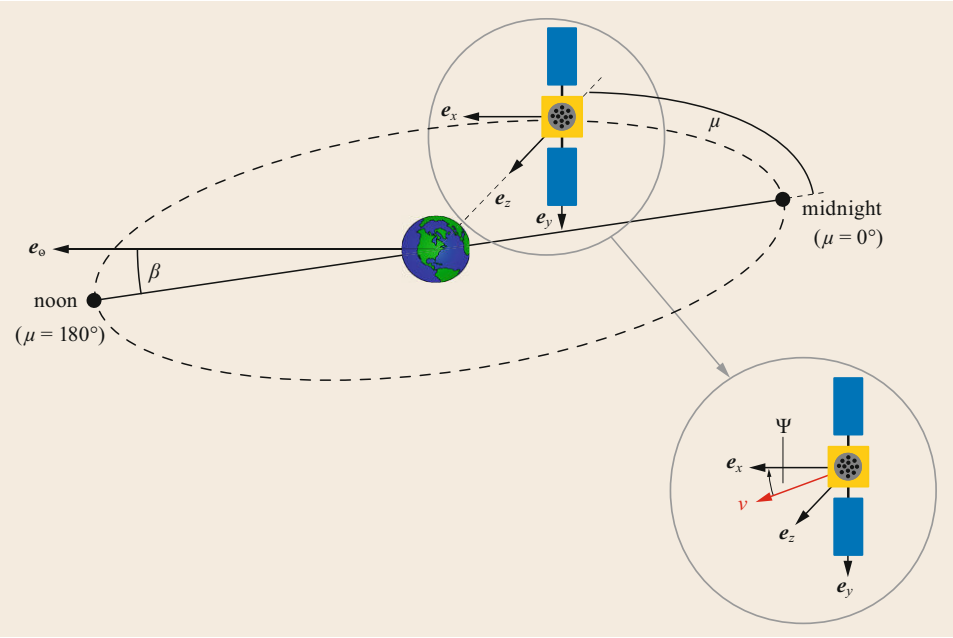

**Fig. 19.3** Orbit of a GNSS satellite depicting the orbit angle $\mu$ with the orbit noon and midnight positions respectively, the Sun incidence angle $\beta$, and the yaw angle $\Psi$

predictable since a modification of the attitude control system was implemented in the mid 1990s. However, the yaw turn direction during the post-shadow recovery maneuver cannot be predicted reliably [19.35]. The newer generation of Block IIR satellites are capable of maintaining the nominal attitude even during eclipse phase but are still limited by a maximum yaw rate of $0.20\,^\circ/\mathrm{s}$, which is reached for $|\beta| < 2.4^\circ$ [19.36]. The midnight and noon turn maneuvers of the newest Block-IIF satellites differ again from the previous satellites. As soon as the satellite enters the Earth's shadow, it starts a rotation with a constant rate, which is selected such that it brings the satellite to the required attitude at shadow exit. Errors of a few degrees with respect to the nominal orientation are corrected with a short recovery maneuver. For noon turn maneuvers with $|\beta| < 4^\circ$, the satellite's rotation is limited to a constant yaw rate of $0.11\,^\circ/\mathrm{s}$. The difference between nominal and actual yaw attitude may amount to $\pm 180^\circ$ or $\pm 90^\circ$ for noon and midnight turn maneuvers respectively [19.37, 38].

GLONASS satellites are likewise affected by the need for special orbit noon and midnight maneuvers. However, the implementation of these maneuvers differs significantly from GPS. The current GLONASS-M satellites perform a midnight turn maneuver directly after shadow entry. The satellite starts a rotation with the maximum hardware yaw rate of approximately $0.24$–$0.26\,^\circ/\mathrm{s}$ until it has reached the nominal orientation required at shadow exit. It then maintains this constant orientation throughout the eclipse phase and follows the yaw-steering attitude law after leaving the Earth's shadow. As a result, the actual yaw angle may precede the nominal angle by up to $\pm 180^\circ$. For the noon turn maneuvers, the nominal yaw rate exceeds the maximal hardware yaw rate for $|\beta|$ less than $2^\circ$. Again, the satellite rotates with its maximum yaw rate during this maneuver. In contrast to GPS satellites though, the rotation already starts before the nominal yaw rate exceeds the maximal possible rate. As a result, the actual yaw orientation first precedes and then lags the nominal one [19.39].

The Galileo In-Orbit Validation (IOV) satellites also follow the yaw steering law for $|\beta| < 2^\circ$. In this case, the attitude control system uses a patented *dynamic yaw steering* concept. The idea behind this concept is to use a modified Sun angle as input for the control law in (19.43), in order to ensure that the maximum hardware yaw rate is not exceeded [19.40, 41].

The first QZSS satellite Michibiki on its elliptical inclined geosynchronous orbit (IGSO) uses a completely different attitude control approach for small $\beta$-angles. Already at $|\beta| < 20^\circ$, the satellite switches from yaw-steering attitude mode to orbit-normal mode, in which the satellite's body-fixed axes are aligned with the orbital frame. As a result, the yaw angle is 0 or $180^\circ$, depending on the convention, and the yaw rate is zero [19.42]. This switch between the two modes is performed as a rotation with a constant yaw rate. When the $\beta$-angle approaches the threshold, the switch typically takes place when the actual attitude is closest to the orientation in the other mode, which happens once per orbit (i. e., once per day). The attitude differences for small $\beta$-angles between the yaw-steering and the orbit-normal mode can be up to $\pm 180^\circ$ [19.43].

The BeiDou constellation consists of satellites on geostationary Earth orbits (GEOs), medium-Earth orbits (MEOs), and IGSOs. The GEO satellites use orbit-normal attitude exclusively [19.44]. The MEO and IGSO satellites are in yaw-steering mode except for small $\beta$-angles [19.45]. Based on the time intervals for orbit normal mode of two IGSO satellites provided in [19.46], the threshold value for the attitude mode switch seems to be close to $\pm 4^\circ$.

Satellite attitude modeling differs quite significantly among the various constellations and also among the satellite types in the same constellation. Exact modeling of the attitude is crucial though for many high-precision applications, as an attitude error of $90^\circ$ already amounts to a carrier-phase error of 0.25 cycles.

## 19.5 Antenna Phase-Center Offset and Variations

In the previous sections, the range to be measured has been referred to as the distance between satellite and receiver. Using a more precise formulation, it is, of course, the distance between the electrical phase centers of the transmitting and receiving antennas. For high-precision applications, however, the introduction of the electrical phase center as a single point that all signals refer to is no longer possible, since variations depending on azimuth, elevation, and frequency occur. This effect exists for code and phase observations. The following sections will introduce the concepts for modeling these effects and briefly explain calibration methods used to compute corrections for it. Finally, examples illustrating the magnitude of the correction will be presented, and the Antenna Exchange (ANTEX) format commonly used to disseminate the corrections will be introduced. For additional information an antennas the reader may also be referred to Chap. 17.

### 19.5.1 Overview

As already mentioned in the introduction, modeling the origin of all signals transmitted or received by an antenna as a single point may not be sufficient for high-accuracy applications due to variations depending on the direction of the incoming signals as well as their frequency. However, through calibration these effects can be removed in the modeling of the observations, which is the reason for the appearance of the correction terms $\xi^s_{r,j}$ in (19.6) and $\zeta^s_{r,j}$ in (19.9). The following introduction will mainly focus on the calibration of carrier-phase-center offsets and variations. However, similar methods have also been applied recently to calibrate the code-phase patterns that affect the pseudorange observations [19.47].

Two applications have mainly motivated the efforts for antenna calibrations [19.48]. The first is real-time kinematic (RTK) positioning with different antenna types. Using identical receiver antennas, the modeling errors due to phase-center offsets and variations cancel out completely in differential processing with short baselines. With different antennas this error cancellation is no longer possible and may adversely affect ambiguity resolution [19.49–51]. The second application is the processing of global network solutions, where omitting phase-center offsets and variations of transmitting and receiving antennas in the modeling has an effect on estimates of station positions and tropospheric delay [19.52–54].

Figure 19.4 shows a schematic of a GNSS choke-ring antenna with radome to illustrate the modeling of phase-center offsets and variations. The antenna reference point (ARP) is introduced as a common physical point for all signals. It is defined by the International GNSS Service (IGS) for most antennas as the intersection of the vertical symmetry axis of the antenna with the bottom of the ground plane or choke ring. The mean electrical phase center differs from the ARP by the phase-center offset vector $\boldsymbol{r}_{\mathrm{PCO},j}$. Note that this offset is frequency dependent. The phase-center offset correction is computed as its projection on the negative line-of-sight vector for the receiving antenna

$$\zeta_{\mathrm{PCO},r,j} = -\boldsymbol{e} \cdot (\mathbf{A}\, \boldsymbol{r}_{\mathrm{PCO},r,j}) \,. \tag{19.44}$$

The matrix $\mathbf{A}$ is a direction cosine matrix, which transforms the phase center offset (PCO) vector, given in an antenna-fixed coordinate system, to the coordinate system, in which $\boldsymbol{e}$ is provided, typically the Earth-Centered Earth-Fixed (ECEF) frame. In the case of a static antenna, for example at a geodetic reference

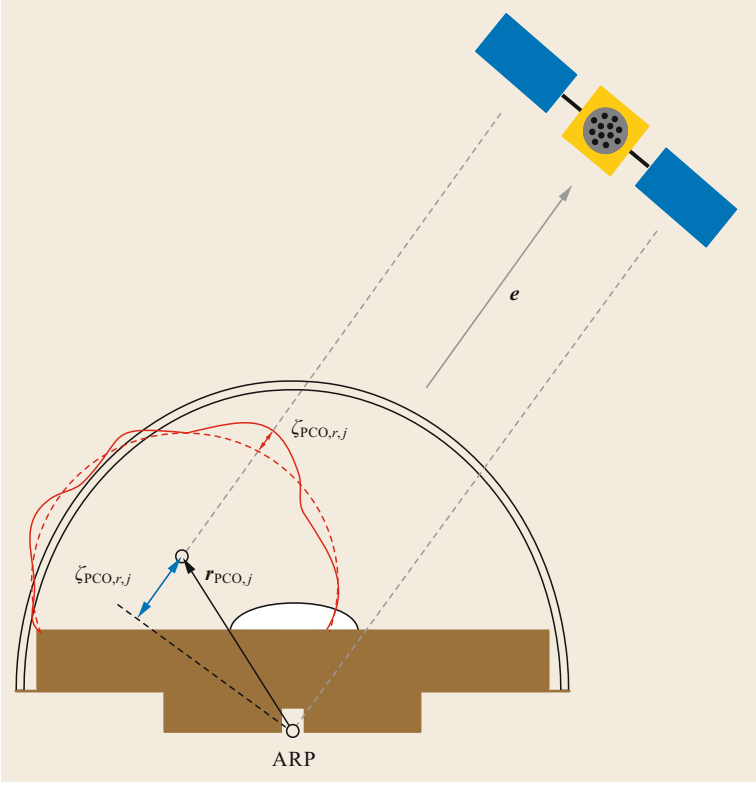

**Fig. 19.4** Schematic of corrections for phase-center offset (*blue*) and phase-center variation (*red*) of a receiving choke-ring antenna with radome. The *solid red line* indicates the elevation- and azimuth-dependent phase-center variations with respect to a reference wavefront (*dotted red line*) (after [19.12])

station, the matrix $\mathbf{A}$ is constant. In other cases, like airborne or space-borne applications, the attitude of the airplane or satellite may change continuously and must be taken into account for proper modeling of the phase-center offset correction.

For the transmitting antenna, the satellite's phase-center offset $\boldsymbol{r}^s_{\mathrm{PCO},j}$ has to be applied. Since transmitting and receiving antenna phase-center offsets are defined using the same convention, the satellite PCO must be projected on the positive line-of-sight vector. The matrix $\mathbf{A}$ now describes the rotation from the satellite antenna coordinate system to the coordinate system choice of $\boldsymbol{e}$

$$\zeta^s_{\mathrm{PCO},j} = \boldsymbol{e} \cdot (\mathbf{A}\, \boldsymbol{r}^s_{\mathrm{PCO},j}) \,. \tag{19.45}$$

Only including the mean antenna phase center in the modeling would still leave a residual error for an individual measurement. Therefore, scalar corrections for the phase-center variation of the transmitting antenna $\zeta^s_{\mathrm{PCV},j}$ and the receiving antenna $\zeta_{\mathrm{PCV},r,j}$ are applied, which may be frequency-, elevation-, and azimuth-dependent [19.48]. The complete correction is then found from

$$\zeta^s_{r,j} = \zeta^s_{\mathrm{PCO},j} + \zeta_{\mathrm{PCO},r,j} + \zeta^s_{\mathrm{PCV},j} + \zeta_{\mathrm{PCV},r,j} \,. \tag{19.46}$$

### 19.5.2 Calibration Techniques

The two main techniques used to find the calibration for the phase-center offset and variations are discussed in this section. The first technique is referred to as relative antenna calibration. In this case, a reference and a test antenna are mounted on concrete pillars at a distance of 5 m. The reference antenna must always be of identical type and its phase-center offset and variations are assumed to be zero. In the case of the calibration procedure carried out by the US National Geodetic Survey (NGS) for IGS, an Allen Osborne Associates Dorne Margolin T antenna is selected as a reference. Using differential carrier-phase observations of live signals, the mean relative phase-center offsets are determined for each frequency. The phase-center variations are then calibrated with respect to the previously estimated phase-center offsets, again independently for each frequency. In the NGS calibrations, only a dependency on elevation is considered [19.51]. Note that the satellite's phase pattern does not affect this calibration procedure, as it cancels out in the single-difference observations.

The relative calibrations are suitable for processing RTK solutions in small networks, since the antennas involved observe a satellite at a similar elevation angle. For global solutions of large-scale networks, this assumption is no longer true. Therefore, calibrations without the dependency on a reference antenna are necessary in this case. They are also referred to as absolute calibrations. Two different methods are available to obtain calibrations for receiving antennas: anechoic chamber tests and robot calibration with live signals.

During anechoic chamber tests, GNSS signals are generated and broadcast through a transmitting antenna to the antenna under test in an environment shielded against external radio-frequency signals and multipath. The test antenna is mounted in such a way that it can be rotated around two axes, to cover the desired range of azimuth and elevation angles. Measurements of phase delays are then obtained by comparing the transmitted and received carrier phase in a network analyzer. These phase delay measurements are afterwards used to estimate the antenna's phase-center offset and azimuth- and elevation-dependent pattern [19.48, 55].

For the second absolute calibration technique, the antenna under test is fixed to a mount that can rotate and tilt the antenna, which is located in an environment where live GNSS signals can be observed. Of course, the test environment cannot be considered to be free of multipath, which will affect the phase-center calibration. For the elimination of these errors, the repetition of the satellite geometry can be exploited. Taking measurements of two different days with repeated satellite geometry in an identical antenna environment will yield identical multipath errors in both measurements. Taking the time difference of these measurements eliminates not only the multipath but unfortunately also the phase-center variations to be calibrated. The solution to this problem is to rotate the test antenna on the second day. The rotation leads to a different phase-center variation effect in the observation but the multipath error and the satellite's antenna phase-center correction are still the same and can be eliminated through the time difference. The differences in tropospheric and ionospheric delays between the two days are eliminated by using measurements of an additional antenna at a short baseline. Because the phase pattern is derived from differential measurements, a common offset in all phase center variations (PCVs) is also eliminated. Since it is identical for all measurements on the same frequency, it can be compensated for in the processing through the clock offset or a hardware delay. Still, the calibration method is referred to as *absolute* calibration, since it is independent of the phase pattern of a reference antenna [19.56, 57].

Further refinements to the previous method have now led to the use of a robot which rapidly rotates and tilts the antenna. In this way the multipath can be removed without the need for a repeating constellation geometry. Through an automated procedure, several thousands of different antenna orientations can be achieved. As a result, the entire hemi-

spherical field of view of the antenna can be evenly covered with measurements and the phase pattern can be determined with high resolution. Furthermore, elevation- and azimuth-dependent corrections can be derived [19.58]. A disadvantage of this technique is that signals on new frequencies cannot easily be calibrated if they are not yet emitted by a sufficient number of satellites.

PCOs and PCVs not only affect GNSS observations at the receiving antenna, but also at the satellite's transmitting antenna. Therefore the observations must also be corrected for the satellite-dependent part of the phase pattern for processing of long baselines or undifferenced observations. Even though attempts have been made to perform absolute robot calibrations of a spare Block II/IIA satellite antenna [19.59], mean offsets and phase patterns are estimated from GNSS data of a global receiver network. The effect of the ionosphere must be removed for the estimation of the PCO and PCV corrections with the ionosphere-free combination of observations. Therefore, the derived parameters do not refer to the phase centers and variations of the individual signals. In the current processing, azimuth dependency in the satellite phase patterns are neglected and only block-specific patterns are estimated. However, significant differences in the mean phase-center offsets in the antenna boresight direction have been identified even between satellites of the same type. Therefore, PCOs are estimated independently for each transmitting antenna [19.60].

Further information on the calibration of receiver and satellite antennas is provided in Sect. 17.6.2 of this Handbook.

### 19.5.3 Examples for Phase-Center Variations

The antenna exchange format (ANTEX) is a data format established within IGS for the dissemination of PCOs and PCV patterns. It allows the storage of data for transmitting and receiving antennas in ASCII format. The PCOs and PCVs can be stored independently for each frequency. The phase patterns can be stored as tabular values with selectable grid size for elevation and azimuth, or as rotational symmetric patterns without azimuth dependency [19.61].

As an example for a geodetic antenna, Fig. 19.5 depicts the PCV pattern of the Leica AR25 geodetic

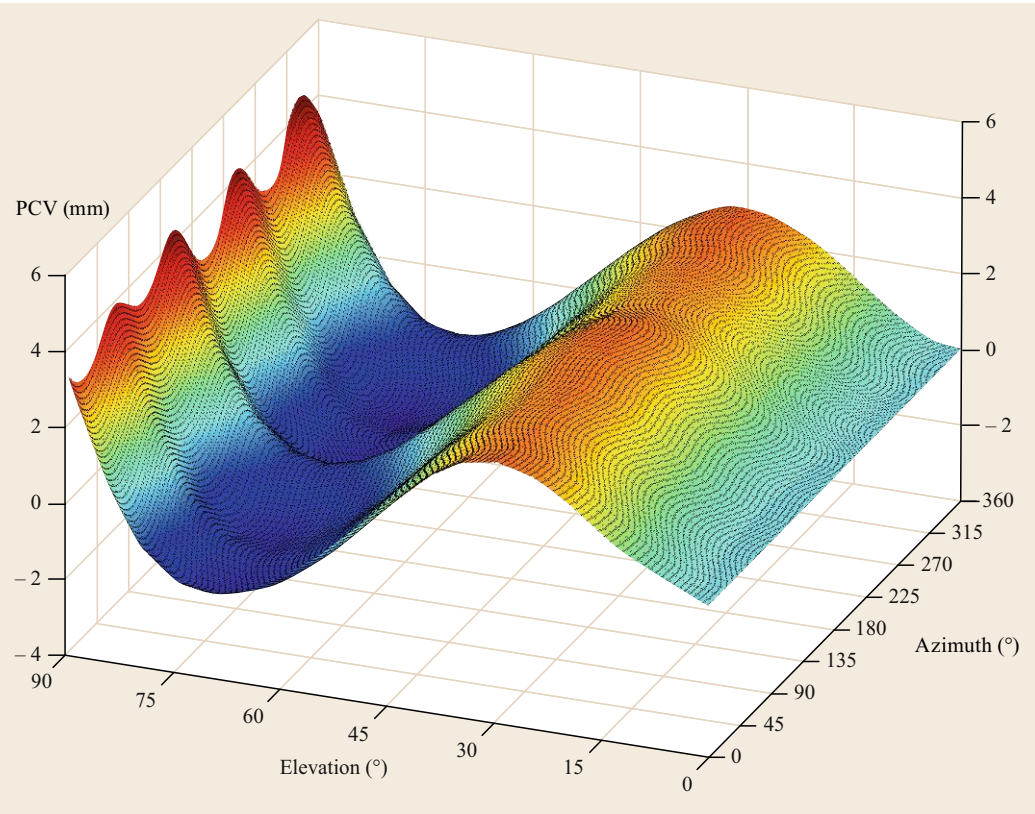

**Fig. 19.5** Phase-center variation pattern for the GPS L1 frequency for a Leica AR25 antenna without radome

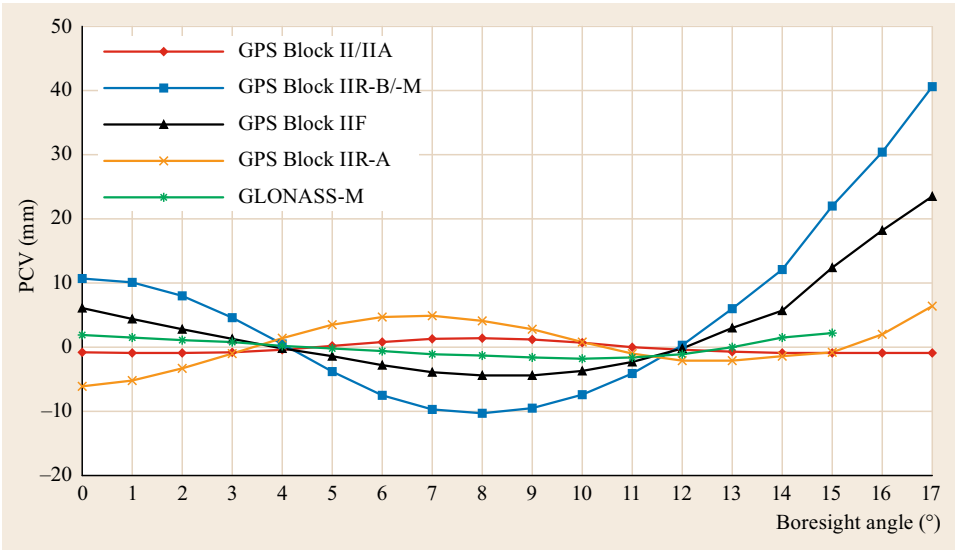

**Fig. 19.6** Ionosphere-free phase-center variation patterns of GPS and GLONASS based on IGS data. GPS Block II and Block IIA satellites as well as Block IIR-B and Block IIR-M satellites have identical phase patterns. GLONASS-M PCVs are only available up to 15° boresight angle

antenna without radome. It becomes obvious that the pattern is normalized to zero at 90° elevation, since the absolute value of the PCV cannot be estimated. An azimuth-dependent pattern is also clearly visible for low elevations. Close to the antenna's horizon, the phase pattern exhibits peak-to-peak variations of approximately 2 mm

The plot in Fig. 19.6 depicts the ionosphere-free phase patterns for selected GPS and GLONASS satellites based on the block-specific calibrations by IGS. Since azimuth dependency of the phase pattern is not considered in the IGS calibrations, the PCV variation is plotted over the boresight angle. The phase patterns for GLONASS satellites are only available for boresight angles up to 15°. For GPS satellites the phase patterns have been extended to 17° based on the observations from low Earth orbit (LEO) satellites. It becomes obvious that the phase patterns are identical for GPS Block II and Block IIA satellites as well as for Block IIR-B and Block IIR-M satellites. The maximum peak-to-peak phase pattern variation is found for the Block IIR-B/IIR-M satellites.

## 19.6 Signal Biases

This section discusses signal biases for pseudorange and carrier-phase observations. Most biases are not directly observable, which hampers the derivation of universally valid definitions. However, their origin will be explained in this section and examples for commonly used bias definitions will be provided.

### 19.6.1 Pseudorange Biases

The model of the pseudorange observation in (19.6) includes biases to account for the instrumental delays. Imperfect synchronization of the different signals is the cause of these delays and they occur at different stages along the signal path from generation to reception.

It is intuitive to separate the total bias into a receiver-dependent and a satellite-dependent term $d_{r,j}$ and $d_j^s$ respectively, as in (19.6). The underlying assumption is that the receiver-dependent part is identical for all signals of this type tracked by the same receiver. The satellite-dependent part is assumed to be equal for every receiver tracking the corresponding signal. Since the processing chains of the various signals differ, their instrumental delays may differ as well and the terms in (19.6) bear the signal index $j$ to denote frequency and signal dependency. The biases are assumed to be time invariant, therefore an explicit dependency on time has been omitted in the notation. These assumptions are made here to simplify the discussion, but they are subject to restrictions that will be discussed at the end of this section.

The satellite-dependent part of the bias is caused by delay differences in the analog and digital paths of the signal generation unit and of the antenna, which are not identical for the various signals. It is important to note that the absolute delay of a single signal is unobservable. Only differential code biases (DCBs) become

observable by selecting one signal (or a combination of signals) and referencing the other signals to it. A differential code bias $d^s_{BA}$ is defined as the difference between the absolute biases of the signals A and B

$$d^s_{BA} = d^s_A - d^s_B \,. \tag{19.47}$$

For each navigation system, the system time refers to a specific signal or to a signal combination, and the satellite clock correction terms refer to the deviation of the satellite clock from the system time. The absolute biases of the reference signal or combination are unobservable and lumped into the satellite clock correction terms. In the case of GPS, the ionosphere-free combination of the legacy P(Y) signals on L1 and L2 is used as a reference to compute the clock solution. If a user processes single frequency observations or a different combination of observations, the corresponding biases must be corrected for. For this purpose, each GPS satellite transmits a correction parameter, the so-called time group delay $T_{GD}$, which allows the correction of the bias between the ionosphere-free linear combination of L1/L2-P(Y) signals and the single-frequency P(Y) signals. The $T_{GD}$ is expressed in terms of the L1/L2 P(Y) DCB as

$$T_{GD} = -\frac{f^2_{L2}}{f^2_{L1} - f^2_{L2}} \left(d^s_{GC1W} - d^s_{GC2W}\right) \,. \tag{19.48}$$

In this notation, the frequency index $j$ has been replaced by a four-letter signal label, which consists of the three-letter receiver independent exchange (RINEX) v3 observation code preceded by a satellite system indicator, in this case G for GPS. With the help of the time group delay correction, the P(Y) single frequency observations can be aligned with the ionosphere-free clock reference. The newer generation of GPS satellites will also transmit so-called inter-signal corrections (ISCs), which contain the necessary DCBs for single-frequency positioning with C/A, L2C, and L5 code. In addition to the $T_{GD}$ or ISC values provided by the navigation system itself, precise estimates of these values are also available from IGS analysis centers [19.62, 63].

The previous discussion has shown that significant effort is already necessary to process mixed signals, or combinations thereof, from a single navigation system. The situation becomes even more complicated if observations of different navigation systems are being used. In addition to the previously mentioned DCB corrections, which users may have to apply depending on the signal selection for processing, two different navigation systems are likely to exhibit offsets between their system timescales as well. It lumps together into an overall inter-system bias (ISB) [19.64–66] that should be estimated as an additional parameter by the user when processing more than one constellation at a time. Alternatively, it may partly be mitigated by correction values for system-time offsets provided by modernized navigation systems as part of the broadcast data. Consistent estimation, dissemination and application of this variety of corrections remains as a future challenge for GNSS system operators, external service providers and users.

Different signal paths from the antenna to the correlator in the receiver are responsible for receiver-dependent instrumental delays. These delays often have received lesser attention, since common biases for all observations are simply lumped into the receiver clock estimate. However, in the case of multi-GNSS processing, the receiver-dependent instrumental delays of signals from different GNSSs are not likely to be identical. At this point it becomes important again to estimate this offset as one parameter per additional GNSS or use external corrections.

The pseudorange biases of the legacy signals of the GLONASS system pose an additional challenge. Contrary to most other modern navigation signals, the legacy GLONASS signals on the L1 and L2 band rely on the frequency division multiple access (FDMA) technique. These signals are not transmitted on the same frequency as the code-division multiple access signals (CDMA) but instead on a range of slightly shifted subbands close to the L1 and L2 center frequencies. The receiver distinguishes the signals by tracking on different subbands. In the case of GLONASS, 14 such subbands exist and are shared by two satellites placed on antipodal orbital positions.

It has been recognized already very early in the utilization of GLONASS in combination with GPS that the GLONASS pseudorange and carrier-phase observations are affected by different inter-channel receiver hardware biases. They are caused by filters as well as components of the signal processing chain such as antennas, low-noise amplifiers (LNAs) and cables, which exhibit different delays depending on frequency. These biases may vary even between identical receiver types due to the variability of component characteristics and temperature dependencies [19.67] and thus hamper the separation into a satellite- and receiver-dependent parts.

The remainder of this section shall be dedicated to discuss the limitations of the previous assumptions on the pseudorange biases, namely their invariability with time and their separability into purely receiver- and satellite-dependent parts. The constantness of a signal bias will in practice be limited, for example, by the fact that electrical components change their properties with temperature. Temperature variations inside the receiver [19.68, 69] but also inside the GNSS satellite [19.70] may cause variations of

signal biases. If biases can be assumed constant and over which timescales this assumption is valid very much depends on the application as well as local conditions at the receiving and transmitting equipment.

The second assumption that needs restrictions is the separability of the instrumental delays into the receiver- and satellite-dependent parts also for the CDMA signals. For the example of GPS, close inspection of the interface control document (ICD; [19.71]) reveals that the $T_{GD}$ and ISCs provided through the broadcast data are only valid for a specific receiver type with clearly defined bandwidth as well as correlator type and spacing. The underlying reason is that different correlator implementations may respond differently to possible satellite-specific distortions of the transmitted waveforms. As a result of the signal distortion, the instrumental delays inside the receiver will vary but the change may be different for each satellite and thus cannot be compensated for by a common change in the receiver-dependent signal delay. Care must therefore be taken while estimating and applying satellite-dependent bias corrections to receivers with different correlator settings. This especially holds true for high-performance multipath-mitigation techniques, which are often based on very narrow correlator spacings [19.72, 73].

### 19.6.2 Carrier-Phase Biases

Similar to the pseudorange, the carrier-phase observations are also affected by instrumental delays. These biases are again split up into a satellite- and receiver-dependent part, and are denoted $\delta_j^s$ and $\delta_{r,j}$ in (19.9). Carrier-phase biases are a particular nuisance, since their fractional part prohibits the integer resolution of the unknown ambiguity $N$. In precise positioning (Chaps. 25 and 26), these biases can be eliminated directly by processing double differences of observations using a reference station. Alternatively, the carrier-phase biases can be eliminated with correction values computed from a global or regional reference station network. A universally valid definition of the correction values cannot be provided, since it strongly depends on the parametrization of the estimation system. However, significant effort has been made to characterize the satellite-, and receiver-dependent parts of the carrier-phase biases and enable the provision of carrier-phase bias corrections to allow integer ambiguity resolution [19.74–79].

Similarly to the legacy GLONASS pseudorange observations, also the biases of the carrier-phase measurements of these signals are subject to further complications. As already discussed in the previous section, the employed FDMA signal scheme requires the GLONASS signals to be tracked on different frequencies. This causes decimeter-level inter-frequency biases in the carrier-phase measurements. These biases have been found to have a linear dependency on the frequency and they are approximately equal for L1 and L2, if expressed in units of length. However, the biases have been shown to exhibit significantly different slopes depending on receiver type. Therefore cancellation is not possible in differential processing with different receiver brands [19.80]. It has been demonstrated that the main part of the bias is not created in the analog part of the receiver but in the digital signal processing (DSP) chain. These biases are therefore not dependent on temperature and or receiver components, and can be removed by calibration [19.81].

## 19.7 Receiver Noise and Multipath

Multipath and receiver noise errors have been merged into the error terms $e_{r,j}^s$ and $\epsilon_{r,j}^s$ in (19.6) and (19.9). However, the characteristics of these errors contributions differ significantly. In the following, a brief overview will be provided.

### 19.7.1 Receiver Noise

Measurement noise is introduced by imperfections of the different electrical components in the signal processing chain, including the antenna, cables, and connectors as well as the receiver itself. Additionally, the antenna receives noise from natural or artificial sources in its environment. This noise introduces random errors in the pseudorange and carrier-phase observations. The power ratio between this background noise generated by the environment and the GNSS hardware, and a received signal from a navigation satellite, is a measure of the signal strength. A commonly used metric is the carrier-to-noise-power-density ratio $C/N_0$, which is the ratio of the power level of the carrier signal $C$ to the noise power $N_0$ in a 1 Hz bandwidth. Obviously, a large $C/N_0$ means a strong signal or an ambient noise floor.

The measurement noise of the receiver's DLL for code tracking and its PLL for phase tracking directly depends on the carrier-to-noise-power-density ratio of the received signal (Chap. 14). For $C/N_0 > 35.0$ dB-Hz, the standard deviation of the measurement noise of

a code tracking loop for binary phase shift keying (BPSK)-modulated signals with an early-minus-late correlator can be approximated as

$$\sigma_{\mathrm{DLL}} \approx \sqrt{\frac{dB_{\mathrm{L}}}{2C/N_0}}\lambda_{\mathrm{c}} \,, \tag{19.49}$$

where $d$ is the correlator spacing in units of code chips, $B_{\mathrm{L}}$ is the equivalent code loop noise bandwidth in Hz, and $\lambda_{\mathrm{c}}$ is the wavelength of the code. It becomes obvious from this relation that the noise error of the pseudorange observations decreases with increasing $C/N_0$. Furthermore, the noise depends on the correlator and on the tracking loop design, as well as on the signal's code chip length [19.82, p. 181]. Current receivers achieve a code measurement noise standard deviation of a decimeter or less when tracking the modernized signals with high chip rates. However, a more sophisticated relation than shown in (19.49) has to be used for modernized signals like the binary offset carrier (BOC) and alternative BOC (AltBOC) signals of Galileo [19.83].

The noise of the carrier-tracking loop can be approximated in a similar manner. The standard deviations of the phase lock loop $\sigma_{\mathrm{PLL}}$ assuming high $C/N_0$ can be approximated by

$$\sigma_{\mathrm{PLL}} \approx \sqrt{\frac{B_{\mathrm{P}}}{C/N_0}}\frac{\lambda}{2\pi} \,, \tag{19.50}$$

which depends on the carrier loop noise bandwidth $B_{\mathrm{P}}$ in Hz and on the carrier-phase wavelength $\lambda$. Typically, the standard deviation of carrier-phase noise for high $C/N_0$ is less than a millimeter [19.82, p. 182].

### 19.7.2 Multipath Errors

Multipath errors in pseudorange and carrier-phase observations originate from the reception of the same signal through multiple signal paths (Chap. 15). The ground or other reflective surfaces in the vicinity of the antenna can cause reflections of the direct signal. The reflections arrive with a delay, an attenuation, and a phase shift at the antenna, depending on the characteristics of the reflector and on the relative geometry of satellite, reflector, and receiving antenna. The superposition of the direct signal and its reflections is then tracked by the receiver.

In the case of the code tracking loops, the superimposed signal leads to a distortion of the correlation peak, and thus to a range error in the pseudorange measurement. A common misconception is to believe that multipath always causes the measured pseudorange to be longer. Even though the reflected signal always arrives later than the direct signal, it can be shifted in phase, and the correlation function can be distorted such that the receiver tracks *shorter* pseudoranges. If the delay of the signal is larger than the sum of the code chip length and half the correlator spacing, the correlation process is unaffected by multipath errors as long as the direct signal is tracked. Therefore, the multipath characteristics also depend on the width of the correlator spacing, and on the length of the code chip [19.84, 85].

Carrier-phase observations can likewise be affected by multipath errors. The maximum error for phase observations is $\lambda/4$ and it occurs if the reflected signal arrives with the same amplitude as the direct signal, but with a phase shift of 180° [19.86].

Contrary to measurement noise, multipath errors cannot be characterized as random errors. The temporal variation of multipath errors depends on the change in the geometry between satellite, reflector, and receiver. Due to the change in the relative shift of the direct and of the reflected signal, multipath typically has periodical characteristics with timescales of several seconds to several minutes. Furthermore, the errors do not have a mean value of zero and can therefore not be averaged out [19.86].

# 20. Combinations of Observations

André Hauschild

This chapter introduces the concept of observation combinations, commonly used, for example, to compute positioning solutions with measurements from multiple frequencies or to study measurement noise, multipath, or ionospheric effects. Based on a generic parametrization for pseudorange and carrier-phase observations, a general expression for linear combinations is introduced. The impact of the coefficients on the properties and the noise of the combined observable is explained. The chapter covers combinations using measurements from a single satellite observed by one receiver. The discussion will then be extended to differential observations from two satellites, receivers and epochs.

## 20.1 Fundamental Equations

Forming combinations from multiple observations of the same or different types can be useful for various aspects of global navigation satellite system (GNSS) data processing or analysis. In particular, combining observations can conveniently be used to eliminate nuisance parameters, like, for example, the ionospheric delay. Furthermore, they are a useful measure to isolate and emphasize particular errors or features to be studied, like, for example, multipath errors or ambiguity parameters.

For ease of notation when deriving the combination equations, it is helpful to introduce a term $P^{\mathrm{s}}_{\mathrm{r,IF}}$ [20.1], which is defined as

$$P^{\mathrm{s}}_{\mathrm{r,IF}}(t) = \rho^{\mathrm{s}}_{\mathrm{r}}(t) + c\left(dt_{\mathrm{r}}(t) - dt^{\mathrm{s}}(t) + \delta t^{\mathrm{rel}}(t)\right) + T^{\mathrm{s}}_{\mathrm{r}}(t)\ . \tag{20.1}$$

In the notation adopted for this chapter, the superscript s denotes the observed satellite and the subscript r identifies the receiver. The term $P^{\mathrm{s}}_{\mathrm{r,IF}}$ only depends on the geometric range $\rho^{\mathrm{s}}_{\mathrm{r}}$, the receiver clock offset $dt_{\mathrm{r}}$, the satellite clock offset $dt^{\mathrm{s}}$, the relativistic term $\delta t^{\mathrm{rel}}$, and the tropospheric delay $T^{\mathrm{s}}_{\mathrm{r}}$. All timing delays are converted to units of length by multiplication with the speed of light $c$. Note that not only the ionospheric delay $I^{\mathrm{s}}_{\mathrm{r},j}$, but also all other frequency-dependent terms like receiver bias $d_{\mathrm{r},j}$ and satellite bias $d^{\mathrm{s}}_{j}$, line-of-sight-dependent group-delay variations (or code-phase pattern) $\xi^{\mathrm{s}}_{\mathrm{r},j}$, as well as multipath and noise $e^{\mathrm{s}}_{\mathrm{r},j}$ are excluded. The subscript $j$ is used here as frequency or signal identifier. The full pseudorange observation equation as in (19.6) of Chap. 19 can be restored from

$$p^{\mathrm{s}}_{\mathrm{r},j}(t) = P^{\mathrm{s}}_{\mathrm{r,IF}}(t) + I^{\mathrm{s}}_{\mathrm{r},j}(t) + \xi^{\mathrm{s}}_{\mathrm{r},j}(t) + cd^{\mathrm{s}}_{\mathrm{r},j} + e^{\mathrm{s}}_{\mathrm{r},j}(t)\ . \tag{20.2}$$

The reader may refer to Chap. 19 for a more detailed discussion of the individual terms. An abbreviated notation has been used in (20.2), which combines the receiver bias $d_{\mathrm{r},j}$ and satellites bias $d^{\mathrm{s}}_{j}$ as follows

$$d^{\mathrm{s}}_{\mathrm{r},j} = d_{\mathrm{r},j} + d^{\mathrm{s}}_{j}\ . \tag{20.3}$$

When combinations of observations from satellites of different constellations are formed, a property called inter-system bias (ISB) becomes relevant. The ISB is

generally understood as a combination of delays (or biases) and a system-time offset between two constellations. It has not explicitly been noted in (20.2), since it only manifests itself on differences of observations. However, the contribution of the system-time offset to the ISB is implicitly included in the satellite clock offset term in (20.1) and the contribution of the delays in the signal reception and processing chain is contained in the bias term in (20.2). It is therefore important to note that the clock offsets in (20.1) refer to a single, common time system for all constellations. The clock parameters, which are transmitted in the satellites' navigation message or provided as external corrections, typically refer to the system-time of the corresponding GNSS, however. The subtlety of the ISB will further be elaborated in the discussion of single- and double differences of observations.

An equivalent expression to (20.2) can also be found for the carrier-phase observation $\varphi^{\mathrm{s}}_{\mathrm{r},j}$ ((19.9) in Chap. 19)

$$\begin{aligned}\varphi^{\mathrm{s}}_{\mathrm{r},j}(t) =& P^{\mathrm{s}}_{\mathrm{r,IF}}(t) - I^{\mathrm{s}}_{\mathrm{r},j}(t) + \zeta^{\mathrm{s}}_{\mathrm{r},j}(t) + c\delta^{\mathrm{s}}_{\mathrm{r},j} \\ &+ \lambda_j \left(\omega^{\mathrm{s}}_{\mathrm{r}}(t) + N^{\mathrm{s}}_{\mathrm{r},j}\right) + \epsilon^{\mathrm{s}}_{\mathrm{r},j}(t)\,. \end{aligned} \tag{20.4}$$

In case of the carrier-phase, the correction term due to antenna phase center offset and variation $\zeta^{\mathrm{s}}_{\mathrm{r},j}$, the combined receiver and satellite bias $\delta^{\mathrm{s}}_{\mathrm{r},j}$, the phase wind-up correction $\omega^{\mathrm{s}}_{\mathrm{r}}$, the integer ambiguity $N^{\mathrm{s}}_{\mathrm{r},j}$, and the receiver noise and multipath $\epsilon^{\mathrm{s}}_{\mathrm{r},j}$ appear as extra terms. Note that $\omega^{\mathrm{s}}_{\mathrm{r}}$ and $N^{\mathrm{s}}_{\mathrm{r},j}$ have been converted from cycles to units of length by multiplication with the wavelength $\lambda_j$. Similar to the pseudorange observations, differences of carrier-phase observations between satellites of different constellations will be affected by an ISB, which is again implicitly included in the satellite clock offset term and the carrier-phase biases. Division of (20.4) by the corresponding wavelength yields an expression for the carrier-phase in units of cycles

$$\Phi^{\mathrm{s}}_{\mathrm{r},j}(t) = \frac{\varphi^{\mathrm{s}}_{\mathrm{r},j}(t)}{\lambda_j}\,. \tag{20.5}$$

For later developments, it should also be remembered that the first-order ionospheric delay depends on the frequency $f_j$ and on the total electron content (TEC) along the signal propagation path from the receiver to the satellite as follows ((19.29) in Chap. 19)

$$I^{\mathrm{s}}_{\mathrm{r},j} = \frac{40.3\,\mathrm{TEC}}{f_j^2} = \frac{f_1^2}{f_j^2} I^{\mathrm{s}}_{\mathrm{r},1}\,. \tag{20.6}$$

In (20.6), $f_1$ is an arbitrarily selected reference frequency and $I^{\mathrm{s}}_{\mathrm{r},1}$ is the corresponding ionospheric delay. Higher order ionospheric delays are neglected for simplicity.

Generalized equations for linear combinations of GNSS pseudorange and carrier-phase observations have been introduced in [20.2] and are presented here only slightly modified. Assuming that $n$ different signals are available, the combined observable $o_{\mathrm{c}}$ is the linear combinations of carrier-phase observations $\varphi_j$, scaled with the coefficient $\alpha_j$, and pseudorange observations $p_j$, multiplied with the factor $\beta_j$

$$o^{\mathrm{s}}_{\mathrm{r,c}}(t) = \sum_{j=1}^{n} \left(\alpha_j \varphi^{\mathrm{s}}_{\mathrm{r},j}(t) + \beta_j p^{\mathrm{s}}_{\mathrm{r},j}(t)\right)\,. \tag{20.7}$$

Note that at this point any real number is allowed as the value of coefficients $\alpha_j$ and $\beta_j$. Therefore, (20.7) also allows to form code- or phase-only combinations or to use a different number of code and phase observations from different frequencies. Substituting (20.2)–(20.4), and (20.6) into (20.7) yields

$$\begin{aligned} o^{\mathrm{s}}_{\mathrm{r,c}}(t) =& \left(\sum_{j=1}^{n} \left(\alpha_j + \beta_j\right)\right) P^{\mathrm{s}}_{\mathrm{r,IF}}(t) \\ &- \left(\sum_{j=1}^{n} \left(\alpha_j - \beta_j\right) \frac{f_1^2}{f_j^2}\right) I^{\mathrm{s}}_{\mathrm{r},1}(t) \\ &+ \left(\sum_{j=1}^{n} \left(\alpha_j \zeta^{\mathrm{s}}_{\mathrm{r},j}(t) + \beta_j \xi^{\mathrm{s}}_{\mathrm{r},j}(t)\right)\right) \\ &+ \left(\sum_{j=1}^{n} \left(\alpha_j \delta^{\mathrm{s}}_{\mathrm{r},j} + \beta_j d^{\mathrm{s}}_{\mathrm{r},j}\right)\right) c \\ &+ \left(\sum_{j=1}^{n} \alpha_j \lambda_j N^{\mathrm{s}}_{\mathrm{r},j}\right) + \left(\sum_{j=1}^{n} \alpha_j \lambda_j\right) \omega^{\mathrm{s}}_{\mathrm{r}}(t) \\ &+ \left(\sum_{j=1}^{n} \left(\alpha_j \epsilon^{\mathrm{s}}_{\mathrm{r},j}(t) + \beta_j e^{\mathrm{s}}_{\mathrm{r},j}(t)\right)\right)\,. \end{aligned} \tag{20.8}$$

It becomes obvious from (20.8) that depending on the selection of the coefficient $\alpha_j$ and $\beta_j$ some terms in the equations can be retained, attenuated or completely eliminated. For example, the magnitude of the geometric range, clock offsets, and tropospheric delay contained in $P^{\mathrm{s}}_{\mathrm{r,IF}}(t)$ is controlled through

$$\sum_{j=1}^{n} \left(\alpha_j + \beta_j\right) = h_1\,. \tag{20.9}$$

The scaling factor $h_1$ can take any value depending on the coefficients; however, there are two cases which are commonly used and deserve special attention: if the coefficients are selected such that $h_1 = 1$, the combination is referred to as *geometry-preserving*. If $h_1 = 0$, the term $P^{s}_{r,IF}(t)$ is completely eliminated, and the combination is *geometry-free*.

The first-order ionospheric delay in (20.8) can be scaled through the factor

$$-\sum_{j=1}^{n} (\alpha_j - \beta_j) \frac{f_1^2}{f_j^2} = h_2 \,. \tag{20.10}$$

Selecting the coefficients such that $h_2 = 0$ creates a *ionosphere-free* combination. It should be noted that observation combinations can be ionosphere-free and either geometry-free or geometry-preserving at the same time.

If carrier-phase observations are used in the combined observation (20.8), it is useful to introduce a combined ambiguity $N_c$ and the corresponding wavelength $\lambda_c$. The sum of the individual ambiguities in (20.8) is related to the combined ambiguity as follows

$$\lambda_c N_c = \sum_{j=1}^{n} \alpha_j \lambda_j N_j = \lambda_c \sum_{j=1}^{n} i_j N_j \,, \tag{20.11}$$

where the integer-phase coefficient $i_j$ has been newly introduced as

$$i_j = \alpha_j \frac{\lambda_j}{\lambda_c} = \alpha_j \frac{f_c}{f_j} \,, \tag{20.12}$$

and the combined ambiguity is

$$N_c = \sum_{j=1}^{n} i_j N_j \,. \tag{20.13}$$

Since all $i_j$ are assumed to be integers, the resulting combined ambiguity $N_c$ is also integer. The combined frequency $f_c$ and wavelength $\lambda_c = c/f_c$ can be found from the sum of all coefficients $\alpha$ as

$$f_c = \frac{\sum_{j=1}^{n} i_j f_j}{\sum_{j=1}^{n} \alpha_j} \tag{20.14}$$

and

$$\lambda_c = \frac{\sum_{j=1}^{n} \alpha_j}{\sum_{j=1}^{n} i_j \frac{f_j}{c}} = \frac{\sum_{j=1}^{n} \alpha_j}{\sum_{j=1}^{n} \frac{i_j}{\lambda_j}} \,. \tag{20.15}$$

The stochastic properties of the combined observation are also governed by the selection of coefficients in (20.8). Assume that a vector of uncombined observations $\boldsymbol{o}$ is transformed via a transformation matrix $\mathbf{T}$ into a vector of combined observations $\boldsymbol{o}_c$ as follows

$$\boldsymbol{o}_c = \mathbf{T}\boldsymbol{o} \,. \tag{20.16}$$

The transformation matrix $\mathbf{T}$ contains the coefficients $\alpha$ and $\beta$ for the different measurement combinations. The covariance matrix $\mathbf{Q}_{\boldsymbol{o}_c\boldsymbol{o}_c}$ of the combined observations is then found from the covariance matrix $\mathbf{Q}$ of the uncombined observations

$$\mathbf{Q}_{\boldsymbol{o}_c\boldsymbol{o}_c} = \mathbf{T}\mathbf{Q}_{\boldsymbol{o}\boldsymbol{o}}\mathbf{T}^{\top} \,. \tag{20.17}$$

Assume that the individual observations in $\boldsymbol{o}$ are uncorrelated and combined into a single observable $o_c$. With the standard deviation $\sigma_{e,j}$ for pseudorange and $\sigma_{\epsilon,j}$ for carrier-phase, (20.17) simplifies to the expression

$$\sigma_c = \sqrt{\sum_{j=1}^{n} \left(\alpha_j^2 \sigma_{\epsilon,j}^2 + \beta_j^2 \sigma_{e,j}^2\right)} \tag{20.18}$$

for the standard deviation of the combined observable. In a similar way, the covariances between the combined observations can be obtained. Both the variances and covariances are needed to properly weigh the combined observations in further processing.

The following sections will introduce observation combinations of pseudorange and carrier-phase measurements. Doppler measurements are not considered here. However, for some applications Doppler combinations have practical use, especially in case of the single-, double-, and triple differences or the ionosphere-free combination. In these cases, the Doppler combinations are formed equivalently to the pseudorange and carrier-phase observations.

## 20.2 Combinations of Single-Satellite and Single-Receiver Observations

In this section, observation combinations are introduced, which use measurements from one receiver and one satellite on one or more frequencies. The combinations have been categorized according to the application they have been designed for, namely:

- Carrier-phase ambiguity resolution
- Isolation or elimination of ionospheric errors
- Multipath analysis.

A multitude of combinations can already be found for each of these categories with only the dual-frequency legacy signals. Even more options are available with the additional frequencies of the modernized GNSSs. Therefore, the derivations have been confined to the most commonly used combinations, and only selected examples with modernized GNSS signals are presented, which have so far been found to be of practical interest.

### 20.2.1 Narrow- and Wide-Lane Combinations

It is obvious from (20.14) and (20.15) that combining two or more carrier-phase observations into a new signal leads to a different frequency and wavelength for this combination. In case of a combination for which $\sum \alpha = 1$, the combined frequency $f_c$ is

$$f_c = \sum_{j=1}^{n} i_j f_j \,. \tag{20.19}$$

Noting that all frequencies of a GNSS are derived from a single base frequency $f_0$ by multiplication with an integer $k_j$, the individual frequency is obtained from $f_j = k_j f_0$. Substituting this expression into (20.19) yields

$$f_c = \left( \sum_{j=1}^{n} i_j k_j \right) f_0 = k f_0 \,, \tag{20.20}$$

where $k$ is called the lane number. The corresponding wavelength is

$$\lambda_c = \frac{c}{k f_0} = \frac{\lambda_0}{k} \,, \tag{20.21}$$

where $\lambda_0$ is the wavelength of the base frequency $f_0$. Since all $i_j$ and $k_j$ are integers, $k$ is also an integer. This parameter uniquely defines the frequency and wavelength of the new signal combination [20.3]. For $k = 1$, the combined wavelength is equal to $\lambda_0$, which is the longest wavelength that can be achieved. For the Global Positioning System (GPS) and the Quasi-Zenith Satellite System (QZSS), the base frequency is 10.230 MHz with a corresponding wavelength of $\approx 29.31$ m. In case of the BeiDou Phase II signals as listed in Table 20.1, the base frequency $f_0$ is 2.046 MHz and the largest possible wavelength is $\approx 146.53$ m [20.4]. By selecting larger values for $k$, combined signals with different wavelengths can be created, which are all fractions of $\lambda_0$.

With the help of the lane number $k$, the combinations can be categorized into three groups [20.3]:

1. The *wide-lane* combinations, for which the combined wavelength is larger than the largest individual wavelength in the combination.
2. The *intermediate-lane* combinations, for which $\lambda_c$ lies between the largest and the shortest individual wavelength.
3. The *narrow-lane* combinations, which have a shorter wavelength than the individual signal with the shortest wavelength in the combination.

The group of wide-lane combinations is especially interesting for the purpose of integer ambiguity resolution (Chap. 23) due to their long wavelength. In that case the wide-lane combinations are applied to the double-differenced observations. With observations on multiple frequencies available, many different combinations not only for wide-lanes but for each of the categories can be formed. Even with only dual-frequency measurements, there is a range of possibilities to form wide-lane combinations which have different characteristics concerning the reduction of measurement noise and ionospheric delay [20.5, 6].

In the following, the most common dual-frequency wide-lane (WL) combination will be introduced. It is designed to be a geometry-preserving combination using only carrier-phase measurements on the frequencies $f_A$ and $f_B$. By selecting the integer coefficients as $i_A = +1$ and $i_B = -1$, one obtains the WL carrier-phase combination $\Phi^s_{r,WL}$ in units of cycles

$$\Phi^s_{r,WL} = \Phi^s_{r,A} - \Phi^s_{r,B} = \frac{\varphi^s_{r,A}}{\lambda_A} - \frac{\varphi^s_{r,B}}{\lambda_B} \,. \tag{20.22}$$

The corresponding wavelength $\lambda_{WL}$ is

$$\lambda_{WL} = \frac{c}{f_A - f_B} \,. \tag{20.23}$$

Multiplication of (20.22) with (20.23) leads to the carrier-phase wide-lane combination $\varphi^s_{r,WL}$ in units of

meters

$$\varphi^{\mathrm{s}}_{\mathrm{r,WL}} = \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} - f_{\mathrm{B}}}\varphi^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} - f_{\mathrm{B}}}\varphi^{\mathrm{s}}_{\mathrm{r,B}} \,. \tag{20.24}$$

In a similar way, a geometry-preserving narrow-lane carrier-phase combination can be formed using the integer coefficients $i_{\mathrm{A}} = +1$ and $i_{\mathrm{B}} = +1$

$$\Phi^{\mathrm{s}}_{\mathrm{r,NL}} = \Phi^{\mathrm{s}}_{\mathrm{r,A}} + \Phi^{\mathrm{s}}_{\mathrm{r,B}} = \frac{\varphi^{\mathrm{s}}_{\mathrm{r,A}}}{\lambda_{\mathrm{A}}} + \frac{\varphi^{\mathrm{s}}_{\mathrm{r,B}}}{\lambda_{\mathrm{B}}} \,, \tag{20.25}$$

with the corresponding NL wavelength

$$\lambda_{\mathrm{NL}} = \frac{c}{f_{\mathrm{A}} + f_{\mathrm{B}}} \,. \tag{20.26}$$

The narrow-lane combination in units of meters $\varphi^{\mathrm{s}}_{\mathrm{r,NL}}$ is then

$$\varphi^{\mathrm{s}}_{\mathrm{r,NL}} = \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} + f_{\mathrm{B}}}\varphi^{\mathrm{s}}_{\mathrm{r,\,A}} + \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} + f_{\mathrm{B}}}\varphi^{\mathrm{s}}_{\mathrm{r,B}} \,. \tag{20.27}$$

Evaluating the expressions for the wavelengths in (20.23) and (20.26) illustrates why these combinations bear their names: using, for example, the heritage GPS signals on the frequencies L1 and L2, the wavelength of the narrow-lane combination yields $\approx$ 10.7 cm. Obviously, the narrow-lane observable has a decreased combined wavelength compared to the original observations. The wide-lane combination, on the contrary, has a wavelength of $\approx 0.86$ m for GPS L1/L2.

In case of modernized GPS with signals from three frequencies available, the carrier-phase observations on L1 and L5 can be used in (20.20) to form a combination with a wavelength of $\approx 0.75$ m, which is sometimes referred to as *medium-lane* (ML) signal. Using the signals on the two closer frequencies L2 and L5 in (20.22) yields a wavelength of $\approx 5.86$ m, typically referred to as *extra wide-lane* (EWL) [20.7]. Similar combinations are also possible for other GNSSs, which transmit on more than two frequencies. The three-carrier ambiguity resolution (TCAR) technique for Galileo [20.8, 9] and the cascade integer resolution (CIR) technique for GPS [20.10, 11] utilize these wide-lane and extra wide-lane combinations. Table 20.1 lists the resulting wavelengths of dual-frequency wide-lane and narrow-lane combinations for different GNSS signals. Wide laning is often a good starting point in the construction of the decorrelating Z-transformation (Chap. 23). For a comparison of TCAR, CIR, and the least-squares ambiguity decorrelation adjustment (LAMBDA), see [20.12–14].

Evaluation of the combination factors in (20.24) and (20.27) with (20.18) yields the standard deviation of the measurement noise for the wide-lane combination $\sigma_{\mathrm{WL}}$ and for the narrow-lane combination $\sigma_{\mathrm{NL}}$ in units of meters

$$\sigma_{\mathrm{NL}} = \sqrt{\frac{f_{\mathrm{A}}^2}{(f_{\mathrm{A}} + f_{\mathrm{B}})^2}\sigma_{\mathrm{A}}^2 + \frac{f_{\mathrm{B}}^2}{(f_{\mathrm{A}} + f_{\mathrm{B}})^2}\sigma_{\mathrm{B}}^2} \,, \tag{20.28}$$

$$\sigma_{\mathrm{WL}} = \sqrt{\frac{f_{\mathrm{A}}^2}{(f_{\mathrm{A}} - f_{\mathrm{B}})^2}\sigma_{\mathrm{A}}^2 + \frac{f_{\mathrm{B}}^2}{(f_{\mathrm{A}} - f_{\mathrm{B}})^2}\sigma_{\mathrm{B}}^2} \,. \tag{20.29}$$

Assuming identical noise $\sigma$ for the carrier-phase signals involved in the combinations, one obtains

$$\sigma_{\mathrm{NL}} = \sqrt{\frac{f_{\mathrm{A}}^2 + f_{\mathrm{B}}^2}{(f_{\mathrm{A}} + f_{\mathrm{B}})^2}}\,\sigma \tag{20.30}$$

and

$$\sigma_{\mathrm{WL}} = \sqrt{\frac{f_{\mathrm{A}}^2 + f_{\mathrm{B}}^2}{(f_{\mathrm{A}} - f_{\mathrm{B}})^2}}\,\sigma \,. \tag{20.31}$$

Evaluating these expressions for the GPS frequencies, L1 and L2 shows that the noise of the narrow-lane combination is reduced by a factor of $\approx 0.71$ compared to that of an individual carrier-phase measurement. It is interesting to note that this factor does not only apply for GPS L1 and L2, but is also approximately the same for all current GNSS signal combinations of observations in the lower (1100–1300 MHz) and upper L-band (near 1600 MHz). Forming the wide-lane combination with GPS L1 and L2, on the other hand, leads to a significantly increased noise, which is $\approx 5.7$ times higher than the noise of the individual observations. If adjacent frequencies are used, the increase in noise can be even higher, for example choosing GPS L2 and L5 leads to a factor of $\approx 33.2$, using Galileo E5a and E5b yields a factor of $\approx 65.8$. Though the increase in noise becomes large when the difference of the frequencies in the wide-lane combination is small, it is obvious from Table 20.1 that the resulting carrier-phase noise is still small compared to the increase in the corresponding wavelength.

Of course, narrow-lane and wide-lane combinations can also be formed from pseudoranges by using these observations in place of the carrier-phase in (20.24) and (20.27). This is exploited in the Melbourne–Wübbena combination $o_{\mathrm{MW}}$, which is formed from the difference of narrow-lane pseudorange observations and wide-lane carrier-phase observations [20.15, 16]

$$\begin{aligned} o_{\mathrm{MW}} &= \varphi^{\mathrm{s}}_{\mathrm{r,WL}} - p^{\mathrm{s}}_{\mathrm{r,NL}} \\ &= \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} - f_{\mathrm{B}}}\varphi^{\mathrm{s}}_{\mathrm{r,\,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} - f_{\mathrm{B}}}\varphi^{\mathrm{s}}_{\mathrm{r,B}} \\ &\quad - \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} + f_{\mathrm{B}}}p^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} + f_{\mathrm{B}}}p^{\mathrm{s}}_{\mathrm{r,B}} \,. \end{aligned} \tag{20.32}$$

**Table 20.1** Wavelength of wide-lane combination (20.24) in meters (upper right triangular part, underlined) and wavelength of narrow-lane combination (20.27) in centimeters (lower left triangular part) for different dual-frequency GNSS signals. Base frequency $f_0$ and integer multipliers $k_j$ are listed in parentheses in the header line for code division multiple access (CDMA)-based constellations. Individual carrier-phase frequencies $f_j$ are listed in parentheses in first column. All frequencies are in MHz

This combination fulfills both conditions for geometry-free and ionosphere-free combinations. Substituting (20.2) and (20.24) into (20.32) yields

$$
\begin{aligned}
o_{\mathrm{MW}} = {} & \lambda_{\mathrm{WL}} \left(N^{\mathrm{s}}_{\mathrm{r,A}} - N^{\mathrm{s}}_{\mathrm{r,B}}\right) \\
& + \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} c\delta^{\mathrm{s}}_{\mathrm{r,\,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} c\delta^{\mathrm{s}}_{\mathrm{r,B}} \\
& - \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} + f_{\mathrm{B}}} cd^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} + f_{\mathrm{B}}} cd^{\mathrm{s}}_{\mathrm{r,B}} \\
& + \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} \zeta^{\mathrm{s}}_{\mathrm{r,\,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} \zeta^{\mathrm{s}}_{\mathrm{r,B}} \\
& - \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} + f_{\mathrm{B}}} \xi^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} + f_{\mathrm{B}}} \xi^{\mathrm{s}}_{\mathrm{r,B}} \\
& + \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} \epsilon^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} \epsilon^{\mathrm{s}}_{\mathrm{r,B}} \\
& - \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} + f_{\mathrm{B}}} e^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} + f_{\mathrm{B}}} e^{\mathrm{s}}_{\mathrm{r,B}} \,. \qquad (20.33)
\end{aligned}
$$

The terms in (20.33) are the wide-lane ambiguity, the pseudorange and carrier-phase biases, the group-delay variations and phase-center variations, and the measurement errors due to noise and multipath. Therefore the Melbourne–Wübbena combination yields a biased estimate of the wide-lane ambiguity. It is affected by the combined noise of carrier-phase and pseudorange. The latter is the dominant source of noise although its contribution will be reduced through the narrow-lane combination. The Melbourne–Wübbena combination is commonly used for quality control of carrier-phase observations to detect cycle slips [20.17].

The narrow- and wide-lane combinations introduced here have been confined to using signals from only two frequencies. However, narrow-lane, intermediate-lane, or wide-lane combinations can of course also be formed by using observations on three or more frequencies simultaneously. A variety of different

combinations with different characteristics with respect to noise amplification and suppression of ionospheric delays has been introduced in the literature [20.3, 18, 19]. The references cited here may serve as a starting point for the reader to find more information about these combinations.

### 20.2.2 Ionosphere Combination

Since the ionospheric delay depends on the frequency of the observable, the first-order delay can be isolated with dual-frequency pseudorange or carrier-phase measurements. Based on (20.9) and (20.10), coefficients can be found that eliminate geometry ($h_1 = 0$) and preserve the ionosphere ($h_2 = 1$) using only pseudorange observations. Using these conditions and solving for the coefficients yields

$$\beta_\mathrm{A} = -\beta_\mathrm{B} = -\frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \,. \tag{20.34}$$

Substituting these coefficients into (20.8) and including all terms of (20.2) yields

$$\begin{aligned} -\frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(p^\mathrm{s}_{\mathrm{r,A}} - p^\mathrm{s}_{\mathrm{r,B}}\right) &= I^\mathrm{s}_{\mathrm{r,A}}(t) + \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} c d^\mathrm{s}_{\mathrm{r,AB}} \\ &\quad - \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(\xi^\mathrm{s}_{\mathrm{r,A}}(t) - \xi^\mathrm{s}_{\mathrm{r,B}}(t)\right) \\ &\quad - \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(e^\mathrm{s}_{\mathrm{r,A}}(t) - e^\mathrm{s}_{\mathrm{r,B}}(t)\right) , \end{aligned} \tag{20.35}$$

where the notation

$$d^\mathrm{s}_{\mathrm{r,AB}} = d^\mathrm{s}_{\mathrm{r,B}} - d^\mathrm{s}_{\mathrm{r,A}}$$

has been used for the combined satellite- and receiver-dependent differential code bias (DCB). It becomes obvious that the scaled difference of two pseudorange observables yields the first-order ionospheric delay on $f_\mathrm{A}$ biased by the DCB of the corresponding signals. It is also affected by the combined group-delay variations, multipath, and noise.

In the same way the coefficients for carrier-phase observations can be found

$$\alpha_\mathrm{A} = -\alpha_\mathrm{B} = \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \,. \tag{20.36}$$

Note the different sign of the coefficients for pseudorange and carrier-phase. These coefficients yield after substitution into (20.8) using all terms of (20.4)

$$\begin{aligned} \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(\varphi^\mathrm{s}_{\mathrm{r,A}} - \varphi^\mathrm{s}_{\mathrm{r,B}}\right) &= I^\mathrm{s}_{\mathrm{r,A}}(t) + \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} c \left(\delta^\mathrm{s}_{\mathrm{r,A}} - \delta^\mathrm{s}_{\mathrm{r,B}}\right) \\ &\quad + \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(\lambda_\mathrm{A} N^\mathrm{s}_{\mathrm{r,A}} - \lambda_\mathrm{B} N^\mathrm{s}_{\mathrm{r,B}}\right) \\ &\quad + \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(\zeta^\mathrm{s}_{\mathrm{r,A}}(t) - \zeta^\mathrm{s}_{\mathrm{r,B}}(t)\right) \\ &\quad + \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(\lambda_\mathrm{A} - \lambda_\mathrm{B}\right) \omega^\mathrm{s}_\mathrm{r}(t) \\ &\quad + \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \left(\epsilon^\mathrm{s}_{\mathrm{r,A}}(t) - \epsilon^\mathrm{s}_{\mathrm{r,B}}(t)\right) . \end{aligned} \tag{20.37}$$

Similarly to the pseudorange, the scaled difference of the dual-frequency carrier-phase observations yields the ionospheric delay biased by the combined carrier-phase biases and ambiguities. In addition, the difference of the phase-center offset and variations, the phase wind-up and the carrier-phase noise and multipath are present in the observation equation.

The standard deviation of the measurement noise for the ionosphere combination $\sigma_\mathrm{IC}$ can be obtained from (20.18) assuming identical noise for both observations used in (20.35) or (20.37)

$$\sigma_\mathrm{IC} = \sqrt{2} \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \sigma \,. \tag{20.38}$$

Figure 20.1 shows the ionosphere combination of pseudoranges and carrier-phases for two GPS satellites. The different noise level of both observations becomes immediately obvious from the plots. It is also interesting to note that neither the pseudorange nor the carrier-phase combination represent the true slant ionospheric delay. The pseudorange combination is offset by the biases of the observations. This causes the combination of one of the satellite to be negative, physically impossible for the true ionospheric delay. The same reasoning is also true for the carrier-phase combination, where, in addition to the biases, the combined ambiguities can cause arbitrary offsets. It can also be seen in the plot how the slant delays change with satellite elevation and with the diurnal change in local ionospheric activity at the receiver site. The ionosphere is rather calm at the beginning and becomes more and more active toward the end.

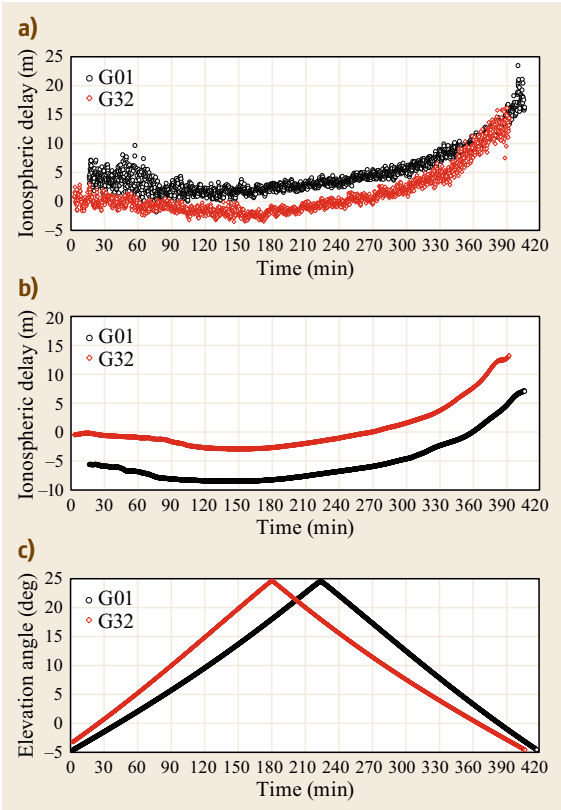

**Fig. 20.1a–c** Plot of slant ionospheric delay based on pseudorange **(a)** and carrier-phase **(b)** from L1 C/A and L2 P(Y) observations for two GPS satellites and corresponding satellite elevation angle **(c)**

### 20.2.3 Ionosphere-Free Combination

This section introduces signal combinations which are frequently used to eliminate the signal delay originating from the ionosphere. If only single-frequency observations are available, the GRAPHIC combination can be formed. The acronym GRAPHIC stands for group and phase ionospheric calibration [20.20]. Since it only requires pseudorange and carrier-phase observations on one frequency, it is even suitable for use with inexpensive single-frequency receivers. The GRAPHIC combination exploits the opposite sign of the ionospheric error in the pseudorange and carrier-phase and is formed from

$$\begin{aligned} o_{\mathrm{GPH}(p_j,\varphi_j)} &= \frac{1}{2}\left(p^{\mathrm{s}}_{\mathrm{r},j} + \varphi^{\mathrm{s}}_{\mathrm{r},j}\right) \\ &= P^{\mathrm{s}}_{\mathrm{r,IF}} + \frac{1}{2}c\left(d^{\mathrm{s}}_{\mathrm{r},j} + \delta^{\mathrm{s}}_{\mathrm{r},j}\right) + \frac{1}{2}\left(\xi^{\mathrm{s}}_{\mathrm{r},j}(t) + \zeta^{\mathrm{s}}_{\mathrm{r},j}(t)\right) \\ &\quad + \frac{1}{2}\lambda_j\left(\omega^{\mathrm{s}}_{\mathrm{r}}(t) + N^{\mathrm{s}}_{\mathrm{r},j}\right) + \frac{1}{2}\left(e^{\mathrm{s}}_{\mathrm{r},j}(t) + \epsilon^{\mathrm{s}}_{\mathrm{r},j}(t)\right) . \end{aligned} \tag{20.39}$$

The factors of the combination satisfy the condition for preservation of geometry $h_1 = 1$ and elimination of ionosphere $h_2 = 0$. In addition to the elimination of the error due to the ionosphere, all pseudorange errors and biases are reduced by a factor of 0.5. However, the new observable is now also affected by all nuisance parameters of the carrier-phase observable weighted with a factor of 0.5. Most significant is the effect of the carrier-phase ambiguity $N$ in (20.39), which requires to introduce it as additional estimation parameter in positioning applications. As a result, the GRAPHIC combination must be treated in the processing similar to a carrier-phase observation; however, its measurement noise is dominated by the larger contribution of the pseudorange.

With observations on two or more different frequencies, more sophisticated ionosphere-free signal combinations can be formed. They exploit the fact that the ionosphere is a dispersive medium and thus observations on different frequencies are affected differently by the corresponding delay. With at least two observations on different frequencies, it is thus possible to determine the delay and eliminate it from the observation equations, at least to first order.

To begin with, the well-established dual-frequency ionosphere-free combination is introduced. It is formed using two pseudorange or two carrier-phase observations on different frequencies. Contrary to the ionosphere combination in the previous section where the ionospheric delay was isolated, this time a combination is desired which preserves geometry ($h_1 = 1$) and eliminates the ionosphere ($h_2 = 0$). The coefficients $\beta_\mathrm{A}$ and $\beta_\mathrm{B}$ for a dual-frequency pseudorange combination can then be obtained from (20.9) and (20.10)

$$\beta_\mathrm{A} = 1 - \beta_\mathrm{B} = \frac{f_\mathrm{A}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} , \tag{20.40}$$

where pseudoranges on the frequencies A and B are used in the combination. This leads to the ionosphere-free pseudorange combination equation

$$p^{\mathrm{s}}_{\mathrm{r,IF}} = \frac{f_\mathrm{A}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} p^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} p^{\mathrm{s}}_{\mathrm{r,B}} . \tag{20.41}$$

With the same coefficients, an ionosphere-free carrier-phase combination can also be formed as follows

$$\varphi^{\mathrm{s}}_{\mathrm{r,IF}} = \frac{f_\mathrm{A}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \varphi^{\mathrm{s}}_{\mathrm{r,A}} - \frac{f_\mathrm{B}^2}{f_\mathrm{A}^2 - f_\mathrm{B}^2} \varphi^{\mathrm{s}}_{\mathrm{r,B}} . \tag{20.42}$$

The advantage of eliminating the error of the first-order ionospheric delay comes at a price, however: the standard deviation of the combined observable will be significantly increased compared to the original uncombined observations. If identical noise $\sigma$ is assumed for

both observations in the combination, (20.18) yields

$$\sigma_{\mathrm{IF}} = \sqrt{\frac{f_{\mathrm{A}}^2 + f_{\mathrm{B}}^2}{f_{\mathrm{A}}^2 - f_{\mathrm{B}}^2}}\,\sigma\,, \tag{20.43}$$

where $\sigma_{\mathrm{IF}}$ is the noise of the ionosphere-free combination. The noise increases by a factor of approximately 3.0 for GPS L1/L2 signals, and by about 2.6 for signals on the GPS L1/L5 or Galileo E1/E5a bands [20.1]. It becomes obvious that the noise is lower when the signal bands have a larger separation in frequency. Combining observations on frequency bands closely together would lead to an even higher increase in noise, for example, by a factor of $\approx 16.6$ for GPS L2/L5 or even $\approx 27.5$ for Galileo E5a/E5b. Of course, the noise amplification in (20.43) holds for both pseudorange and carrier-phase observations.

For the ionosphere-free carrier-phase combination the resulting wavelength is of interest. The ionosphere-free condition $h_2 = 0$ yields from (20.10) that

$$\frac{\alpha_{\mathrm{A}}}{f_{\mathrm{A}}^2} + \frac{\alpha_{\mathrm{B}}}{f_{\mathrm{B}}^2} = 0\,. \tag{20.44}$$

Substituting the integer coefficients from (20.12) and the expression for the base frequency from (20.20) yields the following condition

$$\frac{i_{\mathrm{A}}}{i_{\mathrm{B}}} = -\frac{f_{\mathrm{A}}}{f_{\mathrm{B}}} = -\frac{k_{\mathrm{A}}}{k_{\mathrm{B}}}\,. \tag{20.45}$$

Noting from the geometry-preserving conditions that $\sum \alpha_j = 1$, the corresponding wavelength of the ionosphere-free combination can be found from (20.15)

$$\lambda_{\mathrm{IF}} = \frac{\lambda_{\mathrm{A}}\lambda_{\mathrm{B}}}{i_{\mathrm{A}}\lambda_{\mathrm{B}} + i_{\mathrm{B}}\lambda_{\mathrm{A}}}\,. \tag{20.46}$$

It becomes obvious from (20.45) that multiple choices are possible for the integer coefficients. One option is to set the integers equal but with opposite sign to the base frequency multiplication factors $k_j$, divided by their lowest common denominator. This choice also yields the largest wavelength. Substituting numerical values for the GPS signals on L1 and L2 into (20.46) yields a wavelength of only approximately 6 mm, hampering ambiguity resolution. Non-integer choices for $i_j$, which satisfy (20.46), destroy the integerness of the resulting combined ambiguity.

For modeling the carrier-phase wind-up correction it is helpful to define the wavelength $\lambda_{\mathrm{IF,\,PWU}}$ as follows

$$\lambda_{\mathrm{IF,\,PWU}} = \lambda_{\mathrm{A}}\frac{f_{\mathrm{A}}^2}{f_{\mathrm{A}}^2 - f_{\mathrm{B}}^2} - \lambda_{\mathrm{B}}\frac{f_{\mathrm{B}}^2}{f_{\mathrm{A}}^2 - f_{\mathrm{B}}^2} = \frac{c}{f_{\mathrm{A}} + f_{\mathrm{B}}}\,, \tag{20.47}$$

which is identical to the narrow-lane wavelength (compare (20.26) and Table 20.1). It is worthwhile to emphasize that the dual-frequency ionosphere-free combinations for pseudorange and carrier-phase are only constructed from observations of the same type. Thus, in contrast to the GRAPHIC combination, they maintain their basic characteristic properties and can be processed similarly to the original uncombined observations except for the increased noise.

With dual-frequency measurements, only one ionosphere-free combination can be formed. With signals on more than two frequencies available, several possibilities to eliminate the ionosphere are possible and preserve the integer nature of the combined ambiguity [20.21, 22]. It is also possible to completely eliminate second-order ionospheric effects from the observations. Under normal ionospheric conditions, this error is on the order of a few centimeters in zenith direction for single-frequency observations and is already reduced by a factor of $\approx 30\%$ in the dual-frequency combination. With triple-frequency observations, the ionosphere can be completely eliminated up to second order, leaving only third-order residual errors, which then typically amount to less than a millimeter in this combination [20.23]. However, the noise amplification of these combinations is large when only L-band signals are used, which may limit their practical use [20.24].

It should also be noted that the use of multi-frequency signal combinations has been suggested, which do not completely eliminate the first-order ionosphere, but reduce it to a level where the effect becomes tolerable or negligible for ambiguity resolution. They are often referred to as ionosphere-reduced signal combinations [20.3, 25, 26]. The great variety of these new combinations prohibits their detailed discussion in this section. The reader may refer to specialized literature for further information on these combinations.

### 20.2.4 Multipath Combination

Multipath effects are mostly considered a nuisance in GNSS measurements and it is important to have an understanding of the magnitude of this error on the observations (Chap. 15). Multipath combinations can be used for this purpose.

The most frequently used multipath combination to assess pseudorange multipath on a single-frequency observation consists of one pseudorange observations on frequency A and two carrier-phase observations on frequencies A and B [20.27]

$$o_{\mathrm{MP}(p_{\mathrm{A}})} = p^{\mathrm{s}}_{\mathrm{r,A}} - \varphi^{\mathrm{s}}_{\mathrm{r,A}} - 2k\left(\varphi^{\mathrm{s}}_{\mathrm{r,A}} - \varphi^{\mathrm{s}}_{\mathrm{r,B}}\right), \tag{20.48}$$

with $k$ defined as

$$k = \frac{f_B^2}{f_A^2 - f_B^2} \,. \tag{20.49}$$

It becomes obvious from (20.9) and (20.10) that this multipath combination is geometry-free and ionosphere-free. Note the similarity of the last term in (20.48) to (20.37): essentially, this multipath combination is a code-carrier-difference minus twice the ionospheric delay. The remaining terms in the resulting combined observation $o_{\mathrm{MP}(p_A)}$ are group-delay variations, signal biases, receiver noise, and multipath of the pseudorange observables, as well as a combination of phase-center variation and offset, signal biases, phase wind-up, ambiguities, noise, and multipath of the carrier-phase observable. The effect of phase wind-up, however, is reduced by a factor of 0.10–0.15 and amounts to only a few centimeters.

Assuming, firstly, that multipath and noise of the carrier-phase observations are negligible compared to the corresponding terms of the pseudorange and, secondly, that all other terms are constant, the evaluation of the multipath combination over time yields the temporal variation of this nuisance parameter biased by a combination of the remaining terms

$$\begin{aligned} o_{\mathrm{MP}(p_A)} = {} & e^s_{r,A}(t) - ((1+2k)\,\lambda_A + 2k\lambda_B)\,\omega^s_r(t) \\ & + \xi^s_{r,A}(t) - (1+2k)\,\zeta^s_{r,A}(t) + 2k\zeta^s_{r,B}(t) + \Gamma \,, \end{aligned} \tag{20.50}$$

with the constant term $\Gamma$ defined as

$$\begin{aligned} \Gamma = {} & c d^s_{r,A} - (1+2k)\,c\delta^s_{r,A} + 2kc\delta^s_{r,B} \\ & - (1+2k)\,\lambda_A N^s_{r,A} + 2k\lambda_B N^s_{r,B} \,. \end{aligned} \tag{20.51}$$

According to the previous assumption, the noise of this multipath combination is dominated by the noise of the pseudorange measurement. However, for special low-noise pseudorange signals, like Galileo alternative BOC (AltBOC), both code and phase noise may be relevant.

An example of this multipath combination is shown in Fig. 20.2. The figure depicts the multipath errors of C/A-code pseudorange measurements from a GPS satellite over time tracked by a geodetic grade receiver. After the satellite elevation angle drops below 12° at 900 s the multipath errors become clearly visible. The effect can also be observed in the periodic oscillations of the measured $C/N_0$, typical for the alternating destructive and constructive interference of multipath signals [20.28]. At elevation angles less than 6°, the multipath becomes so severe that the receiver loses lock repeatedly and the ambiguities in (20.51) change.

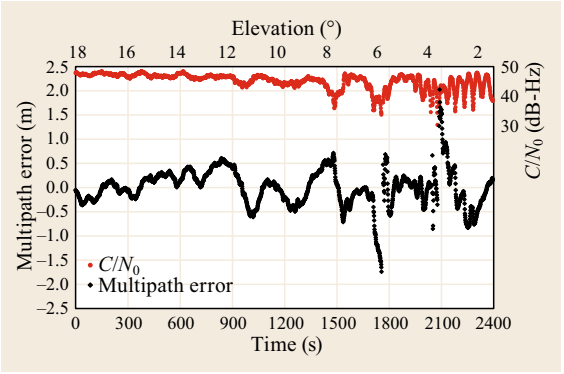

**Fig. 20.2** Plot of multipath combination (*black*) and measured carrier-to-noise-power-density ratio $C/N_0$ (*red*) over time and satellite elevation angle for L1 C/A code measurements of a GPS satellite. Note that the change of the elevation angle is approximately linear over the plot interval

The previous derivations have shown how multipath on a single pseudorange measurement can be assessed with the help of two carrier-phase observations on different frequencies. With a combination of observations from three frequencies, isolation of the multipath errors is possible to some extent for pseudorange and carrier-phase observations separately [20.29]. Consider the following triple-frequency combinations for pseudorange $o_{\mathrm{MP}(p_A,p_B,p_C)}$ and carrier-phase $o_{\mathrm{MP}(\phi_A,\phi_B,\phi_C)}$

$$o_{\mathrm{MP}(p_A,p_B,p_C)} = \beta_A p^s_{r,A} + \beta_B p^s_{r,B} + \beta_C p^s_{r,C} \tag{20.52}$$

and

$$o_{\mathrm{MP}(\phi_A,\phi_B,\phi_C)} = \alpha_A \phi^s_{r,A} + \alpha_B \phi^s_{r,B} + \alpha_C \phi^s_{r,C} \,, \tag{20.53}$$

where the linear coefficients are defined as

$$\begin{aligned} \alpha_A = \beta_A &= \frac{\left(\lambda_C^2 - \lambda_B^2\right)}{\Lambda} \,, \\ \alpha_B = \beta_B &= \frac{\left(\lambda_A^2 - \lambda_C^2\right)}{\Lambda} \,, \\ \alpha_C = \beta_C &= \frac{\left(\lambda_B^2 - \lambda_A^2\right)}{\Lambda} \,, \\ \Lambda^2 &= \left(\lambda_C^2 - \lambda_B^2\right)^2 + \left(\lambda_A^2 - \lambda_C^2\right)^2 + \left(\lambda_B^2 - \lambda_A^2\right)^2 . \end{aligned} \tag{20.54}$$

Evaluating the geometry scaling factor (20.9) and the ionospheric scaling factor (20.10) with the coefficients (20.54) reveals that this combination is both geometry- and ionosphere-free. Furthermore, evaluation of (20.18) yields a noise-amplification factor of one

assuming that all three observables have identical noise levels [20.30]. Substituting (20.2) into (20.52) yields for pseudorange

$$
\begin{aligned}
&o_{\mathrm{MP}(p_\mathrm{A},p_\mathrm{B},p_\mathrm{C})} \\
&\quad = \beta_\mathrm{A} e^\mathrm{s}_{\mathrm{r,A}}(t) + \beta_\mathrm{B} e^\mathrm{s}_{\mathrm{r,B}}(t) + \beta_\mathrm{C} e^\mathrm{s}_{\mathrm{r,C}}(t) \\
&\qquad + \beta_\mathrm{A} \xi^\mathrm{s}_{\mathrm{r,A}}(t) + \beta_\mathrm{B} \xi^\mathrm{s}_{\mathrm{r,B}}(t) + \beta_\mathrm{C} \xi^\mathrm{s}_{\mathrm{r,C}}(t) \\
&\qquad + c\left(\beta_\mathrm{A} d^\mathrm{s}_{\mathrm{r,A}} + \beta_\mathrm{B} d^\mathrm{s}_{\mathrm{r,B}} + \beta_\mathrm{C} d^\mathrm{s}_{\mathrm{r,C}}\right) . \qquad (20.55)
\end{aligned}
$$

The corresponding factors for open-service signals of the new and modernized GNSS can be found in Table 20.2. It becomes obvious that the terms associated with the first, highest frequency are attenuated compared to the other two frequencies, which have similar weights. For pseudorange, the combination depends on the combined multipath errors and receiver noise $e^\mathrm{s}_{\mathrm{r},j}$, a combination of the individual group-delay variations $\xi^\mathrm{s}_{\mathrm{r},j}$, and a combination of the pseudorange delays $d^\mathrm{s}_{\mathrm{r},j}$. Although the latter are generally assumed constant, investigations with triple-frequency multipath combinations suggest that frequency-dependent line-bias variations exist for some satellites [20.31].

Figure 20.3 shows the triple-frequency pseudorange combination with GPS L1 C/A, L2C, and L5 observations for the same satellite and time period as in Fig. 20.2. Again, the multipath effects are clearly visible at low satellite elevation angles.

Similar to pseudorange, the triple-frequency carrier-phase multipath combination is found from substituting (20.4) into (20.53)

$$
\begin{aligned}
&o_{\mathrm{MP}(\phi_\mathrm{A},\phi_\mathrm{B},\phi_\mathrm{C})} \\
&\quad = \alpha_\mathrm{A} \epsilon^\mathrm{s}_{\mathrm{r,A}}(t) + \alpha_\mathrm{B} \epsilon^\mathrm{s}_{\mathrm{r,B}}(t) + \alpha_\mathrm{C} \epsilon^\mathrm{s}_{\mathrm{r,C}}(t) \\
&\qquad + \alpha_\mathrm{A} \zeta^\mathrm{s}_{\mathrm{r,A}}(t) + \alpha_\mathrm{B} \zeta^\mathrm{s}_{\mathrm{r,B}}(t) + \alpha_\mathrm{C} \zeta^\mathrm{s}_{\mathrm{r,C}}(t) \\
&\qquad + c\left(\alpha_\mathrm{A} \delta^\mathrm{s}_{\mathrm{r,A}} + \alpha_\mathrm{B} \delta^\mathrm{s}_{\mathrm{r,B}} + \alpha_\mathrm{C} \delta^\mathrm{s}_{\mathrm{r,C}}\right) \\
&\qquad + \omega^\mathrm{s}_\mathrm{r}\left(\alpha_\mathrm{A}\lambda_\mathrm{A} + \alpha_\mathrm{B}\lambda_\mathrm{B} + \alpha_\mathrm{C}\lambda_\mathrm{C}\right) \\
&\qquad + \alpha_\mathrm{A}\lambda_\mathrm{A} N^\mathrm{s}_{\mathrm{r,A}} + \alpha_\mathrm{B}\lambda_\mathrm{B} N^\mathrm{s}_{\mathrm{r,B}} + \alpha_\mathrm{C}\lambda_\mathrm{C} N^\mathrm{s}_{\mathrm{r,C}} . \qquad (20.56)
\end{aligned}
$$

**Table 20.2** Coefficients for selected triple-frequency multipath combinations of different GNSSs. The last column lists the effective wavelength of the phase wind-up term

| GNSS | $\alpha_j, \beta_j$ | | | $\sum \alpha_j \lambda_j$ (mm) |
|---|---|---|---|---|
| GPS, QZSS L1,L2,L5 | 0.142 | −0.767 | 0.626 | −0.99 |
| Galileo E1,E5b,E5a | 0.085 | −0.746 | 0.661 | −0.63 |
| GLONASS L1,L2,L3 | 0.121 | −0.760 | 0.639 | −0.82 |
| BeiDou B1,B3,B2 | 0.183 | −0.781 | 0.597 | −0.94 |

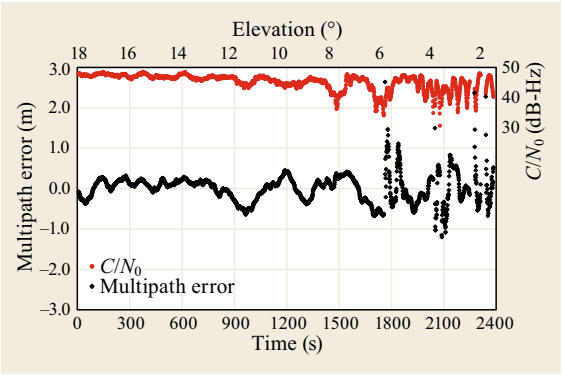

**Fig. 20.3** Plot of triple-frequency multipath combination (*black*) for L1 C/A, L2C, and L5 pseudorange observations and measured L1 C/A carrier-to-noise-power-density ratio $C/N_0$ (*red*) over time and satellite elevation angle of a GPS satellite. Note that the change of the elevation angle is approximately linear over the plot interval

Besides the combined effect of multipath and noise $\epsilon^\mathrm{s}_{\mathrm{r},j}$, the carrier-phase combination depends on the combinations of phase-center variations $\zeta^\mathrm{s}_{\mathrm{r},j}$, the combined phase biases $\delta^\mathrm{s}_{\mathrm{r},j}$, a linear combination of the ambiguities $N^\mathrm{s}_{\mathrm{r},j}$, as well as the phase wind-up $\omega^\mathrm{s}_\mathrm{r}$. The last column in Table 20.2 lists the combined multiplication factors for this term. It is on the order of a millimeter and thus virtually eliminated from the carrier-phase combination.

Figure 20.4 shows the triple-frequency carrier-phase combination with GPS observations of the L1 C/A, L2C, and L5 signals for the same satellite and time period as in the previous two multipath plots. The effect

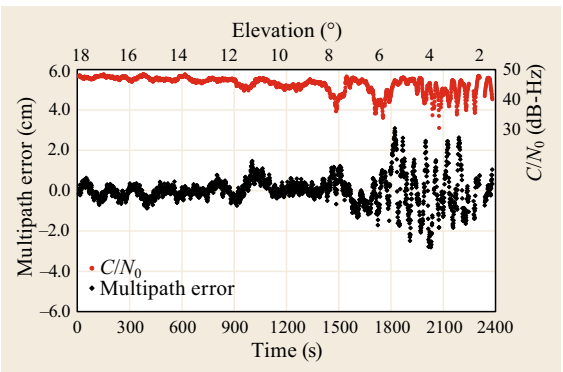

**Fig. 20.4** Plot of multipath combination (*black*) for a triple-frequency carrier-phase combination of L1 C/A, L2C, and L5 observations and measured L1 C/A carrier-to-noise-power-density ratio $C/N_0$ (*red*) over time and satellite elevation angle of a GPS satellite. Note that the change of the elevation angle is approximately linear over the plot interval

of the combined multipath becomes visible in the high-frequency oscillations at low elevation angles. Note that the ordinate axis has a different scale compared to Fig. 20.3, since the carrier-phase multipath is two orders of magnitude smaller. For a detailed discussion of multipath effects, the reader may refer to Chap. 15.

## 20.3 Combinations of Multisatellite and Multireceiver Observations

In the previous sections observations combinations have only been formed from measurements of a single satellite tracked by a single receiver. Of course, combinations can also be formed between two satellites or between two receivers. The latter is a long-established technique for differential positioning and allows for convenient elimination of nuisance parameters from the observables. Differences of observations of two satellites at one receiver or of two receivers for the same satellite are called single differences. Taking the difference between two single differences leads to a double-difference observable. Finally, the time difference between two double differences at different epochs is referred to as triple difference. At the end of the section, the special case of a zero-baseline configuration will be introduced, where two receivers are connected through a power-splitter to the same antenna. Single-, double-, and triple differences with this setup are very useful for the characterization of GNSS signals or receiver measurements.

A short note on notation shall be added at this point: so far all time-dependent terms have succeeded by $(t)$. For the remainder of the chapter, this indicator for time dependency is dropped to achieve a more concise notation.

### 20.3.1 Between-Receiver Single Difference

Assume that time-synchronized measurements of the same satellite k from two receivers 1 and 2 as depicted in Fig. 20.5 are available. The between-receiver single differences (BRSD) $p^{\mathrm{k}}_{12}$ of the pseudorange observations are then computed from

$$p^{\mathrm{k}}_{12,\boxtimes} = p^{\mathrm{k}}_{2,\boxtimes} - p^{\mathrm{k}}_{1,\boxtimes} \,. \tag{20.57}$$

Note the symbol ⊠ in place of the signal index $j$. This notation has been chosen here to indicate that the single differences are typically formed between identical signals, but not necessarily basic single observations. One could, for example, also use an ionosphere-free observable or any other signal combination in the single difference depending on the desired application. For the remainder of this section, only single, uncombined measurements will be considered and the placeholder ⊠ will therefore be dropped for brevity. Substituting (20.2) into (20.57) and considering all the terms yields for the single-difference pseudorange

$$p^{\mathrm{k}}_{12} = \rho^{\mathrm{k}}_{12} + c\left(dt_{12} + \delta t^{\mathrm{rel,k}}_{\mathrm{stc},12}\right) + cd^{\mathrm{k}}_{12} + \xi^{\mathrm{k}}_{12} + T^{\mathrm{k}}_{12} + I^{\mathrm{k}}_{12} + e^{\mathrm{k}}_{12} \,. \tag{20.58}$$

The brief notation $\rho^{\mathrm{k}}_{12} = \rho^{\mathrm{k}}_{2} - \rho^{\mathrm{k}}_{1}$ has been used for the differential geometric range and equivalently also for all other terms. A different notation can also often be found in literature, which denotes a between-receiver single difference as $\Delta p^{\mathrm{k}}_{12}$ and is equivalent to (20.57). However, in this case an extra $\Delta$ would be included in the observation equation for each term, which can lead to a rather cumbersome notation.

The term for the satellite clock offset, which is of course identical for two time-synchronized observations at different receivers irrespective of the antenna distance, has dropped out of (20.58). The same also holds true for the relativistic correction for the satellite clock due to noncircular orbits (19.15) and the $J_2$-correction (19.18). The terms for the differential relativistic space–time curvature correction $\delta t^{\mathrm{rel,k}}_{\mathrm{stc},12}$, tropospheric delay $T^{\mathrm{k}}_{12}$, ionospheric delay $I^{\mathrm{k}}_{12}$, and group delay variation $\xi^{\mathrm{k}}_{12}$ are still present in the equations, but strongly correlate with the distance of the two antennas. For antenna distances of only up to a few 100 m, the signal transmit paths in the atmosphere are virtually the same, which also leads to identical delays of the signals and these terms drop out of (20.58). For larger antenna separations, the electron content in the ionosphere and

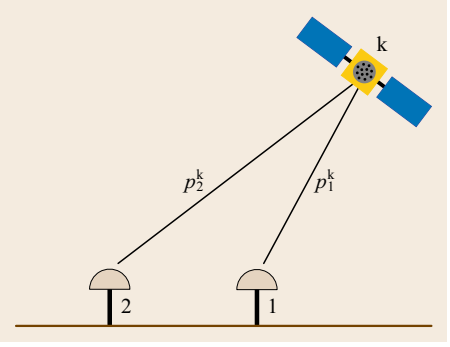

**Fig. 20.5** Single difference of observations from satellite k between receivers 1 and 2

the atmospheric parameters in the troposphere may differ and become significant. A similar reasoning also holds true for the differential group delay variation $\xi^{k}_{12}$, since for small antenna baseline lengths, the azimuth and off-boresight angle of the antenna-satellite line-of-sight vectors are practically identical, thus the signal is affected by the same group delays. For larger baselines the group delays may differ. The relativistic correction due to space–time curvature (19.14) also depends on the line-of-sight vector, and thus the term $\delta t^{rel,k}_{stc,12}$ decorrelates for large baselines.

The differential biases $d^{k}_{12}$ have been retained in (20.58). The reason for this is that only if receivers with identical correlators are used in the single difference, the combined satellite and receiver bias can be split up into the individual terms as in (20.3). In this case, the satellite-dependent part drops out of the single difference, whereas the differential receiver-dependent part is retained. Finally, the terms for differential receiver clock offset $dt_{12}$ and noise and multipath errors $e^{k}_{12}$ remain in the equations irrespective of the antenna separation.

In a similar manner, a single-difference carrier-phase between two receivers $\varphi^{k}_{12}$ can be formed

$$\varphi^{k}_{12} = \rho^{k}_{12} + c\left(dt_{12} + \delta t^{rel,k}_{stc,12}\right) + c\delta^{k}_{12} + \zeta^{k}_{12} + T^{k}_{12} - I^{k}_{12} + \lambda\left(\omega^{k}_{12} + N^{k}_{12}\right) + \epsilon^{k}_{12} \,. \qquad (20.59)$$

In (20.59) the differential terms for the range $\rho^{k}_{12}$, the receiver clock $dt_{12}$, the relativistic clock correction $\delta t^{rel}_{stc}$, the differential tropospheric delay $T^{k}_{12}$, the ionospheric delay $I^{k}_{12}$, the phase-center variation $\zeta^{k}_{12}$, the carrier-phase biases $\delta^{k}_{12}$, and the noise and multipath $\epsilon^{k}_{12}$ are identical or similar to the single difference pseudorange equation and their discussion, therefore, not repeated here. Two additional terms have appeared in (20.59): the differential phase wind-up $\omega^{k}_{12}$ and the single-difference ambiguity $N^{k}_{12}$.

The phase wind-up term depends on the relative orientation of the transmitting and receiving antennas. Assuming that the orientation of the receiving antennas does not change with respect to each other, the residual phase wind-up effect in differential measurements over short baselines on the order of a few 100 km or less will be on the order of a few millimeters and may thus be neglected. The residual effects increase with increasing baseline length and can theoretically amount to half a wavelength for receiving antennas on opposite sides of the Earth [20.32]. The receiving antennas may rotate with respect to each other, for example, in case of one antenna being setup as a reference station and the other antenna being mounted on a moving vehicle. In this case, the change in the differential phase wind-up between the two antennas must also be accounted for.

Figure 20.6 shows the between-receiver single differences for pseudorange observations Fig. 20.6a and carrier-phase observations Fig. 20.6b of three GPS satellites over an interval of 4 h. The two antennas are mounted at a distance of 4.8 m, thus differential troposphere, ionosphere, and group-delay variations are eliminated. The remaining terms are the differential range, the differential receiver clock offset and bias, the differential relativistic effects due to space–time curvature, and differential receiver noise and multipath errors. The carrier-phase single differences are also arbitrarily offset by the differential ambiguity. In this case, however, both receivers keep their carrier-phase observations closely aligned to the pseudorange. Therefore the ordinates of both plots still have the same scale. It becomes immediately obvious from the

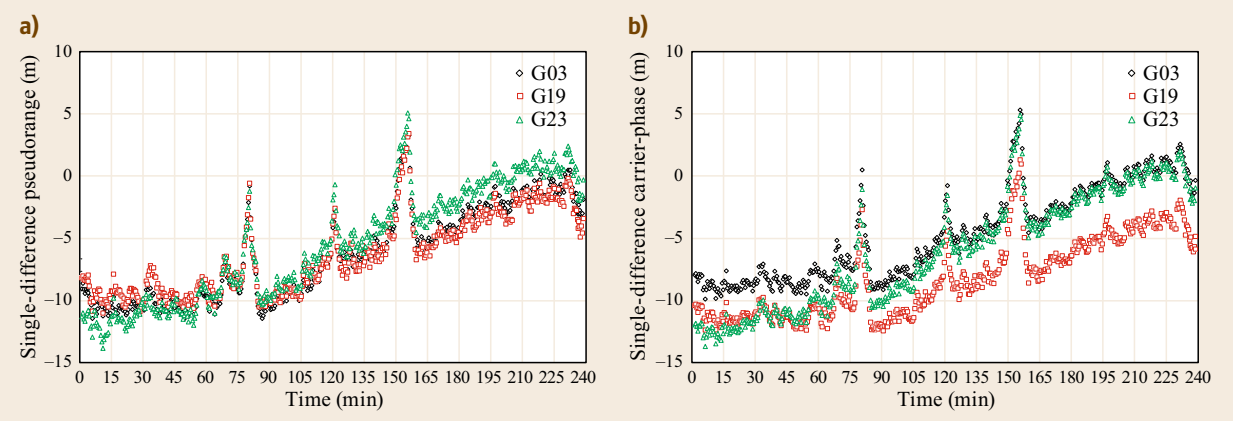

**Fig. 20.6a,b** Between-receiver single differences of pseudorange (a) and carrier-phase (b) observations for three GPS satellites and two antennas with a baseline length of 4.8 m over a time interval of 4 h

plots that both pseudorange and carrier-phase single differences exhibit identical short-term temporal variations, which are especially pronounced at 75, 120, and 150 min. These variations are due to the differential receiver clock offsets, since the receivers have been operated using their independent internal oscillators. In addition, the change of differential range over time also contributes to an identical systematic variation of both observables over time. Since it only depends on the satellite motion, this change is slow in time for a static baseline. At maximum it can only vary over twice the baseline length, in this case from −4.8 to +4.8 m.

### 20.3.2 Between-Satellite Single Difference

The single-difference equations (20.58) and (20.59) have been formed between two receivers using observations of the same satellite. Of course, single differences

$$\begin{aligned} p_1^{kl} &= p_1^l - p_1^k \,, \\ \varphi_1^{kl} &= \varphi_1^l - \varphi_1^k \,, \end{aligned} \tag{20.60}$$

can also be formed using two observations of different satellites k and l at the same receiver 1 as shown in Fig. 20.7. In case the more elaborate notation is used, the between-satellite single differences (BSSD) are denoted $\nabla p_1^{kl}$ and $\nabla \varphi_1^{kl}$. Note that $\nabla$ is used for BSSD instead of $\Delta$ for BRSD.

The observations equations for satellite–satellite single differences of pseudoranges $p_1^{kl}$ and carrier-phases $\varphi_1^{kl}$ are as follows

$$\begin{aligned} p_1^{kl} &= \rho_1^{kl} + c\left(dt^{kl} + \delta t^{rel,kl}\right) + cd_1^{kl} + \xi_1^{kl} \\ &\quad + T_1^{kl} + I_1^{kl} + e_1^{kl} \,, \end{aligned} \tag{20.61}$$

$$\begin{aligned} \varphi_1^{kl} &= \rho_1^{kl} + c\left(dt^{kl} + \delta t^{rel,kl}\right) + c\delta_1^{kl} + \zeta_1^{kl} \\ &\quad + T_1^{kl} - I_1^{kl} + \epsilon_1^{kl} \\ &\quad + \lambda^l\left(\omega_1^l + N_1^l\right) - \lambda^k\left(\omega_1^k + N_1^k\right) . \end{aligned} \tag{20.62}$$

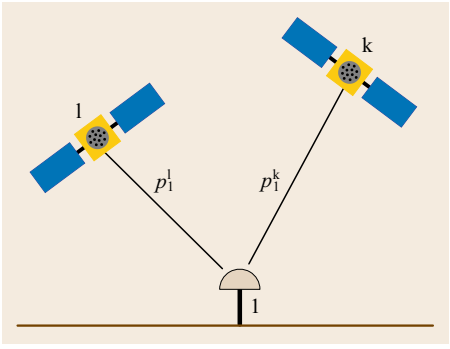

**Fig. 20.7** Single difference of observations from receiver 1 between satellites k and l

The offset and the corresponding relativistic effect of the receiver clock drop out the equations for the between-satellite difference. All other terms are retained. In the carrier-phase equation (20.62), the expressions for the differences of phase wind-up and ambiguity are more complicated, since they may involve frequencies with different wavelengths $\lambda^k$ and $\lambda^l$. When the single difference is formed between two satellites of different constellations, the ISB of these two constellations will manifest itself in the combined observable, which is the combination of a system-time offset and measurement biases. In (20.1) and (20.62), the contribution of the system-time offset is contained in the differential satellite clock offset $dt^{kl}$. The contribution of the biases in the ISB is contained in the differential pseudorange bias term $d_1^{kl}$ and the differential carrier-phase bias term $\delta_1^{kl}$.

Figure 20.8 depicts between-satellite single differences for pseudorange (Fig. 20.8a) and carrier-phase (Fig. 20.8b) for the same time interval as in Fig. 20.6 using data from one receiver only for the same three GPS satellites. The observations have been corrected for the differential geometric range and satellite clock offset, which can amount to several kilometers. As expected, the variations due to the change in the receiver clock have now vanished and the different levels of noise and multipath errors of the pseudorange and carrier-phase observations become distinguishable. Differential tropospheric and ionospheric delays, and differential group-delay variations and phase-center variations contribute to the temporal changes of the satellite–satellite single differences. Note the differences in the temporal variation between pseudorange and carrier-phase due to the different sign of the ionospheric delay. This effect is also referred to as code-carrier divergence.

As for most of the other combinations, the elimination of parameters from the measurement equations comes at the price of increased noise. The noise of the between-receiver single-difference $\sigma_{12}$ or between-satellite single-difference $\sigma^{kl}$ is

$$\sigma_{12} = \sigma^{kl} = \sqrt{2}\sigma \,, \tag{20.63}$$

assuming identical standard deviation $\sigma$ for the uncombined observables.

### 20.3.3 Double Difference

A double-difference observation can be formed if observations from a pair of receivers 1 and 2 and a pair of satellites k and l are available as depicted in Fig. 20.9. For pseudorange measurements, it can be formed from two receiver–receiver single differences as follows

$$p_{12}^{kl} = p_{12}^l - p_{12}^k \,. \tag{20.64}$$

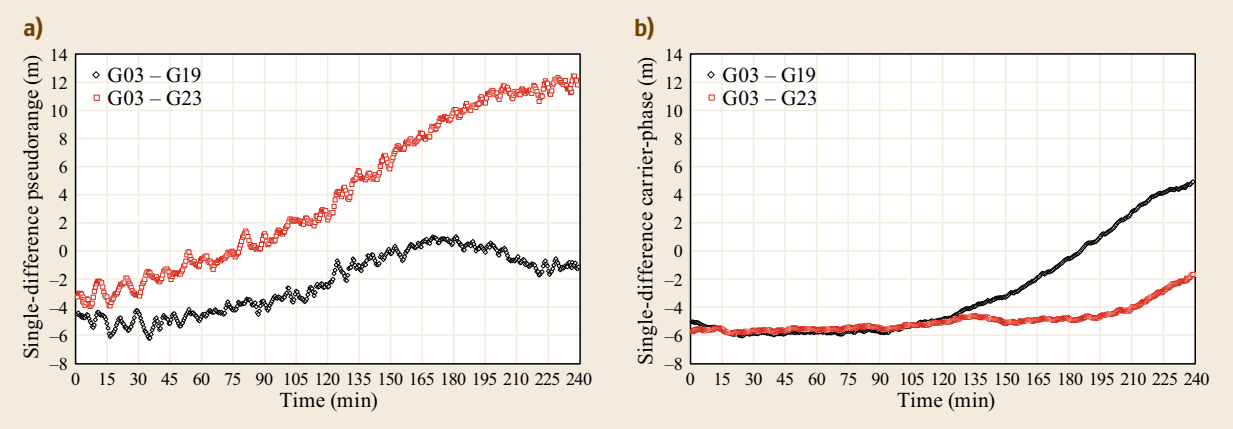

**Fig. 20.8a,b** Between-satellite single differences of pseudorange (a) and carrier-phase (b) observations for three GPS satellites over a time interval of 4 h. The observations have been corrected for the differential geometric range and the satellite clock offsets

Of course, the same result can also be obtained through the combination of two single differences between satellites $p_{12}^{kl} = p_2^{kl} - p_1^{kl}$. In the alternative notation, the double difference would be written as $\Delta\nabla p_{12}^{kl}$. Substituting (20.58) into (20.64) yields

$$p_{12}^{kl} = \rho_{12}^{kl} + cd_{12}^{kl} + \xi_{12}^{kl} + T_{12}^{kl} + I_{12}^{kl} + e_{12}^{kl} \,. \qquad (20.65)$$

Note that the receiver and satellite clock offsets as well as the relativistic corrections have been eliminated from the double difference, but the double difference of the geometric range are still retained. The terms for the troposphere, the ionosphere, and the code-phase pattern variation are also still present in this most general from of the equation, but are canceled out for small antenna separations. Receiver noise and multipath $e_{12}^{kl}$ are still be retained.

The bias double differences $d_{12}^{kl}$ are present unless receivers with identical front-end characteristics and correlator settings are used. If satellites of different constellations are used in the double difference, parts of the corresponding ISB are still retained in the combined observable. The system-time offset between the two constellations is of course identical for both receivers and is completely eliminated like the satellite clocks. However, the two receivers involved may exhibit different biases for different constellations. As a result, the double-difference biases of satellites from the same constellation may vanish, but can still be present when the two satellites are from different constellations.

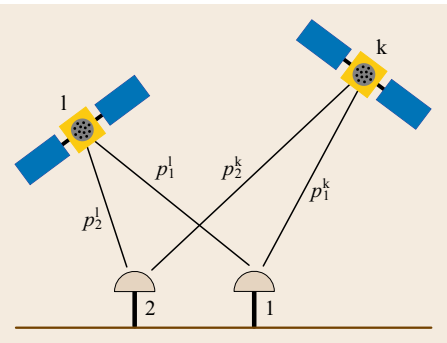

**Fig. 20.9** Double difference of observations from receiver 1 and 2 and satellites k and l

The equivalent double-difference equation for carrier-phase observation $\varphi_{12}^{kl}$ is given by

$$\varphi_{12}^{kl} = \rho_{12}^{kl} + c\delta_{12}^{kl} + \zeta_{12}^{kl} + T_{12}^{kl} - I_{12}^{kl} + \lambda\left(\omega_{12}^{kl} + N_{12}^{kl}\right) + \epsilon_{12}^{kl} \,. \qquad (20.66)$$

The double differences of geometric range, tropospheric, and ionospheric delays are already known from (20.65). The term $\zeta_{12}^{kl}$ describes the double difference of the phase-center variation. The double differences of the carrier-phase biases $\delta_{12}^{kl}$ are retained in the equations and will only drop out if receivers with compatible front-end and correlator design are used. The combined errors due to receiver noise and multipath are summarized in the double-difference term $\epsilon_{12}^{kl}$. Finally, the phase wind-up term $\omega_{12}^{kl}$ and the ambiguity term $N_{12}^{kl}$ are multiplied with the wavelength $\lambda$. It is implicitly assumed in this derivation that all carrier-phase observations involved in the double difference have the same wavelength. The phase wind-up term is included in the double difference, since this effect becomes negligible only for short baselines of a few 100 km. It can theoretically amount to half a wavelength for receiving antennas on opposite sides of the Earth. Only the contribution of a relative rotation of the receiving antennas cancels out for all baseline lengths in case of double dif-

ferences, since it is identical in both single difference observations involved in (20.66).

Figure 20.10 depicts double differences for pseudorange (Fig. 20.10a) and carrier-phase (Fig. 20.10b) for the same time interval using the same satellites and receivers as in the examples in the previous section. The short baseline length of 4.8 m eliminates all atmospheric delays and the effects due to group-delay variations and phase-center offset variation. Only the double difference of geometric range, signal biases, noise, and multipath remain. The change of $\rho_{12}^{kl}$ amounts to a few meters and can clearly be recognized in the plots for both observables. The noise and multipath of the double-difference pseudoranges are also clearly visible. For the carrier-phases, these effects are much smaller and not distinguishable on this scale.

The noise of the double-difference equation is increased by a factor of $\sqrt{2}$ compared to the single-difference combination, since four observations with uncorrelated stochastic errors are involved. Using the expression for the single-difference standard deviation defined in (20.63) together with the error propagation law (20.18), one obtains

$$\sigma_{12}^{kl} = \sqrt{2}\sigma_{12} = \sqrt{2}\sigma^{kl} = 2\sigma \,, \tag{20.67}$$

for the measurement noise $\sigma_{12}^{kl}$ the double differences.

### 20.3.4 Triple Difference

Forming single and double differences of observations has proven effective to eliminate some nuisance parameters, especially on short baselines where spatial correlation of signals delays can be exploited. Another method to eliminate errors is to take advantage of temporal correlation and take the difference of observations at different epochs. The time difference of two double-difference observations is typically referred to as a triple difference [20.33]

$$\partial p_{12}^{kl} = p_{12}^{kl}(t_i) - p_{12}^{kl}(t_{i-1}) \,. \tag{20.68}$$

The operator $\partial$ is used to denote the time difference of observations between the two epochs $t_i$ and $t_{i-1}$. The time difference will eliminate all parameters in (20.66), which are constant over time. In the most general case, these are the double-difference terms for carrier-phase biases $\delta_{12}^{kl}$ and the carrier-phase double-difference ambiguity $N_{12}^{kl}$ as long as no cycle slip occurs. The full triple-difference measurement equations including all terms are

$$\partial p_{12}^{kl} = \partial\rho_{12}^{kl} + \partial\xi_{12}^{kl} + \partial T_{12}^{kl} + \partial I_{12}^{kl} + \partial e_{12}^{kl} \,, \tag{20.69}$$

$$\partial\varphi_{12}^{kl} = \partial\rho_{12}^{kl} + \partial\zeta_{12}^{kl} + \partial T_{12}^{kl} - \partial I_{12}^{kl} + \partial\epsilon_{12}^{kl} + \partial\omega_{12}^{kl} \,. \tag{20.70}$$

Should the terms for the tropospheric and ionospheric delays, the phase-center variation, and the phase wind-up not be completely eliminated already in the double difference, their magnitude is further reduced in the triple difference, especially when observations of the time interval $t_i - t_{i-1}$ are small.

Figure 20.11 depicts triple differences for pseudorange (Fig. 20.11a) and carrier-phase (Fig. 20.11b). The triple differences have been formed from the double differences depicted in Fig. 20.10. Note the different scale of the ordinates for pseudorange and carrier-phase. Only the time differences of the geometric range and the receiver noise are still present in the triple-difference observations on the short baseline of 4.8 m.

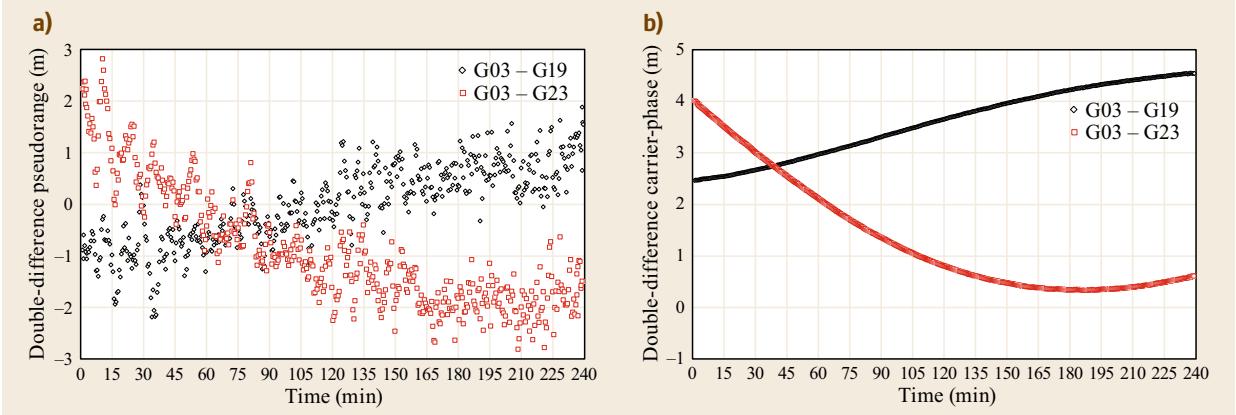

**Fig. 20.10a,b** Double differences of pseudorange **(a)** and carrier-phase **(b)** observations for three GPS satellites and two antennas with a baseline of 4.8 m over a time interval of 4 h

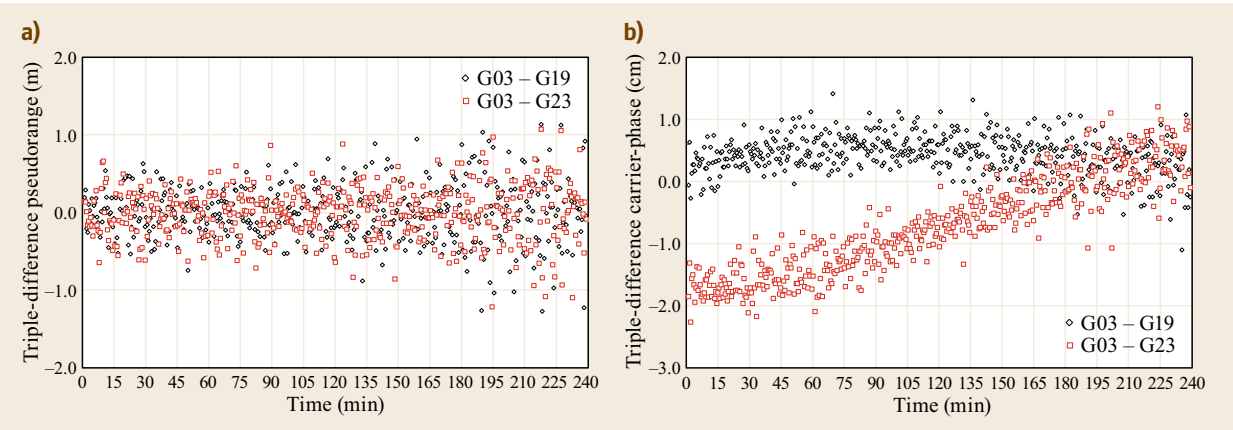

**Fig. 20.11a,b** Triple differences of pseudorange **(a)** and carrier-phase **(b)** observations for three GPS satellites and two antennas with a baseline length of 4.8 m over a time interval of 4 h. Note the different scales of the ordinates for pseudorange (m) and carrier-phase (cm)

Application of the error propagation law (20.18) and assuming equal noise for both double differences leads to the following expression for the noise of the triple-difference $\sigma_{\delta_{12}^{kl}}$

$$\sigma_{\delta_{12}^{kl}} = \sqrt{2}\sigma_{12}^{kl} = \sqrt{8}\sigma \,, \tag{20.71}$$

which uses (20.63) and (20.67) to relate to the noise of the individual observations.

### 20.3.5 Single and Double Difference on Zero-Baselines

A setup, where two or more receivers are connected via a power splitter to the same antenna, is commonly referred to as a zero-baseline configuration. It is depicted in Fig. 20.12. Since the signals are tracked by both receivers referred to the same antenna-phase center, the differential geometry, group-delay variations, phase-center offsets and variations, and the atmospheric delays are canceled completely in zero-baseline single differences. The only remaining terms are differential receiver clock offsets, biases, multipath, and receiver noise in case of pseudorange observations. For carrier-phase observations, the single-difference ambiguity is also retained. Dropping all terms in the single-difference observation equations (20.58) and (20.59), which cancel due to the identical signal transmission path, yields the following equations for the zero-baseline case

$$p_{12,ZB}^{k} = c\left(dt_{12} + d_{12}^{k}\right) + e_{12}^{k} \,, \tag{20.72}$$

$$\varphi_{12,ZB}^{k} = c\left(dt_{12} + \delta_{12}^{k}\right) + \lambda N_{12}^{k} + \epsilon_{12}^{k} \,. \tag{20.73}$$

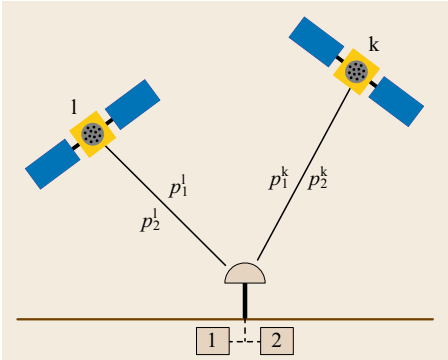

**Fig. 20.12** Zero-baseline configuration of receiver 1 and 2 connected to the same antenna

Forming double differences further eliminates the receiver clock

$$p_{12,ZB}^{kl} = cd_{12}^{kl} + e_{12}^{kl} \,, \tag{20.74}$$

$$\varphi_{12,ZB}^{kl} = c\delta_{12}^{kl} + \lambda N_{12}^{kl} + \epsilon_{12}^{kl} \,. \tag{20.75}$$

Due to this convenient elimination of nuisance parameters, a zero-baseline configuration is a convenient setup for receiver characterization as well as signal studies.

The derived equations model the zero-baseline observations for the most general case using a pair of arbitrary receivers, which are not necessarily of the same type. Further terms may cancel when identical receiver models, or receivers with the same correlator and front-end configuration, are used in the zero-baseline configuration. In this case, also the pseudorange and carrier-phase bias terms will drop out, since the correlator will produce the same tracking error for the satellite's chip-shape distortions. For the same reason, the multipath errors, implicitly contained in the terms $e_{12}^{kl}$ and $\epsilon_{12}^{kl}$, will also cancel out in this case.

It should also be noted that the aforementioned full cancellation of the geometry term $\rho_{12}^{kl}$ is only true for time-synchronized observations between the two receivers. The maximum range rate for a GPS satellite and a ground-based user at the equator is approximately 1000 m/s when the satellite is close to the horizon. If the observation epochs of two receivers in a zero-baseline setup for this satellites have a synchronization error of 1 ms, the satellite has moved approximately 1 m with respect to the user. This range change will then still be present in the differential measurement. For the analysis of carrier-phase observations it is desirable to confine the maximum range change to less than 1 mm, which requires the receiver clock synchronization errors to be less than 1 μs. This can typically be achieved by activating the internal receiver clock synchronization to a GNSS system time or, in post-processing, by extrapolating the observations of the two receivers to a common epoch computed from pseudorange-based positing solutions.

Figure 20.13 depicts singe-differences of pseudorange observations for GPS, Galileo, and BeiDou satellites. The receivers are different models and have their internal clocks synchronized to GPS time within a few nanoseconds. This becomes obvious from the single differences of the three GPS satellites, which contain the differential receiver clock offset. It is on the order of a few meters and its variation over time is identical for all three satellites. In addition, differential receiver noise and multipath are present, but significant biases between the GPS satellites cannot be distinguished. Interestingly, the single differences of the BeiDou and the Galileo satellites between the two receivers exhibit a large offset compared to the GPS satellites. The reason for this offset is the difference of the ISB between these two receivers. Even though the contribution of the system-time offset of the ISB is eliminated in the single difference, the differential biases between the different signals are still retained. In case of GPS and Galileo, the between-receiver ISB difference is ≈ 23 m. For GPS and BeiDou, it is on a similar order of magnitude, but not identical. Note that the temporal variation of the differential receiver clock is also visible in the Galileo and BeiDou single differences. The BeiDou satellite C12 exhibits increased differential noise and multipath errors at the beginning of the data arc, since it is tracked at very close to the horizon at an elevation angle of less than 10° for the first 15 min of the plotted data.

Figure 20.14 depicts the double differences of pseudorange and carrier-phase observations for the same time period, satellites, and receivers as in Fig. 20.13. A GPS satellite has been selected as reference satellite for all combinations. Inspection of the GPS double differences for pseudoranges in the top plot makes obvious that the differential clock offset and its variations are now removed and the double differences for GPS are centered at zero. As already expected, the mixed-constellation double differences with Galileo and BeiDou satellites are still offset due to the effect of the differential biases.

The carrier-phase double differences in the bottom plot of Fig. 20.14 are plotted in units of cycles. Note that the offset due to the integer ambiguity has been removed from the data. It becomes obvious that the GPS carrier-phase double differences are centered at zero, whereas the Galileo satellites exhibit an offset of −0.5 cycles and the BeiDou satellites have an offset of approximately 0.25 cycles. These offsets are the result of different carrier-phase tracking alignments implemented in different receivers and the resulting biases

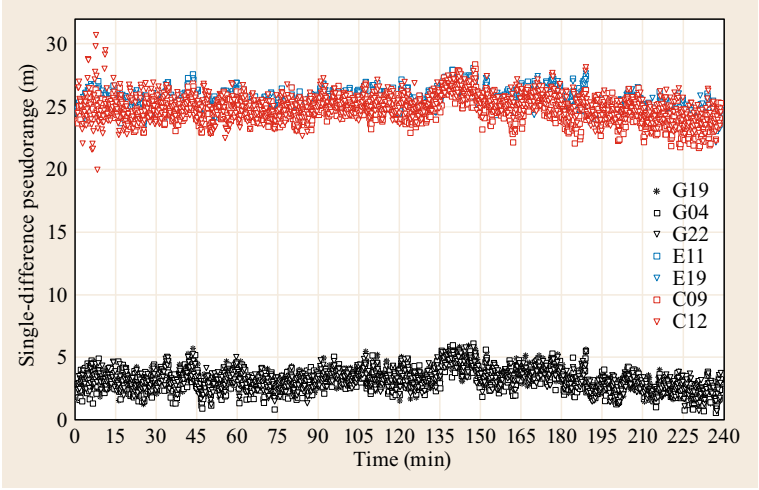

**Fig. 20.13** Single differences of pseudorange observations for GPS (*black*), Galileo (*blue*), and BeiDou (*red*) satellites on a zero-baseline over a time interval of 4 h

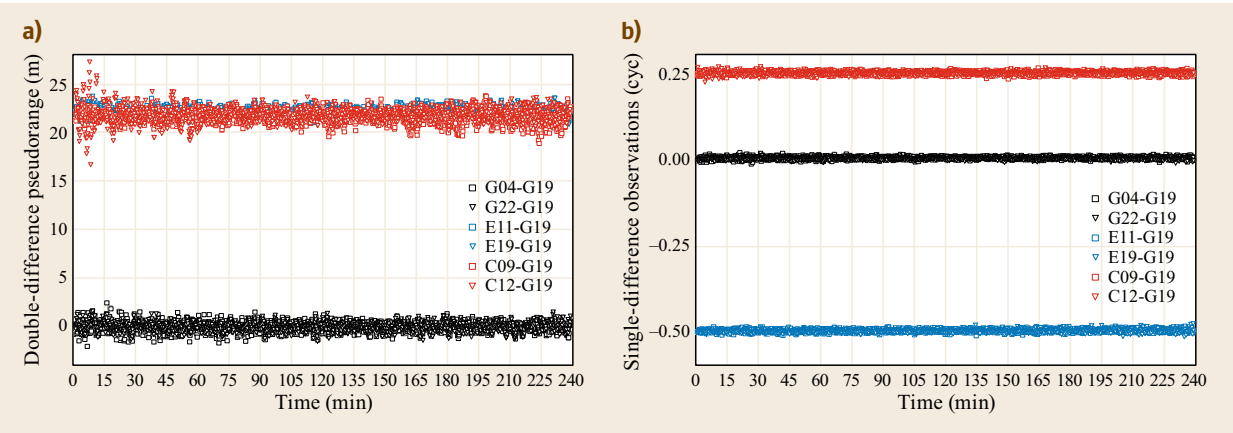

**Fig. 20.14a,b** Double differences of pseudorange **(a)** and carrier-phase **(b)** observations for GPS (*black*), Galileo (*blue*), and BeiDou (*red*) satellites on a zero-baseline over a time interval of 4 h. Note the different scales of the ordinates for pseudorange (m) and carrier-phase (cycles)

must be corrected for or estimated in order to enable inter-constellation ambiguity resolution [20.34, 35].

The examples for double differences of observations on a zero-baseline have demonstrated that all nuisance parameters except for differential biases, noise, and multipath can be eliminated from the observations. This makes zero-baseline configurations particularly useful for receiver or signal tests, for example, for the characterization of elevation-dependent noise or receiver and satellite biases.

## 20.4 Pseudorange Filtering

The combination of GNSS observations discussed in the preceding sections typically either eliminated certain nuisance parameters (e.g., ionospheric path delays), isolated certain errors or effects (e.g., multipath or ionospheric delays), and make them accessible to the analysis.

A special type of combination is given by the joint use of pseudorange and carrier-phase measurements to obtain pseudorange observations with a reduced noise level. As discussed in Chap. 22 in full detail, such carrier-phase-adjusted pseudoranges can be obtained from a series of pseudorange and phase observations using either a batch least squares estimator or a recursive filter.

A widespread implementation of this concept is the Hatch filter, which uses time differences of carrier-phase observations to obtain smoothed pseudoranges. Hatch filters are commonly used inside GNSS receivers to reduce the raw pseudorange noise.

Even though the single-channel phase-based pseudorange *smoothing* does not achieve the same quality as the rigorous estimation of phase-adjusted pseudoranges (Sect. 22.3.1 and [20.36]), for certain applications these limitations can be accepted and the Hatch filter is an attractive alternative due to its computational simplicity.

For the derivation of the Hatch filter, time differences of the pseudorange (20.2) and carrier-phase (20.4) observation are considered

$$\begin{aligned} \partial p^{\mathrm{s}}_{\mathrm{r},j} &= \partial P^{\mathrm{s}}_{\mathrm{r,IF}} + \partial I^{\mathrm{s}}_{\mathrm{r},j} + \partial e^{\mathrm{s}}_{\mathrm{r},j} \,, \\ \partial \varphi^{\mathrm{s}}_{\mathrm{r},j} &= \partial P^{\mathrm{s}}_{\mathrm{r,IF}} - \partial I^{\mathrm{s}}_{\mathrm{r},j} + \partial \epsilon^{\mathrm{s}}_{\mathrm{r},j} \,. \end{aligned} \tag{20.76}$$

Note that several terms have been omitted in the above equations. Based on the assumption that no cycle-slips occur, the constant carrier-phase ambiguity terms drop out in the time difference. Also pseudorange and carrier-phase biases are completely eliminated. The change in carrier-phase wind-up as well as group delay and phase-center variation is assumed to be negligibly small over the time interval.

If the change in the ionospheric delay is neglected, a predicted pseudorange at epoch $t_i$ can be computed based on the observed pseudorange at the previous epoch $t_i$ and the carrier-phase difference $\partial \varphi^{\mathrm{s}}_{\mathrm{r},j}$

$$p^{\mathrm{s}}_{\mathrm{r},j}(t_i) = p^{\mathrm{s}}_{\mathrm{r},j}(t_{i-1}) + \partial \varphi^{\mathrm{s}}_{\mathrm{r},j} \,. \tag{20.77}$$

The prediction based on the phase difference has low noise since $\partial \epsilon^{\mathrm{s}}_{\mathrm{r},j} \ll \partial e^{\mathrm{s}}_{\mathrm{r},j}$. This advantage can be exploited in a recursive filter, which produces a smoothed

pseudorange $\tilde{p}^{s}_{r,j}(t_i)$ based on the weighted average of the observed pseudorange $p^{s}_{r,j}(t_i)$ and the prediction from (20.77) using the smoothed value from the previous epoch

$$\tilde{p}^{s}_{r,j}(t_i) = w p^{s}_{r,j}(t_i) + (1-w)\left(\tilde{p}^{s}_{r,j}(t_{i-1}) + \partial\varphi^{s}_{r,j}\right) . \tag{20.78}$$

In the traditional formulation of the Hatch filter, the weight $w$ is set to a constant value of $w = \tau/\tau_s$, where $\tau$ is the data rate of the observations and $\tau_s$ is the filter smoothing time constant. The filter is initialized with $\tilde{p}^{s}_{r,j}(t_0) = p^{s}_{r,j}(t_0)$ [20.37]. Other formulations use a time-dependent weighting factor, for example, starting with $w = 1$ when the filter is initialized and reducing the weight by a factor of $\tau/\tau_s$ step-by-step with every new epoch until $w = 0$. After the time interval $\tau_s$, the weight factor remains zero and the smoothed pseudoranges are only based on the carrier-phase predictions [20.38]. In both cases, a cycle-slip destroys the continuity of the prediction and requires the filter to be initialized again.

The Hatch filter is an efficient yet simple measure to reduce the noise of pseudorange measurements and improve the position solution based on the smoothed observations. Its simplicity comes with a disadvantage, though: due to the opposite sign of the ionospheric term in (20.76), the smoothed pseudorange may diverge significantly from original pseudorange, when the ionosphere is active and non-negligibly varying during the smoothing interval. A similar reasoning also holds true for the nonstochastic multipath errors. Thus, when selecting the weight for the Hatch filter, care must be taken to choose a value which yields sufficiently smoothed observations, but prevents significant errors due to code-carrier divergence.

The adverse effects of the ionosphere can be eliminated when dual-frequency measurements are available. One option is to replace the single-frequency carrier-phase time difference in (20.78) with a ionosphere-corrected carrier-phase $\partial\tilde{\varphi}^{s}_{r}$ based on (20.37)

$$\begin{aligned}\partial\tilde{\varphi}^{s}_{r} &= \partial\varphi^{s}_{r,A} + 2\partial I^{s}_{r,A} \\ &= \partial\varphi^{s}_{r,A} + 2\frac{f_B^2}{f_A^2 - f_B^2}\left(\partial\varphi^{s}_{r,A} - \partial\varphi^{s}_{r,B}\right) ,\end{aligned} \tag{20.79}$$

where $f_A$ and $f_B$ are the corresponding frequencies to the differential carrier-phase observations $\partial\varphi^{s}_{r,A}$ and $\partial\varphi^{s}_{r,B}$. The ionosphere-corrected carrier-phase has identical ionospheric delay variation as the time difference of pseudorange and the instantaneous ionospheric delay is retained in the smoothed pseudorange. This approach is referred to in literature as divergence-free smoothing [20.39].

The second option is to use a ionosphere-free combination of pseudorange and carrier-phase observations according to (20.41) and (20.42) as input for the Hatch filter. This method is often called ionosphere-free smoothing. The result is then free of ionospheric effects, but affected by the increased noise of the ionosphere-free combination [20.39].

In order to visualize the effects of filter divergence, simulated pseudorange and carrier-phase measurements at a data rate of 1 Hz with realistically modeled ionospheric error and measurement noise have been processed with different smoothing intervals in a Hatch filter with constant weight factor. The results are depicted in Fig. 20.15. The errors of the raw pseudoranges without smoothing compared to the true pseudoranges are plotted as black diamonds. Note that only the receiver noise appears here, since both raw and true

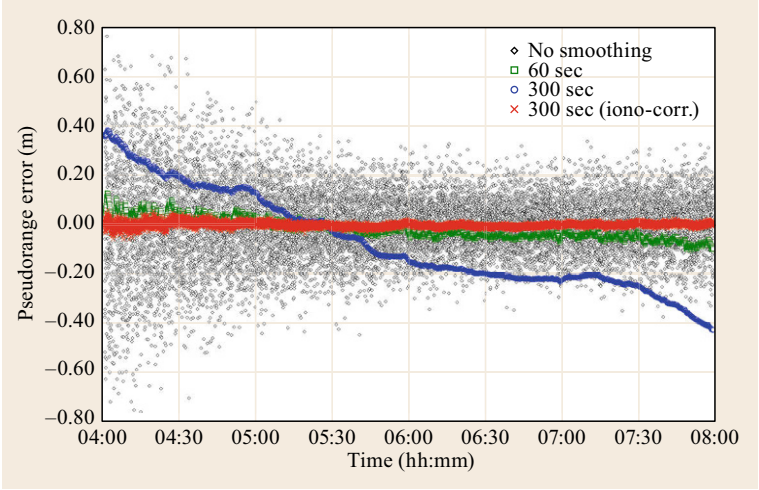

**Fig. 20.15** Results for smoothed pseudorange observations over time from different Hatch filters based on simulated measurements. The plot shows the errors of the original observations (*black diamonds*), the results of single-frequency Hatch filters with smoothing intervals of 60 s (*green squares*) and 300 s (*blue circles*), and a divergence-free Hatch filter with 300 s smoothing interval (*red crosses*)

pseudoranges contain the ionospheric delay. The single-frequency Hatch filter with 60 s smoothing interval significantly reduces the noise, but small systematic effects are already visibly. For a smoothing interval of 300 s, the filtered measurements are smoother, but large systematic pseudorange errors are visible. Making use of a second carrier-phase measurement in a divergence-free Hatch filter completely eliminated the systematic errors despite the same smoothing interval. However, note the slightly increased noise in the filtered pseudorange.

It should finally be mentioned that Hatch filtering cannot only be applied to observations of a single receiver, but also to single or double differences of observations. These techniques are relevant, for example, in case of differential GPS (DGPS) for aircraft landing. Even though most of the ionospheric delay is already canceled out through differential-processing, which may in general allow for longer smoothing intervals, the divergence of the Hatch filter can still become significant during anomalous ionospheric conditions like ionospheric storms [20.39, 40].

# 21. Positioning Model

Dennis Odijk

The focus of this chapter is on the models for positioning. Since the global navigation satellite system (GNSS) observation equations are nonlinear in the position coordinates, the chapter is started with a section on the linearization of the observation equations for pseudorange (code) and carrier-phase. After that, absolute (point) positioning models are discussed, starting with the code-based single point positioning (SPP) model, followed by the model for precise point positioning (PPP), based on code and phase. The relative positioning models can be distinguished into code-dominated (differential GNSS or DGNSS) models and phase-dominated (real-time kinematic or RTK) models. For the latter type of models, a general multifrequency undifferenced model is presented, which may form the basis of both relative network model and the (absolute) model that enables PPP users to perform integer ambiguity resolution (*PPP-RTK*). After that the link is made between the undifferenced model and the single and double differenced versions of the positioning model and an overview is given of the various positioning concepts.

## 21.1 Nonlinear Observation Equations

In this section, the nonlinear observations equations for code and phase are reviewed, first for a single global or regional navigation satellite system (GNSS or RNSS) and after that the observation equations in case the GNSS receiver tracks observations from more than one constellation (the multiconstellation case).

### 21.1.1 Single-GNSS Observation Equations

Recall from Chap. 19, the nonlinear observation equations for $j = 1, \ldots, f_S$ frequencies of a certain GNSS constellation S, at time of observation $t$ in the GNSS system time. Then the observation equation for the code or pseudorange from satellite $s$ tracked by receiver $r$ at epoch $t$ can be given as

$$\begin{aligned} p^s_{r,j}(t) = {} & \rho^s_r\left(t, t-\tau^s_r\right) + T^s_r(t) \\ & + c\left[dt_r(t) + d^{\mathrm{S}}_{r,j}(t) + \Delta d^s_{r,j}(t)\right] \\ & - c\left[dt^s\left(t-\tau^s_r\right) - d^s_j\left(t-\tau^s_r\right)\right] \\ & + \mu^{\mathrm{S}}_j I^s_r(t) + e^s_{r,j}(t)\,, \end{aligned} \tag{21.1}$$

while the carrier-phase observation equation reads

$$\begin{aligned} \varphi^s_{r,j}(t) = {} & \rho^s_r\left(t, t-\tau^s_r\right) + T^s_r(t) \\ & + c\left[dt_r(t) + \delta^{\mathrm{S}}_{r,j}(t) + \Delta\delta^s_{r,j}(t)\right] \\ & - c\left[dt^s\left(t-\tau^s_r\right) - \delta^s_j\left(t-\tau^s_r\right)\right] \\ & - \mu^{\mathrm{S}}_j I^s_r(t) + \lambda^{\mathrm{S}}_j N^s_{r,j} + \varepsilon^s_{r,j}(t)\,. \end{aligned} \tag{21.2}$$

The constellation identifier S is chosen in agreement with the RINEX convention (Annex A *Data Formats*) such that $\mathrm{S} \in \{\mathrm{G}, \mathrm{R}, \mathrm{E}, \mathrm{C}, \mathrm{J}, \mathrm{I}, \ldots\}$, for GPS, GLONASS, Galileo, BeiDou (BDS), QZSS, IRNSS, etc. The notation in (21.1) and (21.2) is as follows

$p^s_{r,j}$ Code/pseudorange observable (m)
$\varphi^s_{r,j}$ Carrier-phase observable (m)
$\rho^s_r$ Receiver–satellite range (m)
$\tau^s_r$ Signal travel time (s)
$T^s_r$ Tropospheric delay (m)
$c$ Velocity of light (m/s)
$dt_r$ Receiver clock error (s)
$dt^s$ Satellite clock error (s)
$d^{\mathrm{S}}_{r,j}$ Receiver code hardware bias (s)
$\delta^{\mathrm{S}}_{r,j}$ Receiver phase hardware bias (s)
$\Delta d^s_{r,j}$ Code interchannel bias (s)
$\Delta\delta^s_{r,j}$ Phase interchannel bias (s)
$d^s_j$ Satellite code hardware bias (s)
$\delta^s_j$ Satellite-phase hardware bias (s)
$\mu^{\mathrm{S}}_j$ Ionospheric coefficient
$I^s_r$ Ionospheric delay (m)
$\lambda^{\mathrm{S}}_j$ Wavelength (m)
$N^s_{r,j}$ Carrier-phase ambiguity (cyc)
$e^s_{r,j}$ Random code noise (m)
$\varepsilon^s_{r,j}$ Random carrier-phase noise (m).

The receiver hardware biases in (21.1) and (21.2), denoted as $d^{\mathrm{S}}_{r,j}(t)$ and $\delta^{\mathrm{S}}_{r,j}(t)$, are in principle different for each constellation (that is why they have a constellation index S), even when the signals are tracked on frequency bands that overlap between the constellations [21.1], as for example GPS L1 and Galileo E1. These hardware biases are caused by various reasons, including analog group delays in the frontend and digital delays. The correlation process in the receiver affects the resulting delays as well [21.2]. The difference in receiver hardware biases between signals of different constellations is referred to as *intersystem bias* (ISB) [21.3–5].

For constellations that transmit signals based on the *frequency division multiple access* (FDMA) technology (Chap. 4), the frequency is different per channel. In case of the GLONASS FDMA signals, the L1 frequency equals $f^{\mathrm{Rs}}_1 = 1602 + \kappa^s(9/16)$ MHz (Chap. 8), where $\kappa^s$ denotes the channel number that can take on the following integers: $\kappa^s \in \{-7, -6, \ldots, +5, +6\}$. The GLONASS L2 frequency equals $f^{\mathrm{Rs}}_2 = 1246 + \kappa^s(7/16)$ MHz. In case of FDMA signals, the code and phase observation equations are also contaminated by *interchannel biases* (ICBs), denoted by $\Delta d^s_{r,j}(t)$ and $\Delta\delta^s_{r,j}(t)$. For signals that are based on the *code division multiple access* (CDMA) technology, the frequency is identical for all channels and the satellite index can thus be omitted. Also no ICBs show up for CDMA signals: $\Delta d^s_{r,j}(t) = 0$ and $\Delta\delta^s_{r,j}(t) = 0$.

It is emphasized that both satellite code bias and phase bias in (21.1) and (21.2), denoted as $d^s_j(t-\tau^s_r)$ and $\delta^s_j(t-\tau^s_r)$, respectively, are, like the receiver hardware biases, considered as additive parameters, that is, they have a (net) plus sign in the observation equations (whereas the satellite clock has a minus sign). The reason for doing so is to be consistent with the convention adopted by the International GNSS Service (IGS) [21.6].

In the above observation equations, it has been implicitly assumed that (frequency-dependent) offsets between the center of mass of the satellite and the satellite antenna reference point, as well as (frequency-dependent) offsets between the receiver antenna reference point and the receiver's point to be determined by positioning, can be taken into account through dedicated terms on the right-hand side of the observation equations. However, within the following discussion,

the terms are not further considered for the ease of notation, and the receiver–satellite range $\rho_r^s(t, t-\tau_r^s)$ is taken common for both code and phase, as well as for all frequencies.

In the code and phase-observation equations, the dispersive (first-order) ionospheric delays are mapped to one frequency, that is, $I_{r,j}^s(t) = \mu_j^{\mathrm{S}} I_r^s(t)$. Usually $I_r^s(t)$ denotes the ionospheric delay for the first frequency, such that the frequency-dependent ionospheric coefficient is defined as follows

$$\mu_j^{\mathrm{S}} = \left(\frac{\lambda_j^{\mathrm{S}}}{\lambda_1^{\mathrm{S}}}\right)^2 = \left(\frac{f_1^{\mathrm{S}}}{f_j^{\mathrm{S}}}\right)^2 . \tag{21.3}$$

From this definition, it follows that for the first frequency ($j = 1$), the ionospheric coefficient equals $\mu_1^{\mathrm{S}} = 1$. In case of GLONASS FDMA signals, although the frequencies differ per channel, their (squared) L1–L2 ratio is *independent* of the channel, since in case of dual-frequency GLONASS

$$\mu_2^{\mathrm{R}} = \left(\frac{\lambda_2^{\mathrm{Rs}}}{\lambda_1^{\mathrm{Rs}}}\right)^2 = \left(\frac{f_1^{\mathrm{Rs}}}{f_2^{\mathrm{Rs}}}\right)^2 = \left(\frac{9}{7}\right)^2 . \tag{21.4}$$

Note that for dual-frequency GPS $\mu_2^{\mathrm{G}} = (77/60)^2$.

Effects that have not been accounted for in (21.1) and (21.2) are, among others, phase-center offsets and variations, phase wind-up (phase only), relativistic effects, a-priori tropospheric model, etc. (Chap. 19). For the present chapter they are dropped from the observation equations to ease the notation and to focus on the illustration of the basic positioning concepts.

### 21.1.2 Multi-GNSS Observation Equations

#### Constellation-Specific Time Frames

To derive the observation equations for multiple constellations, for simplicity it is assumed that a multi-GNSS receiver tracks data of two constellations, denoted as A and B. If the observations of system A are collected at receiver time $t_r$ (this is the time tag in the RINEX observation file), this (measured) receiver time deviates from the (unknown) system time of the first constellation $t^{\mathrm{A}}$ by means of a receiver clock error $dt_r$

$$t_r(t^{\mathrm{A}}) = t^{\mathrm{A}} + dt_r(t^{\mathrm{A}}) . \tag{21.5}$$

Note that for reasons of simplicity, we have ignored effects due to receiver hardware delays and other errors like receiver noise and multipath in above expression. Observations of system B that are collected at the same receiver time $t_r$ use different physical clocks to realize their own GNSS system time [21.7]. However, they can be expressed as function of the receiver clock error in the system time of A

$$t_r(t^{\mathrm{B}}) = t^{\mathrm{B}} + dt_r(t^{\mathrm{B}}) = t^{\mathrm{B}} + dt_r(t^{\mathrm{A}}) - t^{\mathrm{AB}} , \tag{21.6}$$

with $t^{\mathrm{AB}} = t^{\mathrm{B}} - t^{\mathrm{A}}$, the *system time offset* (thus: $t_r(t^{\mathrm{A}}) = t_r(t^{\mathrm{B}})$, see also Fig. 21.1). In case the first constellation is GPS and the second is Galileo, this offset is also known as GPS-to-Galileo time offset (GGTO) [21.8]. The time of transmission at a satellite of constellation A, which is denoted using superscript $s$, reads, ignoring satellite hardware delays

$$t^s\left(t^{\mathrm{A}} - \tau_r^s\right) = t^{\mathrm{A}} - \tau_r^s + dt^s\left(t^{\mathrm{A}} - \tau_r^s\right) . \tag{21.7}$$

For a satellite of constellation B, denoted by superscript $q$, it reads

$$t^q\left(t^{\mathrm{B}} - \tau_r^q\right) = t^{\mathrm{B}} - \tau_r^q + dt^q\left(t^{\mathrm{B}} - \tau_r^q\right) . \tag{21.8}$$

Converted to pseudoranges this yields for the two constellations, now including atmospheric delays, hardware delay parameters and noise terms

$$\begin{aligned}
p_{r,j}^s(t^{\mathrm{A}}) &= c\left[t_r(t^{\mathrm{A}}) - t^s\left(t^{\mathrm{A}} - \tau_r^s\right)\right] \\
&= \rho_r^s(t^{\mathrm{A}}, t^{\mathrm{A}} - \tau_r^s) + T_r^s(t^{\mathrm{A}}) \\
&\quad + c\left[dt_r(t^{\mathrm{A}}) + d_{r,j}^{\mathrm{A}}(t^{\mathrm{A}}) + \Delta d_{r,j}^s(t^{\mathrm{A}})\right] \\
&\quad - c\left[dt^s(t^{\mathrm{A}} - \tau_r^s) - d_j^s(t^{\mathrm{A}} - \tau_r^s)\right] \\
&\quad + \mu_j^{\mathrm{A}} I_r^s(t^{\mathrm{A}}) + e_{r,j}^s(t^{\mathrm{A}}) , \\
p_{r,j}^q(t^{\mathrm{B}}) &= c\left[t_r(t^{\mathrm{B}}) - t^q\left(t^{\mathrm{B}} - \tau_r^q\right)\right] \\
&= \rho_r^q\left(t^{\mathrm{B}}, t^{\mathrm{B}} - \tau_r^q\right) + T_r^q(t^{\mathrm{B}}) \\
&\quad + c\left[dt_r(t^{\mathrm{A}}) - t^{\mathrm{AB}} + d_{r,j}^{\mathrm{B}}(t^{\mathrm{B}}) + \Delta d_{r,j}^q(t^{\mathrm{B}})\right] \\
&\quad - c\left[dt^q\left(t^{\mathrm{B}} - \tau_r^q\right) - d_j^q\left(t^{\mathrm{B}} - \tau_r^q\right)\right] \\
&\quad + \mu_j^{\mathrm{B}} I_r^q(t^{\mathrm{B}}) + e_{r,j}^q(t^{\mathrm{B}}) .
\end{aligned} \tag{21.9}$$

Note that instead of the receiver clock in the time system of B, we have used the receiver clock in the

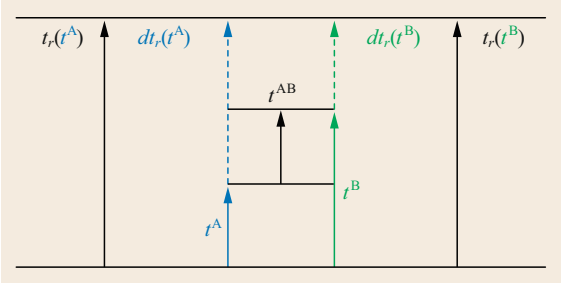

**Fig. 21.1** Relation between time frames, receiver time, receiver clock error, and time offset of constellations A and B

time system of A, together with the system time offset, making use of (21.6), from which follows that $dt_r(t^B) = dt_r(t^A) - t^{AB}$. We can do something similar for the receiver hardware bias of the observations of constellations B, making use of the following definition of the ISB

$$\mathrm{ISB}^{AB}_{r,j}(t^A, t^B) = \left[d^B_{r,j}(t^B) - d^A_{r,j}(t^A)\right] + \left[\Delta d^q_{r,j}(t^B) - \Delta d^s_{r,j}(t^A)\right]. \quad (21.10)$$

It is remarked that the interchannel terms only appear in case one of the constellations is based on FDMA. In that case, the ISB becomes satellite dependent; otherwise it is receiver dependent. Based on the ISB reparameterization, the code-observation equation for constellation B can be rewritten as

$$\begin{aligned} p^q_{r,j}(t^B) = {} & \rho^q_r\left(t^B, t^B - \tau^q_r\right) + T^q_r(t^B) \\ & + c\left[dt_r(t^A) + d^A_{r,j}(t^A) + \Delta d^s_{r,j}(t^A)\right] \\ & + c\left[\mathrm{ISB}^{AB}_{r,j}(t^A, t^B) - t^{AB}\right] \\ & - c\left[dt^q\left(t^B - \tau^q_r\right) - d^q_j\left(t^B - \tau^q_r\right)\right] \\ & + \mu^B_j I^q_r(t^B) + e^q_{r,j}(t^B)\,. \end{aligned} \quad (21.11)$$

Compared to the code-observation equation of constellation A (see first equation in (21.9)), its counterpart for constellation B is now given as a function of the receiver clock, receiver hardware bias, as well as ICB (in case of GLONASS FDMA) of signals of constellation A. Also the ionospheric delays for the signals of constellation B can be expressed as ionospheric delays on the first frequency of constellation A by setting the ionospheric coefficient for B equal to $\mu^B_j = (\lambda^B_j/\lambda^A_1)^2$. For the phase-observation equation of constellation B a similar derivation can be made. Advantage of the formulation that involves an ISB parameter over the original formulation is that under certain conditions it is possible to *calibrate* the ISBs. When the ISB and also the system time offset are known, the observations of the two constellations can be processed *as if* they correspond to one system.

The code observation equation (21.11) is written as a function of the time stamps in two different systems, that is, $t^A$ and $t^B$. For most GNSS systems, the differences between the time systems are sufficiently small, such that they may be neglected for the evaluation of observables and parameters in (21.11). This also holds for the purpose of the evaluation of the times of transmission at the satellites (Sect. 21.4.1). For these purposes from now on, we will simply use a common $t$ for the time stamps of different systems. However, the system time offset that itself is present as parameter in (21.11), that is, $t^{AB}$, may *not* be ignored in the observation equations of the second constellation, since it is multiplied by the velocity of light. For example, the offset between GPS time (GPST) and Galileo system time (GST) can be several tens of nanoseconds or tens of meters (Chap. 9 or [21.9]). The offset between QZSS time (QZSST) and GPST is less than two meters [21.10]. The offset between IRNSS time (IRNSST) and GPST can be up to 3 m [21.11]. The difference between GPST and GLONASS system time can be several hundreds of nanoseconds (equivalent to hundreds of meters). The intersystem time offsets are broadcast as part of the navigation messages [21.12, 13] such that a user can correct his observations. The offset between GPST and GLONASS system time are broadcast as part of the navigation message of the GLONASS-M satellites [21.14]. Alternatively, the user can treat the offset as unknown parameter in his processing.

### Constellation-Specific Reference Frames

Besides that each GNSS constellation realizes its own system time, its broadcast satellite positions are defined in its own coordinate system, see Table 21.1 for an overview. In order to solve multiconstellation positioning models, all satellite positions need to be defined in one common reference frame. Otherwise, transformation parameters need to be estimated together with the other model parameters. Although the realization of the reference frames depends on the full deployment of the ground-station network of new constellations, the differences are expected to be small, as they are all realizations of the International Terrestrial Reference System (ITRS). WGS84 coincides with the ITRF at the level of a few centimeters (Chap. 2). The difference between GTRF and WGS84 is aimed at the level of 3 cm [21.15], while the offset between JGS and WGS84 is expected to be less than 2 cm [21.10]. IRNSS uses WGS84 as its coordinate system [21.16]. The difference between CGCS2000 and WGS84 is at the level of a few centimeters. Also, the latest release PZ-90.11 of the GLONASS reference frame is consistent with ITRF at epoch 2011.0 at the centimeter level [21.17].

**Table 21.1** Reference frames for GNSS–RNSS constellations

| GNSS | Reference frame |
|---|---|
| GPS | World Geodetic System 1984 (WGS84) |
| GLONASS | Parametry Zemli 1990 (PZ-90) |
| Galileo | Galileo Terrestrial Reference Frame (GTRF) |
| BeiDou | China Geodetic Coordinate System 2000 (CGCS2000) |
| QZSS | Japanese Geodetic System (JGS) |
| IRNSS | World Geodetic System 1984 (WGS84) |

For (multiconstellation) SPP (Sect. 21.3.5), of which the positioning accuracy is at the 10 m level, it is not needed to take the differences between the constellation-specific reference frames into account. Also for relative (short-baseline) positioning these differences do not have to be taken into account, as they are, similar to orbit errors, canceled out if the baseline is of restricted length (Sect. 21.4.2). For PPP(-RTK) and long-baseline applications (Sect. 21.3.7 and Sect. 21.4) one can, however, not ignore these differences and they need to be accounted for. It should be noted that in case of *precise* IGS orbits, the satellite positions of the different constellations are all defined with respect to one reference frame (i. e., ITRF; Chap. 33).

## 21.2 Linearization of the Observation Equations

Since the GNSS observation equations are nonlinear in the parameters of interest, that is, the receiver position coordinates, they need to be *linearized*. In this section, the focus is on the linearization of the receiver–satellite range.

### 21.2.1 Linearizing the Receiver–Satellite Range

The GNSS observation equations are nonlinear in both the receiver and satellite position. Using $t = t_r(t) - dt_r(t)$ (see (21.5)), the receiver–satellite range can be written as the following function

$$\begin{aligned}\rho_r^s(t, t-\tau_r^s) &= \|\boldsymbol{r}^s(t-\tau_r^s) - \boldsymbol{r}_r(t)\| \\ &= \left\|\boldsymbol{r}^s\left[t_r(t) - dt_r(t) - \tau_r^s\right]\right. \\ &\quad \left. - \boldsymbol{r}_r[t_r(t) - dt_r(t)]\right\| . \end{aligned} \tag{21.12}$$

The norm of a vector is defined as $\|\cdot\| = \sqrt{(\cdot)^\top(\cdot)}$, where $(\cdot)^\top$ denotes a transposed vector (or matrix). The satellite position vector reads $\boldsymbol{r}^s = [x^s, y^s, z^s]^\top$ and the receiver position vector $\boldsymbol{r}_r = [x_r, y_r, z_r]^\top$.

With the true GNSS time $t$ unknown, according to *Taylor's theorem* (Chap. 22) the receiver–satellite range can be linearized with respect to the unknown receiver position $\boldsymbol{r}_r(t)$, satellite position $\boldsymbol{r}^s(t-\tau_r^s)$, and receiver clock error $dt_r(t)$, as follows

$$\rho_r^s\left(t, t-\tau_r^s\right) \doteq \rho_r^s\left(t, t-\tau_r^s\right)|_0 + \triangle\rho_r^s\left(t, t-\tau_r^s\right) . \tag{21.13}$$

The incremental receiver–satellite range is computed as

$$\begin{aligned}\triangle\rho_r^s\left(t, t-\tau_r^s\right) &= \left[\partial_{\boldsymbol{r}_r(t)}\rho_r^s\left(t, t-\tau_r^s\right)|_0\right]^\top \triangle\boldsymbol{r}_r(t) \\ &\quad + \left[\partial_{\boldsymbol{r}^s(t-\tau_r^s)}\rho_r^s\left(t, t-\tau_r^s\right)|_0\right]^\top \triangle\boldsymbol{r}^s\left(t-\tau_r^s\right) \\ &\quad + \partial_{dt_r(t)}\rho_r^s\left(t, t-\tau_r^s\right)|_0 \triangle dt_r(t) . \end{aligned} \tag{21.14}$$

Here the incremental parameters are denoted as $\triangle(\cdot) = (\cdot) - (\cdot)|_0$, where $(\cdot)$ denotes the original parameter and $(\cdot)|_0$ its *approximate value*. For all positioning models discussed in this chapter it is assumed that the *satellite positions* are *known*, and need not be estimated in the positioning model. This implies that $\triangle\boldsymbol{r}^s(t-\tau_r^s) = 0$. Knowing the satellite positions means that they are computed either from the broadcast ephemeris transmitted in the navigation message, or from the more precise ephemeris made available by the IGS (Chap. 33).

The derivative of the range with respect to the receiver position can be given as

$$\partial_{\boldsymbol{r}_r(t)}\rho_r^s\left(t, t-\tau_r^s\right)|_0 = -\underbrace{\frac{\left[\boldsymbol{r}^s\left(t-\tau_{r,0}^s\right) - \boldsymbol{r}_{r,0}(t)\right]}{\left\|\boldsymbol{r}^s\left(t-\tau_{r,0}^s\right) - \boldsymbol{r}_{r,0}(t)\right\|}}_{\boldsymbol{e}_{r,0}^s(t)} , \tag{21.15}$$

with $\boldsymbol{e}_{\mathrm{r},0}^s(t)$ denoting the *line-of-sight* (LOS) vector of unit length. The derivative of the range with respect to the receiver clock error can be computed as

$$\partial_{dt_r(t)}\rho_r^s\left(t, t-\tau_r^s\right)|_0 = \underbrace{\left.\frac{\partial\rho_r^s\left(t, t-\tau_r^s\right)}{\partial t}\right|_0}_{\dot\rho_{r,0}^s(t)} \underbrace{\left.\frac{\partial t}{\partial dt_r(t)}\right|_0}_{-1} . \tag{21.16}$$

The time derivative of the receiver–satellite range that shows up here, denoted as $\dot\rho_{\mathrm{r},0}^s(t)$, is also referred to as *range rate*. The time derivative of the time itself with respect to the receiver clock error follows from $t = t_r(t) - dt_r(t)$. Summarizing, the linearized receiver–satellite range can be compactly presented as

$$\begin{aligned}\triangle\rho_r^s\left(t, t-\tau_r^s\right) &= -\left[\boldsymbol{e}_{r,0}^s(t)\right]^\top \triangle\boldsymbol{r}_r(t) \\ &\quad - \dot\rho_{r,0}^s(t)\triangle dt_r(t) . \end{aligned} \tag{21.17}$$

The computation of the LOS vector $\boldsymbol{e}_{r,0}^s(t)$, as well as the receiver–satellite range $\rho_r^s(t, t-\tau_r^s)|_0$, requires the availability of the satellite position vector $\boldsymbol{r}^s(t-\tau_{r,0}^s)$.

Also the range rate $\dot{\rho}^s_{r,0}(t)$ needs to be computed. How this can be done is explained in the following subsections.

### Computation of the Receiver–Satellite Ranges, Satellite Positions, and Line-of-Sight Vectors

In the computation of the partial derivative in (21.15), we need to evaluate the receiver–satellite range based on the known satellite position, as well as the approximate receiver position. The problem is that we do not know the propagation time $\tau^s_r = \rho^s_r(t, t-\tau^s_r)/c$, since it is itself a function of the unknown receiver–satellite range. In addition, the satellite position must be calculated at *transmission time*, since the satellite range can change as much as 60 m from the time the signal was transmitted, to the time the signal was received, approximately 0.07 s later. If the receiver time was used instead, the error in computed range could be tens of meters.

We follow the procedure for determining the travel time and computation of the receiver–satellite range as described in [21.18]. In (21.12), the receiver and satellite position are assumed to be defined in an Earth-centered inertial (ECI) coordinate system. However, we want to use these positions given in an Earth-centered-Earth-fixed (ECEF) coordinate system, such as WGS-84 in case of GPS. Rewriting the receiver–satellite range expression in ECEF coordinates yields [21.19]

$$\rho^s_r\left(t, t-\tau^s_r\right) = \left\| \mathbf{R}\left(t-\tau^s_r\right) \boldsymbol{r}^s_{\mathrm{ECEF}}\left(t-\tau^s_r\right) - \mathbf{R}(t)\boldsymbol{r}_{r,\mathrm{ECEF}}(t) \right\| . \tag{21.18}$$

The matrix $\mathbf{R}(T)$ describes the rotation from the ECEF to the ECI coordinate system, which reads (Chap. 2)

$$\mathbf{R}(T) = \begin{bmatrix} +\cos(\omega_\oplus T) & +\sin(\omega_\oplus T) & 0 \\ -\sin(\omega_\oplus T) & +\cos(\omega_\oplus T) & 0 \\ 0 & 0 & 1 \end{bmatrix} . \tag{21.19}$$

Here $T$ denotes the appropriate time argument and $\omega_\oplus$ the Earth's rotation rate (in rad/s) [21.18]. The inclusion of this rotation can be understood, since the Earth has rotated between the time of transmission and the time of reception of the signal. Using the property of rotations that $\mathbf{R}(t-\tau^s_r) = \mathbf{R}(t)\mathbf{R}(-\tau^s_r)$, the rotation at the time $t$ can be taken outside the norm in (21.18), such that the receiver–satellite range expression becomes

$$\rho^s_r\left(t, t-\tau^s_r\right) = \left\| \mathbf{R}\left(-\tau^s_r\right) \boldsymbol{r}^s_{\mathrm{ECEF}}\left(t-\tau^s_r\right) - \boldsymbol{r}_{\mathrm{r,ECEF}}(t) \right\| . \tag{21.20}$$

The signal travel time $\tau^s_r$ as well as the satellite position at the time of transmission $\boldsymbol{r}^s_{\mathrm{ECEF}}(t-\tau^s_r)$ can now be determined using an *iterative procedure*. One starts with evaluating (21.20) with $\tau^s_r = 0$ and computes a new value of the travel time as $\tau^s_r = \rho^s_r(t,t)/c$. This value is used to compute a refined estimate of the receiver–satellite range. Usually three iterations are sufficient to get differences between the receiver–satellite ranges of the last two iterations within the order of $10^{-8}$ m [21.18]. Based on the iterated signal travel time and satellite position, the LOS vector is finally computed as

$$\boldsymbol{e}^s_{r,\mathrm{ECEF}}(t) = \frac{\mathbf{R}\left(-\tau^s_r\right)\boldsymbol{r}^s_{\mathrm{ECEF}}\left(t-\tau^s_r\right) - \boldsymbol{r}_{\mathrm{r,ECEF}}(t)}{\left\|\mathbf{R}\left(-\tau^s_r\right)\boldsymbol{r}^s_{\mathrm{ECEF}}\left(t-\tau^s_r\right) - \boldsymbol{r}_{\mathrm{r,ECEF}}(t)\right\|} . \tag{21.21}$$

Note that $\boldsymbol{e}^s_{r,\mathrm{ECEF}}(t) = \mathbf{R}(-t)\boldsymbol{e}^s_r(t)$. The above procedure requires approximate values for the receiver's position $\boldsymbol{r}_{r,\mathrm{ECEF}}(t)$. These are available, provided that the above iterative procedure is integrated inside the Gauss–Newton iteration scheme (Chap. 22) to solve the nonlinear single point positioning (SPP) model (Sect. 21.3).

### Computation of the Receiver–Satellite Range Rate

The derivative of the receiver–satellite range with respect to time can be computed from the projection of the relative satellite–receiver velocity onto the LOS vector [21.18]

$$\dot{\rho}^s_r(t) = \left[\frac{\partial\left(\boldsymbol{r}^s\left(t-\tau^s_r\right) - \boldsymbol{r}_r(t)\right)}{\partial t}\right]^\top \boldsymbol{e}^s_r(t) , \tag{21.22}$$

with $\boldsymbol{r}^s$ and $\boldsymbol{r}_r$ defined in the ECI frame. The time derivative of the satellite position can be computed as follows [21.20]

$$\begin{aligned} \frac{\partial \boldsymbol{r}^s\left(t-\tau^s_r\right)}{\partial t} &= \frac{\partial \boldsymbol{r}^s\left(t-\tau^s_r\right)}{\partial\left(t-\tau^s_r\right)} \frac{\partial\left(t-\tau^s_r\right)}{\partial t} \\ &= \dot{\boldsymbol{r}}^s\left(t-\tau^s_r\right) \frac{\partial\left(t-\frac{\rho^s_r(t,t-\tau^s_r)}{c}\right)}{\partial t} \\ &= \dot{\boldsymbol{r}}^s\left(t-\tau^s_r\right)\left[1-\frac{\dot{\rho}^s_r(t)}{c}\right], \end{aligned} \tag{21.23}$$

where $\dot{\boldsymbol{r}}^s(t-\tau^s_r)$ denotes the satellite's velocity vector in the ECI frame. The receiver's velocity also appears in (21.22) and is denoted equivalently as $\frac{\partial \boldsymbol{r}_r(t)}{\partial t} = \dot{\boldsymbol{r}}_r(t)$, also in the ECI frame. Using this, we obtain the following expression for the range rate

$$\dot{\rho}^s_r(t) = \frac{\left[\dot{\boldsymbol{r}}^s\left(t-\tau^s_r\right) - \dot{\boldsymbol{r}}_r(t)\right]^\top \boldsymbol{e}^s_r(t)}{1+\frac{1}{c}\left[\dot{\boldsymbol{r}}^s\left(t-\tau^s_r\right)\right]^\top \boldsymbol{e}^s_r(t)} . \tag{21.24}$$

gThis expression has also been derived in [21.21]. To evaluate it, the relative velocity of the GNSS satellite with respect to the receiver is required, as well as the relative geometry (line-of-sight). If we want to use velocity vectors in the ECEF frame, then the following relations hold between the vectors in the ECI and ECEF frames

$$\begin{aligned}\dot{\boldsymbol{r}}^s\left(t-\tau_r^s\right) &= \mathbf{R}\left(t-\tau_r^s\right)\dot{\boldsymbol{r}}^s_{\mathrm{ECEF}}\left(t-\tau_r^s\right) \\ &\quad + \dot{\mathbf{R}}\left(t-\tau_r^s\right)\boldsymbol{r}^s_{\mathrm{ECEF}}\left(t-\tau_r^s\right) \\ \dot{\boldsymbol{r}}_r(t) &= \mathbf{R}(t)\dot{\boldsymbol{r}}_{r,\mathrm{ECEF}}(t) + \dot{\mathbf{R}}(t)\boldsymbol{r}_{r,\mathrm{ECEF}}(t)\ .\end{aligned} \tag{21.25}$$

The time derivative of the rotation matrix $\mathbf{R}(T)$ in (21.19) can be given as

$$\dot{\mathbf{R}}(T) = \omega_\oplus \begin{bmatrix} -\sin(\omega_\oplus T) & +\cos(\omega_\oplus T) & 0 \\ -\cos(\omega_\oplus T) & -\sin(\omega_\oplus T) & 0 \\ 0 & 0 & 0 \end{bmatrix}. \tag{21.26}$$

Note that the following property holds for the ECEF to ECI rotation matrix and its derivative

$$\dot{\mathbf{R}}(T)^\top \mathbf{R}(T) = \begin{bmatrix} 0 & -\omega_\oplus & 0 \\ \omega_\oplus & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}. \tag{21.27}$$

Using this result and with $\boldsymbol{e}^s_r(t) = \mathbf{R}(t)\boldsymbol{e}^s_{\mathrm{r,ECEF}}(t)$, the range rate can be computed as follows from the vectors defined in ECEF

$$\dot{\rho}^s_r(t) = \frac{\left[\boldsymbol{v}^s\left(t-\tau_r^s\right) - \boldsymbol{v}_r(t)\right]^\top \boldsymbol{e}^s_{\mathrm{r,ECEF}}(t)}{1+\frac{1}{c}\left[\boldsymbol{v}^s\left(t-\tau_r^s\right)\right]^\top \boldsymbol{e}^s_{\mathrm{r,ECEF}}(t)}\ , \tag{21.28}$$

with

$$\begin{aligned}\boldsymbol{v}^s\left(t-\tau_r^s\right) &= \mathbf{R}\left(-\tau_r^s\right)\dot{\boldsymbol{r}}^s_{\mathrm{ECEF}}\left(t-\tau_r^s\right) \\ &\quad + \boldsymbol{\omega}\times\dot{\mathbf{R}}\left(-\tau_r^s\right)\boldsymbol{r}^s_{\mathrm{ECEF}}\left(t-\tau_r^s\right)\ , \\ \boldsymbol{v}_r(t) &= \dot{\boldsymbol{r}}_{\mathrm{r,ECEF}}(t) + \boldsymbol{\omega}\times\boldsymbol{r}_{r,\mathrm{ECEF}}(t)\ .\end{aligned} \tag{21.29}$$

Here use is made of the *vector cross product* $\times$ and $\boldsymbol{\omega} = (0,0,\omega_\oplus)^\top$. In case of a static receiver on Earth, its velocity in the ECEF frame ($\dot{\boldsymbol{r}}_{\mathrm{r,ECEF}}(t)$) equals zero, while for receivers in motion it can be assessed from positioning solutions at two epochs.

### Local Coordinate System

Usually, the positioning model is solved for the position in an ECEF system, that is, $\boldsymbol{r}_{r,\mathrm{ECEF}}(t)$. From now on, we will omit ECEF in the notation of the position and LOS vectors in this chapter, implicitly assuming they are with respect to the ECEF system. In addition, for the sake of interpretation of the position it is often convenient to work with another coordinate frame, that is, a *local* system which is centered at an assumed or approximate position, denoted as $\boldsymbol{r}_{\mathrm{r},0}$, of the point we would like to determine.

The $x$-axis of this local system is directed east, the $y$-axis directed north, and the $z$-axis is pointing upward and perpendicular to the local ellipsoidal surface (Fig. 21.2). Hence, this coordinate system is referred to as an *east–north-up* system. The coordinates of a point $r$ in this system are denoted as $\boldsymbol{r}_{\mathrm{r,l}} = [E_r, N_r, U_r]^\top$ (omitting the time stamp $t$). Such an east–north-up system is very practical for observers on or close to the Earth's surface, mainly for computation of dilution of precision (DOP) measures (Sect. 21.3.6), as well as for altitude-constrained (2-D) positioning. The ECEF coordinates

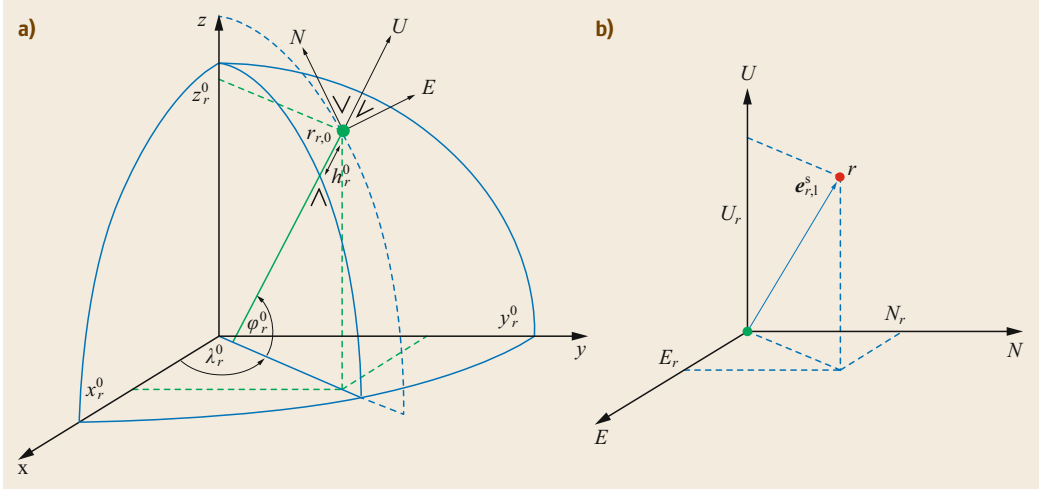

**Fig. 21.2a,b** East-north-up (ENU) local coordinate frame: **(a)** situated in the ECEF ($xyz$) frame with origin at $r,0$ and **(b)** local ENU coordinates of point $r$

of point $r$, denoted as $\boldsymbol{r}_r$, can now be transformed to their east–north-up counterparts as follows

$$\boldsymbol{r}_{r,\mathrm{l}} = \mathbf{R}_x\left(\frac{\pi}{2} - \varphi_r^0\right)\mathbf{R}_z\left(\frac{\pi}{2} + \lambda_r^0\right)\left[\boldsymbol{r}_r - \boldsymbol{r}_{r,0}\right] . \quad (21.30)$$

The product of the rotation matrices is elaborated as

$$\mathbf{R}_x\left(\frac{\pi}{2} - \varphi_r^0\right)\mathbf{R}_z\left(\frac{\pi}{2} + \lambda_r^0\right) = \begin{bmatrix} -\sin\lambda_r^0 & \cos\lambda_r^0 & 0 \\ -\sin\varphi_r^0\cos\lambda_r^0 & -\sin\varphi_r^0\sin\lambda_r^0 & +\cos\varphi_r^0 \\ +\cos\varphi_r^0\cos\lambda_r^0 & +\cos\varphi_r^0\sin\lambda_r^0 & +\sin\varphi_r^0 \end{bmatrix} . \quad (21.31)$$

Here $\boldsymbol{r}_{r,0} = \left[x_r^0, y_r^0, z_r^0\right]^\top$ denotes the approximated ECEF position of point $r$ and $[\varphi_r^0, \lambda_r^0, h_r^0]$ its corresponding ellipsoidal coordinates. When working with ENU coordinates, the LOS vectors should be changed accordingly

$$\boldsymbol{e}_{r,\mathrm{l}}^s = \mathbf{R}_x\left(\frac{\pi}{2} - \varphi_r^0\right)\mathbf{R}_z\left(\frac{\pi}{2} + \lambda_r^0\right)\boldsymbol{e}_r^s , \quad (21.32)$$

with $\boldsymbol{e}_{r,\mathrm{l}}^s$ the LOS vector defined in the local ENU frame.

### 21.2.2 Linearized Observation Equations

Based on the expression for the linearized receiver–satellite range in (21.17) the *observed-minus-computed* counterparts of the observation equations (21.1) and (21.2) can be given as follows, first for code

$$\begin{aligned} \triangle p_{r,j}^s(t) = &-\left[\boldsymbol{e}_r^s(t)\right]^\top \triangle\boldsymbol{r}_r(t) + \triangle T_r^s(t) \\ &+ \left[c - \dot\rho_r^s(t)\right]\triangle dt_r(t) \\ &+ c\left[\triangle d_{r,j}^{\mathrm{S}}(t) + \triangle\triangle d_{r,j}^s(t)\right] \\ &- c\left[\triangle dt^s\left(t - \tau_r^s\right) - \triangle d_j^s\left(t - \tau_r^s\right)\right] \\ &+ \mu_j^{\mathrm{S}}\triangle I_r^s(t) + e_{r,j}^s(t) . \end{aligned} \quad (21.33)$$

For the carrier-phase it can be given as

$$\begin{aligned} \triangle\varphi_{r,j}^s(t) = &-\left[\boldsymbol{e}_r^s(t)\right]^\top \triangle\boldsymbol{r}_r(t) + \triangle T_r^s(t) \\ &+ \left[c - \dot\rho_r^s(t)\right]\triangle dt_r(t) \\ &+ c\left[\triangle\delta_{r,j}^{\mathrm{S}}(t) + \triangle\triangle\delta_{r,j}^s(t)\right] \\ &- c\left[\triangle dt^s\left(t - \tau_r^s\right) - \triangle\delta_j^s\left(t - \tau_r^s\right)\right] \\ &- \mu_j^{\mathrm{S}}\triangle I_r^s(t) + \lambda_j^{\mathrm{S}}\triangle N_{r,j}^s + \varepsilon_{r,j}^s(t) . \end{aligned} \quad (21.34)$$

The approximate values for the parameters that are needed in the linearization of the GNSS observation equations can usually be set to zero, if the linearized model is solved using *Gauss–Newton iteration* (Chap. 22). In case of zero approximate values for the unknown parameters, we can omit the $\triangle$ symbol in their notation. In order to limit the amount of iterations, in case of high-precision applications nonzero approximate values are used for the receiver position (these are usually available from SPP preprocessing, Sect. 21.3.4).

In both linearized code and phase-observation equations, the coefficient for the receiver clock error is $c - \dot\rho_r^s(t)$, that is, the speed of light minus the range rate, where the range rate is due to the linearization of the receiver–satellite range. As shown in the previous subsection, this range rate depends on the speed of the receiver. We can compute it based on approximate values of the receiver's position and velocity, which can be obtained from a SPP solution at a previous epoch. Maximum range rate values for a static receiver on Earth is about 700 m/s, but for a spaceborne receiver in low-Earth orbit this is much higher, about 8000 m/s (Chap. 32). On the other hand, these values of the range rate are still very small compared to the speed of light $c$. And if the linearized model is solved in an iterative manner, in practice the results will be the same after several iterations are made compared to the results based on the observation equations neglecting the range rate [21.18]. In the positioning models treated in this chapter, we will therefore not include the range rate in the coefficients for the receiver clock error in the design matrix.

## 21.3 Point Positioning Models

The simplest positioning strategy is the one in which (single-frequency) pseudorange (code) observations measured by one receiver are processed to solve its position, given the positions of the GNSS satellites and their clock errors as computed from either the broadcast navigation message or precise (IGS) products. Sometimes ionospheric corrections can also be computed using information in the navigation message, or by an externally provided model. This strategy is referred to as single point positioning (SPP), and its solution is often referred to as *navigation solution*. SPP can also be carried out based on dual- or multifrequency code ob-

servations, thereby eliminating the ionospheric delays. Point positioning based on (single- or multifrequency) code *and phase* data, as well as precise products for orbits and clocks, is known as *precise point positioning* (PPP). Figure 21.3 visualizes the concept of point positioning.

### 21.3.1 Computation of the Satellite Clocks and Hardware Code (Group) Delays

In case of point positioning the satellite clock offsets need to be known. In case broadcast ephemeris (SPP) are used they can be computed using a polynomial model of which the coefficients are transmitted in the navigation message (see also the Interface Control Documents or ICDs). For GPS, Galileo, BeiDou, QZSS, and IRNSS the broadcast satellite clock can be calculated as the following second-order polynomial [21.22]

$$dt^s_{\mathrm{S}}(t) = a^s_0\left(t^s_{\mathrm{oc}}\right) + a^s_1\left(t - t^s_{\mathrm{oc}}\right) + a^s_2\left(t - t^s_{\mathrm{oc}}\right)^2 + \Delta t^s_{\mathrm{rel}}(t)\,, \tag{21.35}$$

with $\mathrm{S} \in \{\mathrm{G}, \mathrm{E}, \mathrm{C}, \mathrm{J}, \mathrm{I}\}$. The coefficients of the polynomial are denoted as $a^s_0$, $a^s_1$, and $a^s_2$, representing the offset, drift, and aging of the clock, and $t^s_{\mathrm{oc}}$ denotes the reference time of the clock data, which is also broadcast in the navigation message. The last part of the satellite clock corrections, denoted as $\Delta t^s_{\mathrm{rel}}(t)$, is a *relativistic* correction, because the satellite clock is moving with respect to the receiver. This correction, which depends on the eccentric anomaly, has been discussed in Chap. 19. In the point-positioning algorithm the above clock offset polynomial needs to be evaluated at the time of transmission, that is, $t - \tau^s_r$.

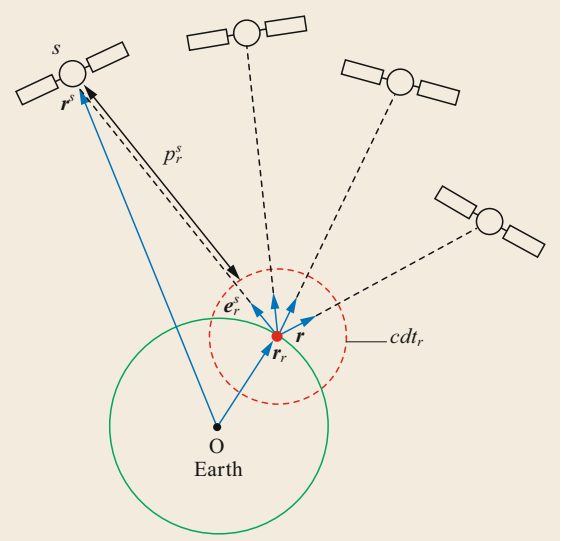

**Fig. 21.3** Point positioning based on 4 GNSS satellites: $\boldsymbol{r}_r$ denotes the receiver position vector, $\boldsymbol{r}^s$ the satellite position vector, $\boldsymbol{e}^s_r$ the line-of-sight unit vector, $cdt_r$ the receiver clock error, and $p^s_r$, the code or pseudo-range observation

#### GPS, Galileo, QZSS, and IRNSS

In case of GPS, Galileo, QZSS, and IRNSS, the broadcast satellite clock correction in fact corresponds to the *ionosphere-free combination* of dual-frequency code observations, see also Chap. 20 for this linear combination

$$dt^s_{\mathrm{S}}(t) = dt^s_{\mathrm{IF}}(t) = dt^s(t) - d^s_{\mathrm{IF}}(t)\,. \tag{21.36}$$

Here $d^s_{\mathrm{IF}}(t)$ denotes the ionosphere-free combination of satellite hardware biases and is defined as

$$\begin{aligned} d^s_{\mathrm{IF}}(t) &= \frac{\mu^{\mathrm{S}}_2}{\mu^{\mathrm{S}}_2 - \mu^{\mathrm{S}}_1} d^s_1(t) - \frac{\mu^{\mathrm{S}}_1}{\mu^{\mathrm{S}}_2 - \mu^{\mathrm{S}}_1} d^s_2(t) \\ &= d^s_j(t) + \frac{\mu^{\mathrm{S}}_j}{\mu^{\mathrm{S}}_2 - \mu^{\mathrm{S}}_1} \underbrace{\left[d^s_1(t) - d^s_2(t)\right]}_{\mathrm{DCB}^s_{12}(t)}, \\ &\quad \text{for } j = 1, 2\,. \end{aligned} \tag{21.37}$$

The ionospheric coefficients corresponding to the two frequencies involved in the combination are denoted as $\mu^{\mathrm{S}}_1$ and $\mu^{\mathrm{S}}_2$ (21.3), where $\mathrm{S} \in \{\mathrm{G}, \mathrm{E}, \mathrm{J}, \mathrm{I}\}$. Note that the ionosphere-free coefficients can also be given as function of the frequencies, that is,

$$\frac{\mu^{\mathrm{S}}_2}{\mu^{\mathrm{S}}_2 - \mu^{\mathrm{S}}_1} = \frac{(f^{\mathrm{S}}_1)^2}{(f^{\mathrm{S}}_1)^2 - (f^{\mathrm{S}}_2)^2} \quad \text{and}$$
$$\frac{\mu^{\mathrm{S}}_1}{\mu^{\mathrm{S}}_2 - \mu^{\mathrm{S}}_1} = \frac{(f^{\mathrm{S}}_2)^2}{(f^{\mathrm{S}}_1)^2 - (f^{\mathrm{S}}_2)^2}\,.$$

The frequency-difference between the satellite hardware biases in (21.37), that is, $d^s_1(t) - d^s_2(t)$, is also known as *differential code bias* (DCB) [21.6], or *inter-frequency bias* (IFB) [21.3]. While for GPS (and QZSS) the ionosphere-free satellite clock applies to the L1 and L2 frequencies, in case of Galileo the broadcast satellite clock corresponds to either the ionosphere-free combination of E1+E5a, or to the combination of E1+E5b. Depending on the Galileo service that is used (Chap. 9), it follows which navigation message type and which ionosphere-free clock is transmitted: E1+E5a in case of the freely accessible navigation message (F/NAV) in the open service and E1+E5b in case of the integrity navigation message (I/NAV) in the safety-of-life service [21.23]. In case of IRNSS the ionosphere-free clock refers to the S-band and L5 frequencies [21.24].

Single-frequency SPP users employing the broadcast satellite clock offset cannot directly use the ionosphere-free satellite clock, but they need to apply another correction, the so-called timing group delay (TGD) difference between the two frequencies, which is defined as [21.25]

$$T^s_{\mathrm{GD}}(t) = -\frac{\mu_1^{\mathrm{S}}}{\mu_2^{\mathrm{S}} - \mu_1^{\mathrm{S}}} \underbrace{\left[d_1^s(t) - d_2^s(t)\right]}_{\mathrm{DCB}^s_{12}(t)} . \tag{21.38}$$

Remind that the ionospheric coefficients read $\mu_1^{\mathrm{S}} = 1$ and $\mu_2^{\mathrm{S}} = (\lambda_2^{\mathrm{S}}/\lambda_1^{\mathrm{S}})^2$. Thus, the TGD is a scaled version of the DCB. Note that the Galileo ICD speaks of BGD (broadcast group delay) instead of TGD. Using the group delays, the combination of satellite clock and hardware delay for the first two frequencies can be reconstructed as

$$dt^s_{\mathrm{S}}(t) - \frac{\mu_j^{\mathrm{S}}}{\mu_1^{\mathrm{S}}} T^s_{\mathrm{GD}}(t) = dt^s(t) - d^s_j(t),\ j = 1, 2 . \tag{21.39}$$

In case of GPS users employing the L1 C/A code instead of the P1 code another correction should be taken into account, which accounts for the difference in hardware biases between the P1 and C/A code

$$dt^s_{\mathrm{G}}(t) - T^s_{\mathrm{GD}}(t) + \mathrm{DCB}^s_{1\mathrm{c}}(t) = dt^s(t) - d^s_{\mathrm{c}}(t) , \tag{21.40}$$

with $\mathrm{DCB}^s_{1\mathrm{c}}(t) = d^s_1(t) - d^s_{\mathrm{c}}(t)$ the DCB between the P1 and C/A code, where $d^s_{\mathrm{c}}(t)$ denotes the hardware bias of the C/A code. This P1-C/A DCB is typically of the order of 2 ns (60 cm) [21.26]. This correction is however not transmitted in the GPS *legacy* navigation message (i. e., the NAV message, modulated on the C/A code), but is transmitted in the modernized civilian NAV (CNAV) messages modulated on the L2C and L5 signals, together with additional group delay corrections that are referred to as *intersignal corrections* (ISCs) [21.27, 28].

### BeiDou (BDS)

In case of BeiDou the broadcast satellite clock is *not* referring to an ionosphere-free combination, but to the single-frequency B3 signal [21.29]

$$dt^s_{\mathrm{C}}(t) = dt^s(t) - d^s_3(t) . \tag{21.41}$$

Single-frequency SPP users that use either the B1 or B2 frequency cannot directly use this broadcast satellite clock offset, but need to apply a TGD, depending on the frequency they use

$$\begin{aligned} T^s_{\mathrm{GD}_1}(t) &= d^s_1(t) - d^s_3(t) , \\ T^s_{\mathrm{GD}_2}(t) &= d^s_2(t) - d^s_3(t) . \end{aligned} \tag{21.42}$$

The BeiDou navigation message provides both these TGDs. Single-frequency B1 and B2 SPP users should apply the respective TGD such that

$$\begin{aligned} dt^s_{\mathrm{C}}(t) - T^s_{\mathrm{GD}_1}(t) &= dt^s(t) - d^s_1(t) , \\ dt^s_{\mathrm{C}}(t) - T^s_{\mathrm{GD}_2}(t) &= dt^s(t) - d^s_2(t) . \end{aligned} \tag{21.43}$$

Dual- or multifrequency BeiDou users can compute their ionosphere-free clock offsets

$$dt^s_{\mathrm{C}}(t) - \frac{\mu_2^{\mathrm{C}}}{\mu_2^{\mathrm{C}} - \mu_1^{\mathrm{C}}} T^s_{\mathrm{GD}_1}(t) + \frac{\mu_1^{\mathrm{C}}}{\mu_2^{\mathrm{C}} - \mu_1^{\mathrm{C}}} T^s_{\mathrm{GD}_2}(t) , \tag{21.44}$$

for B1+B2, and

$$dt^s_{\mathrm{C}}(t) - \frac{\mu_3^{\mathrm{C}}}{\mu_3^{\mathrm{C}} - \mu_1^{\mathrm{C}}} T^s_{\mathrm{GD}_1}(t) \tag{21.45}$$

for B1+B3.

### GLONASS

In case of GLONASS, the satellite clock offset is based on the L1 frequency and is calculated as follows from the navigation message [21.30]

$$dt^s_{\mathrm{R}}(t) = a^s_0(t^s_{\mathrm{oc}}) + a^s_1(t - t^s_{\mathrm{oc}}) , \tag{21.46}$$

where it is noted that in the GLONASS ICD the reference time of the clock data is referred to as $t^s_{\mathrm{b}}$. In contrast to GPS, Galileo, and BeiDou, the clock offset is for GLONASS computed as a first-order polynomial, where it is remarked that the broadcast parameters $a^s_0$ and $a^s_1$ not only account for the satellite clock offset and drift, but also for relativistic effects. A separate compensation for these effects is, therefore, not needed [21.31]. For GLONASS, the difference between satellite hardware delays on the L1 and L2 frequencies is broadcast as well [21.30]

$$\Delta\tau^s_n(t) = d^s_2(t) - d^s_1(t) . \tag{21.47}$$

The combination of satellite clock and hardware delay on GLONASS L1 is then obtained as follows

$$dt^s_{\mathrm{R}}(t) = dt^s(t) - d^s_1(t) , \tag{21.48}$$

while its counterpart on the GLONASS L2 frequency is reconstructed as

$$dt^s_{\mathrm{R}}(t) - \Delta\tau^s_n(t) = dt^s(t) - d^s_2(t) . \tag{21.49}$$

### 21.3.2 Some Remarks on the TGDs/DCBs

The DCB or TGD is initially determined by the satellite manufacturer before launch and can be revised by the GNSS's control segment [21.22]. For GPS, since 1999 JPL determines improved TGD values (as a byproduct of their ionospheric mapping) that are uploaded to the GPS satellites [21.32]. The size of these DCBs (for GPS/GLONASS) is less than 15 ns (4.5 m) [21.27], while for BeiDou less than 20 ns [21.33], and are normally very stable in time (at least over one day) [21.34, 35]. In case precise satellite clocks are used (PPP), these clocks are also based on the ionosphere-free combination [21.36] and hence single-frequency users should correct for the DCBs. Precise satellite DCBs are made available on a regular (daily) basis by the IGS, as part of their global ionospheric map (GIM) product [21.37]. As the constellation-mean value of the DCBs is set by IGS convention to zero [21.6], whereas the GPS broadcast group delays are referenced to an empirical absolute hardware bias [21.25], there is an offset between the DCBs based on the broadcast group delays and those published by the IGS. Galileo determines the group delay as part of the orbit determination and time synchronization (ODTS) process and, like GPS, applies a zero-mean condition to the whole constellation [21.33].

### 21.3.3 Computation/Estimation of the Atmospheric Errors

In case of single-frequency point positioning (SPP or PPP) the GNSS observations may be a-priori corrected for the ionospheric delays. These corrections can be calculated using the models broadcast in the navigation message, such as the Klobuchar model for GPS [21.38], or the NeQuick model for Galileo [21.39]. Otherwise, more precise ionospheric corrections can be extracted from GIM as produced by the IGS. In case of multifrequency point positioning, ionospheric corrections are not required, since the ionospheric delays can be estimated or eliminated from the data themselves. However, estimation (or elimination) weakens the model, which results in longer times for the solution to converge, so for fast multifrequency positioning (precise) ionospheric corrections are essential.

The tropospheric delays can usually be largely corrected for using models such as the *Saastamoinen* model [21.40]. If needed, residual tropospheric delays can be estimated in the model. For more detailed information on atmospheric models, we refer to Chap. 6.

### 21.3.4 Single-Constellation SPP Model

#### Direct (Analytical) SPP Solution

It is possible to compute a SPP solution based on four pseudoranges (in case of one constellation) in *analytical* (or closed) form, based on the nonlinear observation equations and without linearization/iteration and the need for approximate values. The closed-form solution can also be used to serve for fast computation of the approximate receiver position. We refer to the literature, where several approaches have been proposed [21.41–43].

#### Single-Frequency SPP Model

In general, with more than four satellites, say $m_\mathrm{S}$ satellites, tracked by a receiver, the SPP model of single-frequency (linearized) pseudorange (code) observation equations can be given for a single epoch as, making use of the calculated satellite orbits and clocks, satellite hardware delays and atmospheric delays

$$E\left(\underbrace{\begin{bmatrix}\triangle\tilde{p}^1_{r,j}(t)\\ \vdots \\ \triangle\tilde{p}^{m_\mathrm{S}}_{r,j}(t)\end{bmatrix}}_{\triangle\tilde{\mathbf{p}}^\mathrm{S}_{r,j}(t)}\right) = \underbrace{\begin{bmatrix}-[\boldsymbol{e}^1_r(t)]^\top & 1\\ \vdots & \vdots \\ -[\boldsymbol{e}^{m_\mathrm{S}}_r(t)]^\top & 1\end{bmatrix}}_{\mathbf{J}_0}\begin{bmatrix}\triangle\boldsymbol{r}_r(t)\\ cdt^\mathrm{S}_{r,j}(t)\end{bmatrix}. \tag{21.50}$$

Here $E(\cdot)$ denotes the expectation operator and a *tilde* is used to denote the pseudorange observable that is corrected for orbit, clock, hardware biases, and atmospheric delays. A usual choice for SPP is $j = 1$, that is, the first frequency (in case of GPS: L1 C/A), but the model can be solved for other frequencies as well. Matrix $\mathbf{J}_0$ of dimension $m_\mathrm{S} \times 4$ denotes the *Jacobian* (Chap. 22) or *design matrix*, which can be written in the following compact form

$$\mathbf{J}_0 = \left[\mathbf{G}^\mathrm{S}_r(t),\, \boldsymbol{u}_{m_\mathrm{S}}\right], \tag{21.51}$$

Matrix $\mathbf{G}^\mathrm{S}_r(t) = [-\boldsymbol{e}^1_r(t), \ldots, -\boldsymbol{e}^{m_\mathrm{S}}_r(t)]^\top$ of dimension $m_\mathrm{S} \times 3$ contains the LOS unit direction vectors, while the $m_\mathrm{S}$-vector of ones is defined as $\boldsymbol{u}_{m_\mathrm{S}} = (1, \ldots, 1)^\top$. Unknown parameters in the SPP model are the receiver position vector $\triangle\boldsymbol{r}_r(t)$ and the receiver clock error $dt_{r,j}(t)$. This estimable receiver clock is a combination

of the *true* receiver clock error plus the (frequency-dependent) receiver hardware delay, as both terms cannot be separated, that is,

$$dt^{\mathrm{S}}_{r,j}(t) = dt_r(t) + d^{\mathrm{S}}_{r,j} \,. \tag{21.52}$$

Here it is assumed that the receiver hardware bias is stable in time, such that it can be denoted without time stamp. It is noted that in case of GLONASS, the inter-channel hardware biases are so small compared to the noise of the pseudorange observations [21.31] that for the purpose of SPP they can be neglected. If the SPP model is solved in an iterative least-squares sense, the approximate receiver position can be taken zero (corresponding to the center of the Earth). After convergence, this yields the least-squares estimators $\hat{\boldsymbol{r}}_r(t)$ and $\hat{dt}^{\mathrm{S}}_{r,j}(t)$.

The *redundancy* of an observation model is defined as the number of observables minus the number of estimable parameters. For the single-frequency SPP model it reads $m_{\mathrm{S}} - (3+1) = m_{\mathrm{S}} - 4$ (satellites). From this it follows that the model is solvable for $m_{\mathrm{S}} \geq 4$.

### Dual-Frequency SPP Model

In the presence of dual-frequency data, instead of modeling the ionospheric delays, a common procedure is to take the ionosphere-free combination to *eliminate* the ionospheric delays from the data and basically solve the single-frequency SPP model as in (21.50) but then based on the ionosphere-free observations and parameters. Table 21.2 shows the numerical values of the ionosphere-free coefficients for selected dual-frequency combinations of GPS (and QZSS), GLONASS, Galileo, BeiDou, and IRNSS observables.

Instead of working with ionosphere-free combinations, in a dual-frequency situation one could also work with a model that is, like the single-frequency model in (21.50), based on the *uncombined* observables, but which models the ionospheric delays as additional parameters. This model can, however, not be used directly in a least-squares adjustment, as its design matrix is *rank deficient*, which means that some of its columns are linear dependent. The rank deficiency can be overcome by application of the *S-system* or *datum* theory (see Chap. 22 for a general description of the theory of rank-defect least-squares). This means that instead of the original parameters as above, only certain *linear combinations* of parameters are estimable. However, the design matrix corresponding to these linear parameter combinations is of full rank.

**Table 21.2** Numerical values of ionosphere-free coefficients for several dual-frequency combinations of GPS (L#), GLONASS (G#), Galileo (E#), BeiDou (B#), and IRNSS (S+L5) observables

| Signals | $\frac{\mu_2^{\mathrm{S}}}{\mu_2^{\mathrm{S}}-\mu_1^{\mathrm{S}}} = \frac{(f_1^{\mathrm{S}})^2}{(f_1^{\mathrm{S}})^2-(f_2^{\mathrm{S}})^2}$ | $\frac{\mu_1^{\mathrm{S}}}{\mu_2^{\mathrm{S}}-\mu_1^{\mathrm{S}}} = \frac{(f_2^{\mathrm{S}})^2}{(f_1^{\mathrm{S}})^2-(f_2^{\mathrm{S}})^2}$ |
|---|---|---|
| L1+L2 | 2.5457 | 1.5457 |
| L1+L5 | 2.2606 | 1.2606 |
| G1+G2 | 2.5312 | 1.5312 |
| E1+E5a | 2.2606 | 1.2606 |
| E1+E5b | 2.4220 | 1.4220 |
| E1+E5 | 2.3380 | 1.3380 |
| B1+B2 | 2.4872 | 1.4872 |
| B1+B3 | 2.9437 | 1.9437 |
| S+L5 | 1.2868 | 0.2868 |

Based on the (corrected) pseudorange observables, the full-rank dual-frequency SPP model can be given as

$$E\left(\begin{bmatrix}\triangle\tilde{\boldsymbol{p}}^{\mathrm{S}}_{r,1}(t)\\ \triangle\tilde{\boldsymbol{p}}^{\mathrm{S}}_{r,2}(t)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{G}^{\mathrm{S}}_r(t) & \boldsymbol{u}_{m_{\mathrm{S}}} & \mu_1^{\mathrm{S}}\boldsymbol{I}_{m_{\mathrm{S}}}\\ \mathbf{G}^{\mathrm{S}}_r(t) & \boldsymbol{u}_{m_{\mathrm{S}}} & \mu_2^{\mathrm{S}}\boldsymbol{I}_{m_{\mathrm{S}}}\end{bmatrix}\begin{bmatrix}\triangle\boldsymbol{r}_r(t)\\ c\tilde{dt}^{\mathrm{S}}_r(t)\\ \tilde{\boldsymbol{I}}^{\mathrm{S}}_r(t)\end{bmatrix} . \tag{21.53}$$

The estimable ionospheric delay parameters are stored as vector $\tilde{\boldsymbol{I}}^{\mathrm{S}}_r(t) = [\tilde{I}^1_r(t), \ldots, \tilde{I}^{m_{\mathrm{S}}}_r(t)]^\top$. Inside the design matrix, $\mathbf{I}_{m_{\mathrm{S}}}$ denotes the identity matrix of dimension $m_{\mathrm{S}}$, while vector $\boldsymbol{u}_{m_{\mathrm{S}}}$ and matrix $\mathbf{G}^{\mathrm{S}}_r(t)$ are the same as in the single-frequency model.

Apart from the receiver position, the estimable receiver clock and ionospheric parameters have the following interpretation

$$\begin{aligned} \tilde{dt}^{\mathrm{S}}_r(t) &= dt_r(t) + d^{\mathrm{S}}_{r,1} + \frac{\mu_1^{\mathrm{S}}}{\mu_2^{\mathrm{S}}-\mu_1^{\mathrm{S}}}\mathrm{DCB}^{\mathrm{S}}_{\mathrm{r},12} \,,\\ \tilde{I}^s_r(t) &= I^s_r(t) - \frac{1}{\mu_2^{\mathrm{S}}-\mu_1^{\mathrm{S}}}\, c\,\mathrm{DCB}^{\mathrm{S}}_{r,12} \,. \end{aligned} \tag{21.54}$$

Here use is made of the following definition of a *receiver DCB* between the two frequencies

$$\mathrm{DCB}^{\mathrm{S}}_{r,12} = d^{\mathrm{S}}_{r,1} - d^{\mathrm{S}}_{r,2} \,. \tag{21.55}$$

Thus, the receiver DCB is *not* an estimable parameter in this model, but shows up as a *bias* in the interpretation of both the receiver clock and ionospheric parameters. This bias gets, however, eliminated when the observation equations are *reconstructed* from the estimable parameters, since for the first frequency it holds that

$$c\tilde{dt}^{\mathrm{S}}_r(t) + \mu_1^{\mathrm{S}}\tilde{I}^s_r(t) = c\left[dt_r(t) + d^{\mathrm{S}}_{\mathrm{r},1}\right] + \mu_1^{\mathrm{S}} I^s_r(t) \,. \tag{21.56}$$

For the second frequency it holds that

$$\begin{aligned} c\tilde{dt}^{\mathrm{S}}_r(t) + \mu_2^{\mathrm{S}}\tilde{I}^s_r(t) &= c\left[dt_r(t) + d^{\mathrm{S}}_{r,1}\right] + \mu_2^{\mathrm{S}} I^s_r(t)\\ -c\mathrm{DCB}^{\mathrm{S}}_{r,12} &= c\left[dt_r(t) + d^{\mathrm{S}}_{r,2}\right] + \mu_2^{\mathrm{S}} I^s_r(t) \,. \end{aligned} \tag{21.57}$$

We remark that the estimable receiver clock parameter in the dual-frequency SPP model can be rewritten as an *ionosphere-free* receiver clock

$$d\tilde{t}_r^{\,\mathrm{S}}(t) = dt_r(t) + d_{r,\,\mathrm{IF}}^{\mathrm{S}} \,. \tag{21.58}$$

Here $d_{r,\,\mathrm{IF}}^{\mathrm{S}}$ denotes the ionosphere-free combination of the receiver code delays of the two frequencies (similar to that for the satellite code delays, see (21.37)).

The *redundancy* of the dual-frequency SPP model reads $2m_{\mathrm{S}} - [3 + 1 + m_{\mathrm{S}}] = m_{\mathrm{S}} - 4$, which means that the model is solvable if $m_{\mathrm{S}} \geq 4$, which is similar to the single-frequency SPP model.

### 21.3.5 Multiconstellation SPP Model

This subsection focuses on the combined multiconstellation SPP model. Like with the single-constellation SPP model, first one frequency per constellation is assumed, followed by two frequencies per constellation. These frequencies between the constellations may be identical, but can also be different.

#### SPP Model: One Frequency per Constellation

Suppose we have pseudorange data from *two* constellations, denoted as GNSS A tracking single-frequency data of $m_{\mathrm{A}}$ satellites and GNSS B tracking single-frequency data of $m_{\mathrm{B}}$ satellites. We can set up the following combined SPP model

$$E\left(\begin{bmatrix}\triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{A}}(t)\\ \triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{B}}(t)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{G}_r^{\mathrm{A}}(t) & \boldsymbol{u}_{m_{\mathrm{A}}} & \mathbf{0}\\ \mathbf{G}_r^{\mathrm{B}}(t) & \mathbf{0} & \boldsymbol{u}_{m_{\mathrm{B}}}\end{bmatrix}\begin{bmatrix}\triangle\boldsymbol{r}_r(t)\\ cdt_{r,j}^{\mathrm{A}}(t)\\ c\,\mathrm{ISB}_{r,j}^{\mathrm{AB}}\end{bmatrix}. \tag{21.59}$$

The data of both constellations have the receiver coordinates in common, as well as the receiver clock, which is defined to be relative to the system time of constellation A. For the observations of constellation B an additional parameter shows up, which is the ISB

$$\mathrm{ISB}_{r,j}^{\mathrm{AB}} = \left[d_{r,j}^{\mathrm{B}} - d_{r,j}^{\mathrm{A}}\right] - t^{\mathrm{AB}} \,. \tag{21.60}$$

Compared to the ISB definition given in (21.10), the interchannel terms are not present in the above equations, as they may be neglected for the purpose of SPP. Another difference is that in addition to the difference in receiver hardware delays of the signals of the two constellations, the estimable ISB parameter in case of SPP is biased by the time offset between the constellations, that is, $t^{\mathrm{AB}}$ (21.11). The reason is that it cannot be separated from the hardware delays difference and therefore it is only estimable lumped to them. If this time offset is known (e.g., computed from the navigation message), it disappears from the interpretation of the ISB parameter. We furthermore remark that even if the frequencies of the signals of both constellations are identical (e.g., GPS L1 and Galileo E1), these ISBs do not cancel out [21.1, 44]. Instead of solving an ISB parameter, one may also introduce a receiver clock error corresponding to the second constellation in the SPP model. The following relating then holds between the receiver clocks and the ISB

$$\begin{aligned} dt_{r,j}^{\mathrm{B}}(t) &= dt_{r,j}^{\mathrm{A}}(t) + \mathrm{ISB}_{r,j}^{\mathrm{AB}} \\ &= dt_r(t) + d_{r,j}^{\mathrm{B}} - t^{\mathrm{AB}} \,. \end{aligned} \tag{21.61}$$

Based on this, another definition of the ISB can be given as

$$\mathrm{ISB}_{r,j}^{\mathrm{AB}} = dt_{r,j}^{\mathrm{B}}(t) - dt_{r,j}^{\mathrm{A}}(t) \,, \tag{21.62}$$

that is, the difference of the estimable receiver clocks of the two constellations. Instead of parameterizing these constellation-specific receiver clocks, the ISB-parametrization is more advantageous in the event it is possible to *calibrate* the ISB. In that case, the ISB can be assumed known and the observations of constellation B are corrected for it, such that the multiconstellation SPP model becomes

$$E\left(\begin{bmatrix}\triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{A}}(t)\\ \triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{B}}(t)'\end{bmatrix}\right) = \begin{bmatrix}\mathbf{G}_r^{\mathrm{A}}(t) & \boldsymbol{u}_{m_{\mathrm{A}}}\\ \mathbf{G}_r^{\mathrm{B}}(t) & \boldsymbol{u}_{m_{\mathrm{B}}}\end{bmatrix}\begin{bmatrix}\triangle\boldsymbol{r}_r(t)\\ cdt_{r,j}^{\mathrm{A}}(t)\end{bmatrix}, \tag{21.63}$$

with the ISB-corrected observables denoted as

$$\triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{B}}(t)' = \triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{B}}(t) - \boldsymbol{u}_{m_B}\, c\,\mathrm{ISB}_{r,j}^{\mathrm{AB}} \,.$$

In the ISB-corrected model the observations of constellations A and B have the same parameters in common, and the dual-constellation model becomes equivalent to a *single-constellation* SPP model, but now based on $m_{\mathrm{A}} + m_{\mathrm{B}}$ satellites.

The *redundancy* of the combined SPP model based on one frequency per system reads, if the ISB is unknown, $m_{\mathrm{A}} + m_{\mathrm{B}} - 5$. This means that $m_{\mathrm{A}} + m_{\mathrm{B}} \geq 5$, and this can be satisfied by different combinations of satellites. In case of more than two constellations, model (21.59) is extendable with one combined ISB/time-offset parameter for each constellation that is added. The multiconstellation redundancy then reads in general $\sum_{i=1}^{s} m_i - (3 + s)$, where $s$ denotes the number of constellations. In the case the ISB/time-offsets can be assumed known, the multiconstellation redundancy increases to $\sum_{i=1}^{s} m_i - 4$.

#### SPP Model: Two Frequencies per Constellation

The multiconstellation SPP model for two frequencies per constellation can be set up by modeling ionospheric delays as unknown parameters, as done in the single-constellation case in (21.53). In this case, the estimable parameters are, next to the receiver coordinates, an ionosphere-free clock for constellation A, as well as ionospheric delays per constellation that are biased by constellation-specific DCBs (21.54). In addition, an ISB parameter is parameterized, however in this case it is the *ionosphere-free* ISB parameter, defined as

$$\begin{aligned}\mathrm{ISB}^{\mathrm{AB}}_{r,\,\mathrm{IF}} &= \left[d^{\mathrm{B}}_{r,\,\mathrm{IF}} - d^{\mathrm{A}}_{r,\,\mathrm{IF}}\right] - t^{\mathrm{AB}} \\ &= \left[\frac{\mu_2^{\mathrm{B}}}{\mu_2^{\mathrm{B}} - \mu_1^{\mathrm{B}}} d^{\mathrm{B}}_{\mathrm{r},1} - \frac{\mu_1^{\mathrm{B}}}{\mu_2^{\mathrm{B}} - \mu_1^{\mathrm{B}}} d^{\mathrm{B}}_{\mathrm{r},2}\right] \\ &\quad - \left[\frac{\mu_2^{\mathrm{A}}}{\mu_2^{\mathrm{A}} - \mu_1^{\mathrm{A}}} d^{\mathrm{A}}_{\mathrm{r},1} - \frac{\mu_1^{\mathrm{A}}}{\mu_2^{\mathrm{A}} - \mu_1^{\mathrm{A}}} d^{\mathrm{A}}_{\mathrm{r},2}\right] \\ &\quad - t^{\mathrm{AB}} \,. \end{aligned} \tag{21.64}$$

This ionosphere-free ISB corresponds to the definition given by [21.3, 7].

### 21.3.6 Precision and DOP

The impact of the receiver–satellite geometry (captured in matrix $\mathbf{G}^{\mathrm{S}}_r(t)$ in case of a single constellation) on the precision of the receiver position obtained using SPP is usually described using the DOP concept [21.45]. The $4\times4$ cofactor matrix (variance matrix excluding the variance factor) of the receiver position and receiver clock of the single-constellation single-frequency model can analytically be given as [21.46]

$$\left(\mathbf{J}_0^{\top}\mathbf{J}_0\right)^{-1} = \begin{bmatrix} \mathbf{C}^{\mathrm{S}}_{\hat{\boldsymbol{r}}(t)} & \mathbf{C}^{\mathrm{S}}_{\hat{\boldsymbol{r}}(t)}\overline{\boldsymbol{e}}^{\mathrm{S}}_r(t) \\ \overline{\boldsymbol{e}}^{\mathrm{S}}_r(t)^{\top}\mathbf{C}^{\mathrm{S}}_{\hat{\boldsymbol{r}}(t)} & \frac{1}{m_{\mathrm{S}}} + \overline{\boldsymbol{e}}^{\mathrm{S}}_r(t)^{\top}\mathbf{C}^{\mathrm{S}}_{\hat{\boldsymbol{r}}(t)}\overline{\boldsymbol{e}}^{\mathrm{S}}_r(t) \end{bmatrix}. \tag{21.65}$$

This cofactor matrix is based on the design matrix of the SPP model given as in (21.51) and where

$$\overline{\boldsymbol{e}}^{\mathrm{S}}_r(t) = \frac{1}{m_{\mathrm{S}}}\sum_{s=1}^{m_{\mathrm{S}}} \boldsymbol{e}^s_r(t)$$

denotes the mean LOS vector over all satellites. The $3\times3$ cofactor matrix of the receiver position is given as

$$\mathbf{C}^{\mathrm{S}}_{\hat{\boldsymbol{r}}(t)} = \left(\sum_{s=1}^{m_{\mathrm{S}}}\left[\boldsymbol{e}^s_r(t) - \overline{\boldsymbol{e}}^{\mathrm{S}}_r(t)\right]\left[\boldsymbol{e}^s_r(t) - \overline{\boldsymbol{e}}^{\mathrm{S}}_r(t)\right]^{\top}\right)^{-1}. \tag{21.66}$$

From this last expression, one can see that if the satellite LOS vectors differ a lot from each other and from their mean, that is, when $\boldsymbol{e}^s_r(t) - \overline{\boldsymbol{e}}^{\mathrm{S}}_r(t)$ is large, this is favorable for the precision with which the receiver position can be determined.

DOP values can now be computed based on the diagonal elements of the cofactor matrix of the receiver position. If $\boldsymbol{r}(t) = [E, N, U]^{\top}$ denotes the position in a local east–north-up frame, then the following DOPs can be calculated

$$\begin{aligned} \mathrm{GDOP} &= \sqrt{c^2_{\hat{E}} + c^2_{\hat{N}} + c^2_{\hat{U}} + c^2_{\mathrm{cd}\hat{t}^{\mathrm{S}}_{r,j}}}\,, \\ \mathrm{PDOP} &= \sqrt{c^2_{\hat{E}} + c^2_{\hat{N}} + c^2_{\hat{U}}}\,, \\ \mathrm{HDOP} &= \sqrt{c^2_{\hat{E}} + c^2_{\hat{N}}}\,, \\ \mathrm{VDOP} &= \sqrt{c^2_{\hat{U}}}\,. \end{aligned} \tag{21.67}$$

Here

$$c^2_{\hat{E}},\, c^2_{\hat{N}}, \quad \text{and} \quad c^2_{\hat{U}}$$

denote the diagonal elements of $\mathrm{C}_{\hat{\boldsymbol{r}}}(t)$ for the position, whereas

$$c^2_{\mathrm{cd}\hat{t}^{\mathrm{S}}_{r,j}}$$

denotes the diagonal element of (21.65) for the receiver clock. GDOP stands for *geometric* dilution of precision, PDOP for *position* dilution of precision, HDOP for *horizontal* dilution of precision, and VDOP for *vertical* dilution of precision. Unfavorable geometries, however, may lead to poor receiver precision and in some unfortunate cases even the position cannot be determined (geometry singularities). For example, when the end points of the LOS vectors describe a plane (all satellites lie on the surface of a cone) [21.47]. In that case the DOPs are infinitely large.

In case of *multiconstellation* positioning, it is also possible to calculate DOP values. If we assume two constellations, A and B, then these DOPs are computed based on the dual-constellation model (21.59), for which the receiver position cofactor matrix follows as

$$\mathbf{C}_{\hat{\boldsymbol{r}}(t)} = \left[\left(\mathbf{C}^{\mathrm{A}}_{\hat{\boldsymbol{r}}(t)}\right)^{-1} + \left(\mathbf{C}^{\mathrm{B}}_{\hat{\boldsymbol{r}}(t)}\right)^{-1}\right]^{-1}, \tag{21.68}$$

that is, the inverse of a *sum* of the inverse cofactor matrices according to (21.66) that correspond to each individual constellation. From this expression, it easily follows that the dual-constellation DOPs are smaller (or in the worst case: equal) than their single-constellation

counterparts. In case both ISB and time offset are a priori *known*, the receiver position cofactor matrix follows from model (21.63) as

$$\mathbf{C}_{\hat{r}}(t) = \left( \sum_{s=1}^{m_A+m_B} \left[ \boldsymbol{e}_r^s(t) - \overline{\boldsymbol{e}}_r(t) \right] \left[ \boldsymbol{e}_r^s(t) - \overline{\boldsymbol{e}}_r(t) \right]^\top \right)^{-1} , \tag{21.69}$$

with the mean LOS vector taken over *both* constellations, that is,

$$\overline{\boldsymbol{e}}_r(t) = \frac{1}{m_A + m_B} \sum_{s=1}^{m_A+m_B} \boldsymbol{e}_r^s(t) \, .$$

The DOP values based on this model are even smaller than those based on (21.68).

As an example, Fig. 21.4 depicts PDOP values for a certain receiver–satellite geometry of four GPS and four Galileo satellites. Besides constellation-specific PDOPs, the PDOPs are shown for the combined GPS+Galileo model assuming a receiver clock and ISB parameter (similar to assuming a receiver clock per constellation), as well as PDOPs when only one receiver clock parameter is assumed for both GPS and Galileo (ISBs known). The PDOPs of the combined model with one receiver clock are the smallest, as this model is the strongest, although in Fig. 21.4 the PDOPs of this model tend to become equal to the PDOPs of the model with two receiver clocks, but this is due to the actual geometry in this example.

### 21.3.7 PPP Model

If, in addition to the pseudoranges, also the carrier-phase observations are employed for point positioning, in combination with the use of precise (IGS) products, we speak of PPP [21.48, 49]. For the full details and intricacies of the PPP technique, we refer to Chap. 25; here we will restrict ourselves to an overview of the single-frequency and multifrequency PPP models based on one constellation, as to compare to their SPP counterparts. Figure 21.5 visualizes the procedure for PPP, where in the first step a reference network (e.g., the IGS network) determines (satellite-dependent) parameters that are in a second step transmitted to the users. In the third step a user applies this correction information which enables PPP.

PPP users employing the precise (IGS) products should be aware that the precise satellite clocks are based on the *ionosphere-free* combination, similar to the broadcast satellite clock for most constellations. In case of single-frequency PPP, therefore, corrections for the satellite DCBs are required, but these are also provided by the IGS or its analysis centers. In addition, as single-frequency PPP users cannot form the ionosphere-free dual-frequency combination, ionospheric corrections are essential and these can be obtained from the IGS as well, in the GIM format.

Concerning the tropospheric delays, in addition the a-priori model corrections, for precise positioning applications it may be necessary to parameterize (residual) tropospheric delays. A common procedure is to

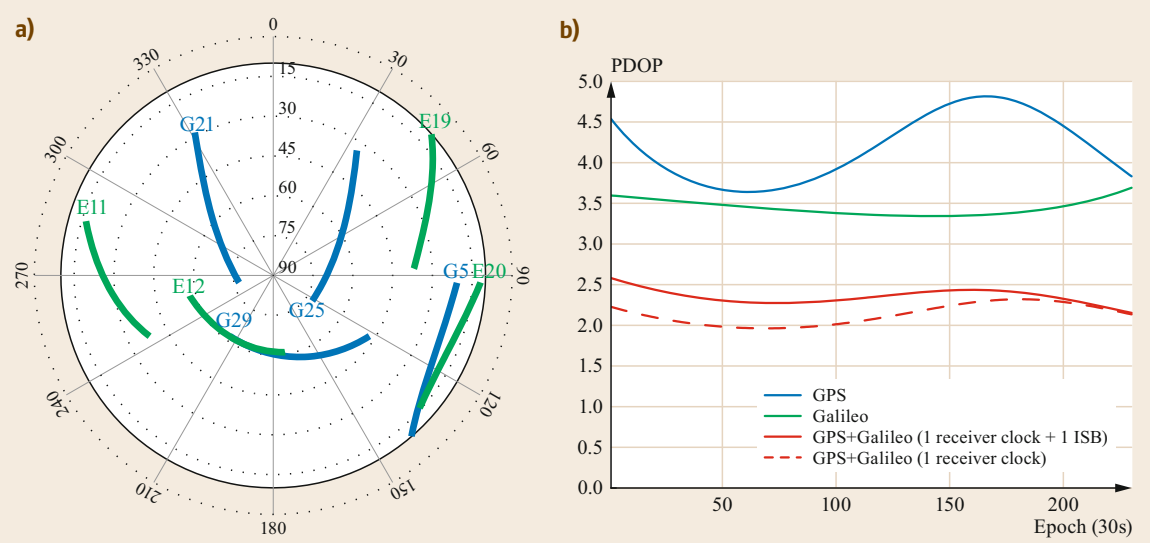

**Fig. 21.4a,b** Skyplot **(a)** and PDOP values **(b)**, based on 4 Galileo-IOV and 4 GPS satellites, above 10 deg cut-off elevation in Perth, Australia, for 04:05–6:00 GPST on 20 March 2013. For the combined GPS+Galileo case, distinction is made between the PDOPs based on model (21.59) and model (21.63)

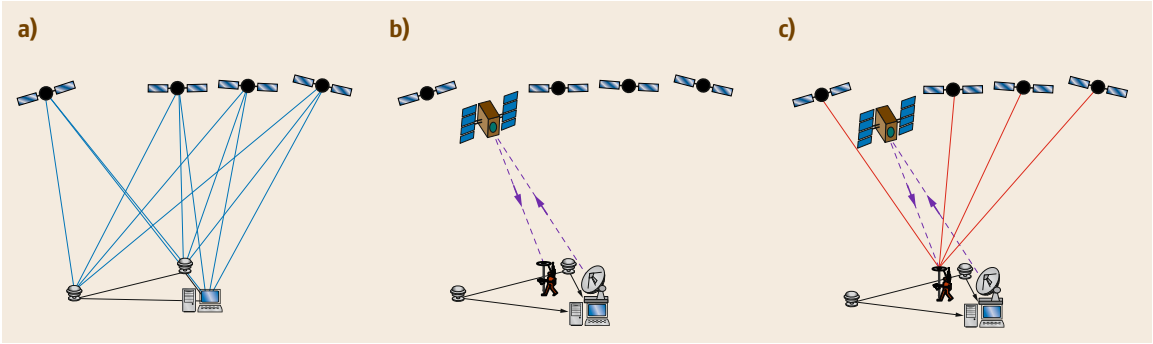

**Fig. 21.5a–c** Visualization of the PPP(-RTK) concept: **(a)** CORS (global or regional) network determines GNSS parameters; **(b)** satellite-dependent parameters are uploaded by the network and downloaded by a user; **(c)** the user applies the corrections to his data, enabling single-receiver precise positioning

map the residual tropospheric delays to local zenith, that is,

$$T_r^s(t) = T_{\mathrm{r},0}^s(t) + m_r^s(t) T_r^z(t) \,,$$

with $T_{r,0}^s(t)$ the a-priori tropospheric correction, $m_r^s(t)$ the mapping function, and $T_r^z$ the zenith tropospheric delay (ZTD). An example of an accurate tropospheric mapping function is *Niell's* mapping function [21.50].

GLONASS PPP (and also RTK) requires a-priori correction of the receiver- and frequency-dependent interchannel or interfrequency biases, at least for the phase data, that is, $\Delta\delta_{r,j}^{\mathrm{S}}$. In [21.51], a table is presented with interchannel corrections for GLONASS receivers of nine different manufacturers. Here we assume that the data are a-priori corrected for these biases, such that GLONASS data can be processed using the general models we present here.

Due to a lack of space, the PPP models discussed here are restricted to one GNSS constellation only. PPP models for multiple constellations can however be developed along similar lines as the multiconstellation SPP model in Sect. 21.3.5. For notational convenience, from now on the system identifier S will be omitted in a single-constellation case.

### Single-Frequency PPP Model

In case of single-frequency PPP it is assumed that identical offsets for the satellite clock and hardware bias apply to both code and phase observations, as well as a-priori corrections for tropospheric and ionospheric delays. Provided that the satellite clock offsets are based on the ionosphere-free combination (as is the case with precise IGS products), the offset terms for code and phase then can be given as

$$o_{p_{r,j}^s}(t) = c\left[dt_{\mathrm{IF}}^s\left(t-\tau_r^s\right) + \frac{\mu_j}{\mu_2-\mu_1}\mathrm{DCB}_{12}^s\right] - T_{\mathrm{r},0}^s(t) - \mu_j I_r^s(t) \,,$$

$$o_{\varphi_{r,j}^s}(t) = c\left[dt_{\mathrm{IF}}^s\left(t-\tau_r^s\right) + \frac{\mu_j}{\mu_2-\mu_1}\mathrm{DCB}_{12}^s\right] - T_{\mathrm{r},0}^s(t) + \mu_j I_r^s(t) \,. \tag{21.70}$$

Like the receiver hardware biases, it is assumed that the satellite hardware biases are stable such that they can be kept as time constants in the model. The DCBs (difference of satellite hardware biases) are needed to convert the ionosphere-free satellite clocks to the clocks plus hardware bias for the required frequency. It is remarked that in case of GPS the code corresponds to the C/A code ($j = 1$), we also need to subtract the P1-C/A DCB (i. e., $\mathrm{DCB}_{1\mathrm{c}}$) from the code correction. Applying the above offsets to the single-frequency code and phase observations yields the (linearized) full-rank single-frequency PPP model as given in Table 21.3 (top row).

The corrected (observed-minus-computed) code and phase observables then read $\triangle\tilde{p}_{r,j}(t) = \triangle p_{r,j}(t) + o_{p_{r,j}^s}(t)$ and $\triangle\tilde{\varphi}_{r,j}(t) = \triangle\varphi_{r,j}(t) + o_{\varphi_{r,j}^s}(t)$, respectively. Precise satellite orbits are used to calculate the LOS vectors in geometry matrix $\mathbf{G}_r(t)$ and to compute approximate values for the receiver–satellite ranges, used in the linearization. In this PPP model, the (residual) ZTD parameter is combined with the position parameters in the four-dimensional vector $\boldsymbol{x}_r(t)$, defined as

$$\boldsymbol{x}_r(t) = \left[\triangle\boldsymbol{r}_r(t)^\top,\, T_r^z(t)\right]^\top \,. \tag{21.71}$$

In addition, the LOS vectors and tropospheric mapping coefficients are stored in the $m\times 4$ matrix $\mathbf{G}_r(t) = [\boldsymbol{g}_r^1(t), \ldots, \boldsymbol{g}_r^m(t)]^\top$, with the $4\times 1$ geometry vector $\boldsymbol{g}_r^s(t)$ now consisting of the LOS vector, *plus* the tropospheric mapping function coefficient, which is defined as

$$\boldsymbol{g}_r^s(t) = \begin{bmatrix} -\boldsymbol{e}_r^s(t) \\ m_r^s(t) \end{bmatrix} . \tag{21.72}$$

Besides the receiver position, unknown parameter for both code and phase is the (biased) receiver clock $d\tilde{t}_r(t)$,

**Table 21.3** Full-rank undifferenced PPP models and their estimable parameters. Note: SF = single-frequency; DF = dual-frequency

of which its interpretation is identical to that of single-frequency SPP.

The phase observables in the PPP model introduce their own specific parameters, which are a receiver-phase bias and phase ambiguity parameters. Unfortunately these parameters cannot be estimated independently, as their columns are linear dependent. To overcome this rank deficiency (of size 1), a choice is to estimate the *between-satellite differences* of the (biased) ambiguity parameters, instead of their undifferenced counterparts, that is, the estimable ambiguity parameter is $\tilde{N}^s_{r,j}$ in Table 21.3, for $s=1,\ldots,m$ and where $s\neq p$. With this reparameterization, there is thus one ambiguity parameter less estimable, since we form between-satellite differences with respect to the $p$th satellite. This arbitrarily chosen satellite is referred to as *pivot satellite*. Thus, the $(m-1)$-vector of estimable ambiguities reads

$$\tilde{\mathbf{N}}_{r,j}=\left[\tilde{N}^1_{r,j},\ldots,\tilde{N}^{p-1}_{r,j},\tilde{N}^{p+1}_{r,j},\ldots,\tilde{N}^m_{r,j}\right]^\top. \quad (21.73)$$

In the PPP design matrix in Table 21.3 this vector is multiplied by the $m \times (m-1)$ matrix $\mathbf{C}_m$, which is defined as

$$\mathbf{C}_m = \begin{bmatrix} \mathbf{I}_{p-1} & \mathbf{0} \\ \mathbf{0} & \begin{pmatrix} \mathbf{0}_{1\times(m-p)} \\ \mathbf{I}_{m-p} \end{pmatrix} \end{bmatrix} . \quad (21.74)$$

This matrix can be regarded as the identity matrix of dimension $m$ having its $p$-th column removed. A consequence of parameterizing between-satellite ambiguity differences for undifferenced observables is that it should be somewhere *compensated* by the other estimable parameters. In this case the estimable receiver-phase bias parameter, that is, $\tilde{\delta}_{r,j}$ in Table 21.3, gets biased by the ambiguity plus hardware biases corresponding to the pivot satellite.

Although the ambiguities $N^s_{r,j}$ have the property of being integer, in the PPP model they are *not* estimable as such, because of the lumping of the satellite-phase and code hardware delays to them (Table 21.3). The consequence is that for every epoch of data the number of phase observations equals the number of phase parameters they introduce, which means that the phase data do *not* contribute to the estimation of the receiver position, which is thus fully governed by the (less precise) code observables. However, this situation changes in *multiepoch* mode; in that case the phase data start to contribute to the solution of the receiver position (as their estimable ambiguity parameters are time constant). The longer this time span, the more it is governed by the phase data; after a certain time the position precision will have converged to a certain level. The *redundancy* of this multiepoch, single-frequency PPP model equals $m-5+(k-1)(2m-5)$, with $k$ denoting the number of epochs. Note that for a single epoch ($k = 1$) this redundancy reduces to $m-5$, which is 1 less than the redundancy of its SPP counterpart. This is due to the parameterization of the ZTD in the PPP model.

In the absence of ionospheric corrections, single-frequency PPP is still possible, thereby making use of the opposite sign of the ionospheric delays for code and phase. In this case the model is, however, not solvable based on a single epoch of data, as there are too many unknown parameters. Based on *two* epochs, however, the full-rank single-frequency PPP model is presented in Table 21.3 (second row). The estimable ambiguity parameters of this *ionosphere-float* model (as ionospheric delays are unknown parameters) have the same interpretation as in the single-frequency ionosphere-corrected PPP model, but the estimable receiver clock has a completely different interpretation; in the ionosphere-float case it is biased by the receiver bias, as well as the pivot satellite ambiguity and hardware biases (there is no estimable receiver bias parameter). The estimable ionospheric parameter is biased by hardware delays and (pivot satellite) ambiguities as well. Based on a minimum of two epochs, the *redundancy* of this single-frequency, ionosphere-float PPP model equals $m-9$, requiring this model a large number of 9 satellites to be solvable. This redundancy is, however, based on the parameterization of different receiver positions for both epochs (i. e., a kinematic solution). If the receiver can be assumed *static* and the ZTD is assumed time constant, the model becomes stronger since $\boldsymbol{x}_r(t_1) = \boldsymbol{x}_r(t_2)$, increasing the redundancy with 4 to $m-5$, which is identical to the redundancy of the single-epoch, single-frequency, ionosphere-corrected PPP model.

Subject to the availability of precise GNSS orbits, clocks, DCBs, and ionosphere products, the *positioning accuracy* of single-frequency PPP is typically at decimeter level after a few minutes of convergence time [21.52].

### Dual-Frequency PPP Model

In the dual-frequency PPP case, the ionospheric delays are assumed as unknown parameters and therefore no ionospheric corrections are incorporated. In that case DCBs are not needed as well. The correction terms for code and phase are in that case equivalent and read

$$o_{p^s_{r,\mathrm{IF}}}(t) = o_{\varphi^s_{r,\mathrm{IF}}}(t) = c dt^s_{\mathrm{IF}}\left(t-\tau^s_r\right) - T^s_{r,0}(t) \; . \quad (21.75)$$

Like in the single-frequency GPS case, if the first frequency corresponds to the C/A code ($j = 1$), we need to subtract the P1-C/A DCB (i. e., $\mathrm{DCB}_{1c}$) from the code correction. The linearized full-rank model for the dual-frequency PPP case is given in Table 21.3 (bottom row).

The estimability and interpretation of the code-related parameters (i. e., receiver position and clock) in this dual-frequency PPP model is exactly the same as in the dual-frequency SPP model (21.54) and (21.58). As a consequence of the absence of the satellite DCB corrections in the dual-frequency PPP model, satellite DCBs get lumped to the estimable ionospheric parameters and hence its interpretation becomes a combination of the true ionospheric delay plus satellite and receiver DCBs (Table 21.3). The ambiguity parameters also get biased by the satellite DCBs.

The phase-ambiguity parameters are in the dual-frequency PPP case estimable as between-satellite differenced parameters (relative to pivot satellite $p$), simi-

lar as in the single-frequency PPP model; however the interpretation between the dual- and single-frequency cases differs (Table 21.3). In both cases, the ambiguities are not integer estimable.

The *redundancy* of the dual-frequency PPP model equals $m-5+(k-1)(3m-5)$, which for a single epoch ($k=1$) reduces to $m-5$, similar to the previously discussed single-frequency PPP models. The *positioning accuracy* of dual-frequency (GPS) PPP can reach centimeter level, however only after a convergence time (based on the constant ambiguity terms) of typically more than 30 min [21.52].

## 21.4 Relative Positioning Models

In this section, we discuss the differential or relative GNSS positioning models, in which observations of more than one receiver are combined such that errors that are common between the receivers can be eliminated or reduced. Another important advantage is that in a relative measurement setup the carrier-phase ambiguities can be estimated to integer values, thereby greatly improving the positioning accuracy. The models in this section are restricted to the single-epoch case. For all relative positioning models it is assumed that in case of FDMA constellations interchannel bias corrections are a-priori corrected and do not show up in the observation equations. As with the models for PPP, the discussion of the relative positioning models in this chapter will be restricted to a single GNSS constellation only.

### 21.4.1 Principle of DGNSS and (PPP-)RTK

The typical accuracy of (single-constellation) SPP is in the order of 10 m. This accuracy is basically due to the uncertainty in the orbits, satellite clocks, and atmospheric delays. Despite the developments of PPP during the past decade, the technique of differential GNSS (DGNSS) has already been applied for decades to improve this positioning accuracy through eliminating or significantly removing errors that are common for receivers simultaneously tracking data of the same GNSS satellites. More details about DGNSS and services based on this concept can be found in Chap. 26. Here, we will briefly review the principle of DGNSS, following the discussion in [21.12].

#### Satellite Clock Evaluation

Due to the difference in travel time between two or more receivers in a relative positioning setup, the satellite clock and satellite hardware delay are evaluated at (slightly) different times of transmission, that is, $t-\tau_1^s$ for the reference receiver, denoted using subscript 1, and $t-\tau_r^s$ for the other (rover) receiver, denoted using subscript $r$ (Fig. 21.6). This difference in travel time, that is, $|\tau_r^s-\tau_1^s|$, is at most 19 ms (for one receiver experiencing the satellite in zenith and the other receiver experiencing the same satellite at zero degrees elevation) [21.18]. This means that the difference in transmission time, that is, $|(t-\tau_1^s)-(t-\tau_r^s)|$, is at most 19 ms as well. Assuming that the satellite clock drifts with a rate of at most $10^{-11}$ s/s (Chap. 5), this means that after 19 ms the satellite clock (in terms of distance) has changed with $c\cdot 10^{-11}\cdot 19\cdot 10^{-3}\approx 0.06$ mm, which is negligible compared to the precision of the phase and code observations. Thus, we may safely assume that for the purpose of evaluation of the satellite clock at the

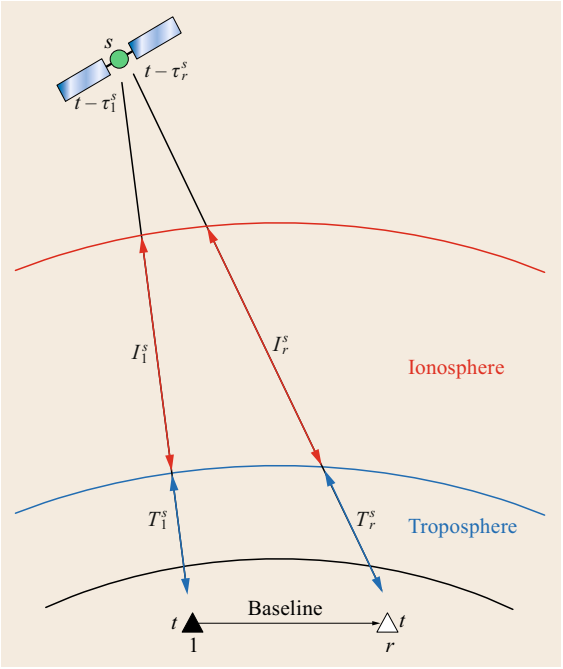

**Fig. 21.6** Relative GNSS positioning: two receivers (reference 1 and rover $r$) quasi-simultaneously receive signals from satellite $s$ at time $t$. On their ways, they propagate through the atmosphere (ionosphere and atmosphere), affecting their travel times (denoted as $\tau_1^s$ and $\tau_r^s$)

time of transmission

$$dt^s(t-\tau_1^s) = dt^s\left(t-\tau_r^s\right) \doteq dt^s(t-\tau^s)\,. \qquad (21.76)$$

### Code-Dominated DGNSS Positioning

Recall the (nonlinear) code observation equation (21.1). Its expectation can be given as

$$\begin{aligned} E(p_{r,j}^s(t)) = {} & \rho_r^s\left(t, t-\tau_r^s\right) + T_r^s(t) + \mu_j I_r^s(t) \\ & + c[dt_r(t) + d_{r,j}] \\ & - c\left[dt^s\left(t-\tau_r^s\right) - d_j^s\right]\,. \end{aligned} \qquad (21.77)$$

Now assume a reference receiver $r = 1$, which is stationed at a *known* location. Based on this known position together with the known position of the satellite (computed from the ephemeris), the range $\rho_1^s(t, t-\tau_1^s)$ can be computed. Subtracting the observed pseudorange from this computed range yields the *pseudorange corrections* (PRC) for satellite $s$

$$\mathrm{PRC}_{p,j}^s(t) = \rho_1^s\left(t, t-\tau_1^s\right) - p_{1,j}^s(t)\,. \qquad (21.78)$$

Applying these pseudorange corrections to the pseudoranges of a user $r$ yields, making use of (21.76)

$$\begin{aligned} E\left(\tilde{p}_{r,j}^s(t)\right) = {} & \rho_r^s\left(t, t-\tau_r^s\right) + T_{1r}^s(t) + \mu_j I_{1r}^s(t) \\ & + c[dt_{1r}(t) + d_{1r,j}]\,. \end{aligned} \qquad (21.79)$$

Here the corrected pseudorange reads

$$\tilde{p}_{r,j}^s(t) = p_{r,j}^s(t) + \mathrm{PRC}_{\mathrm{p},j}^s(t)\,.$$

Furthermore, *between-receiver differenced* unknown parameters are denoted as $(\cdot)_{1r} = (\cdot)_r - (\cdot)_1$. Thus, besides the elimination of satellite clocks and hardware delays, users employing the pseudorange corrections may significantly reduce the errors due to tropospheric and ionospheric delays. For sufficiently *short* distances, these differential atmospheric errors are so small (due to the spatial correlation of the atmosphere), compared to the measurement precision of the code data, that they may be neglected and disappear as unknown parameters. The combined differential receiver clock and hardware delay, that is, $c[dt_{1r}(t) + d_{1r,j}(t)]$, can be regarded as a receiver clock error to be solved by the user using a model which has the same structure as the SPP model discussed in the previous section.

Next to the pseudorange corrections, in practice usually also so-called *range-rate corrections* (RRC) are determined and transmitted (in real-time) to users, as to account for the difference between the time of determination of the corrections at the reference station ($t_0$) and the time the corrections are applied by the users ($t$)

$$\mathrm{PRC}_{p,j}^s(t) = \mathrm{PRC}_{p,j}^s(t_0) + (t-t_0)\mathrm{RRC}_{p,j}^s(t_0)\,, \qquad (21.80)$$

where $t-t_0$ is referred to as *latency*. It will be clear that the accuracy of the pseudorange corrections improves for smaller latencies.

Using the above concept of DGNSS, the positioning accuracy can be improved to 1–2 m. The accuracy can be improved further (to submeter level) by using *carrier-phase smoothing* (Chap. 20), but its performance is limited due to local receiver bias (multipath) and spatial decorrelation of the atmosphere.

### Phase-Dominated DGNSS (RTK or PPP-RTK) Positioning

For the carrier-phase observations, we can apply a similar technique as for code. The expectation of the (nonlinear) phase-observation equation reads (21.2)

$$\begin{aligned} E\left(\varphi_{r,j}^s(t)\right) = {} & \rho_r^s\left(t, t-\tau_r^s\right) + T_r^s(t) - \mu_j I_r^s(t) \\ & + c[dt_r(t) + \delta_{r,j}] + \lambda_j N_{r,j}^s \\ & - c\left[dt^s\left(t-\tau_r^s\right) - \delta_j^s\right]\,. \end{aligned} \qquad (21.81)$$

For a reference receiver 1, we can subtract the observed carrier-phase from the computed range, which yields the *phase-range corrections* (PRC) for satellite $s$

$$\mathrm{PRC}_{\varphi,j}^s(t) = \rho_1^s\left(t, t-\tau_1^s\right) - \varphi_{1,j}^s(t)\,. \qquad (21.82)$$

These phase-range corrections are in a next step applied to correct the carrier-phases of the user $r$, corresponding to the same satellite $s$

$$\begin{aligned} E\left(\tilde{\varphi}_{r,j}^s(t)\right) = {} & \rho_r^s\left(t, t-\tau_r^s\right) + T_{1r}^s(t) - \mu_j I_{1r}^s(t) \\ & + c[dt_{1r}(t) + \delta_{1r,j}] + \lambda_j N_{1r,j}^s\,. \end{aligned} \qquad (21.83)$$

Here the corrected carrier-phase reads $\tilde{\varphi}_{r,j}^s(t) = \varphi_{r,j}^s(t) + \mathrm{PRC}_{\varphi,j}^s(t)$. If the latency of the corrections equals zero, DGNSS positioning with phase (and code) is better known as the *real-time kinematic* (RTK) positioning technique. The accuracy of RTK positioning is at centimeter level (or better), *provided* that the carrier-phase ambiguities can be resolved to their integer values. We remark that the corrected phase-observation equations cannot be directly used for positioning as the system is (as with PPP) rank deficient. How to deal with this is discussed in Sect. 21.4.4.

In practice, under average ionospheric conditions, the differential atmospheric errors can be neglected for distances between the receivers up to about 10 km, and the positioning method is referred to as *short-baseline RTK*. Satellite orbit errors can also be ignored for these short distances (Sect. 21.4.2). RTK based on GPS is a proven positioning concept and when GPS is combined with other constellations even more promising results are obtained (e.g., [21.53] for RTK based on GPS with Galileo and [21.54] for GPS combined

with BeiDou). Extending the RTK technique to longer distances is possible, but then the differential atmospheric errors and orbit errors need to be taken into account (long-baseline RTK) [21.55, 56]. In case of *network RTK* corrections for the atmospheric delays are estimated from a network of surrounding reference stations and transmitted to users. More details about (network) RTK positioning can be found in Chap. 26. The technique of *PPP-RTK* [21.57] (or PPP-AR; AR = Ambiguity Resolution) also relies on correction information provided by a reference network, but the main difference with network RTK is that with PPP-RTK the correction are provided in the *parameter* space, while in case of network RTK the corrections are in the *observation* space. PPP-RTK is discussed in further detail in Sect. 21.4.5.

### 21.4.2 Impact of Orbit Errors

When linearizing the GNSS observation equations, the satellite positions are held fixed to their values as computed (per receiver) in the SPP processing. The accuracy of satellite positions computed from the broadcast ephemeris is at the level of a few meters, while based on precise ephemeris this is (for new constellations: expected) at the level of 5–10 cm [21.58]. Errors in these fixed satellite positions may negatively impact the estimated receiver position. If we denote the errors in the satellite position as vector $\triangle \boldsymbol{r}^s$, then its effect on the relative baseline is upper bounded according to the following rule-of-thumb [21.59]

$$\left|\left[\boldsymbol{e}^s_{1r}(t)\right]^\top \triangle \boldsymbol{r}^s(t)\right| \leq \frac{\|\boldsymbol{r}_{1r}(t)\|}{\|\boldsymbol{r}^s_r(t)\|}\|\triangle \boldsymbol{r}^s(t)\|\,, \qquad (21.84)$$

with $\boldsymbol{e}^s_{1r}(t) = \boldsymbol{e}^s_r(t) - \boldsymbol{e}^s_1(t)$ the between-receiver differenced LOS vector, $\boldsymbol{r}_{1r}(t) = \boldsymbol{r}_r(t) - \boldsymbol{r}_1(t)$ the relative receiver position (baseline) vector, and $\boldsymbol{r}^s_r(t) = \boldsymbol{r}^s(t) - \boldsymbol{r}_r(t)$ the receiver–satellite position vector. For example, the impact of an orbit error of 2 m on a baseline of 100 km is at most only 1 cm (assuming a 20 000 km receiver–satellite range). The above upper bound can also be used to assess the effect of differences in reference frames of the satellite positions in a multiconstellation case.

For longer baselines (and network-RTK or PPP-RTK) precise ephemeris should be used, restricting the impact of orbit errors on the receiver position.

### 21.4.3 Ionosphere-Fixed/Weighted/Float Models

Differential ionospheric delays generally become larger for increasing baseline lengths. To flexibly apply the models to a whole range of baseline lengths, the relative models presented in this section are presented for three different versions regarding the presence of the differential ionospheric delays.

For sufficiently short baselines the *ionosphere-fixed* model is presented, in which the differential ionospheric delays are absent. This corresponds to the assumption that the absolute ionospheric delays for a certain satellite are equal for all receivers, as they intersect the ionosphere in the same part, that is, $I^s_1(t) = I^s_r(t) \doteq I^s(t)$ (Fig. 21.7). For longer baselines the size of the differential ionospheric delays may be within certain bounds such that knowledge can be incorporated in the form of (soft) constraints. The resulting model is referred to as the *ionosphere-weighted* model. For even longer baselines, when we do not have any a-priori knowledge on the differential ionospheric delays, the ionospheric delays are assumed as completely unknown parameters. This is the *ionosphere-float* model. This terminology concerning the tuning of the ionospheric delays is adopted from [21.60].

### 21.4.4 Undifferenced Relative Positioning Models

In this subsection, the relative positioning model is presented based on the original *undifferenced, uncombined* observation equations for code and phase. The link with the models based on differenced observations will be

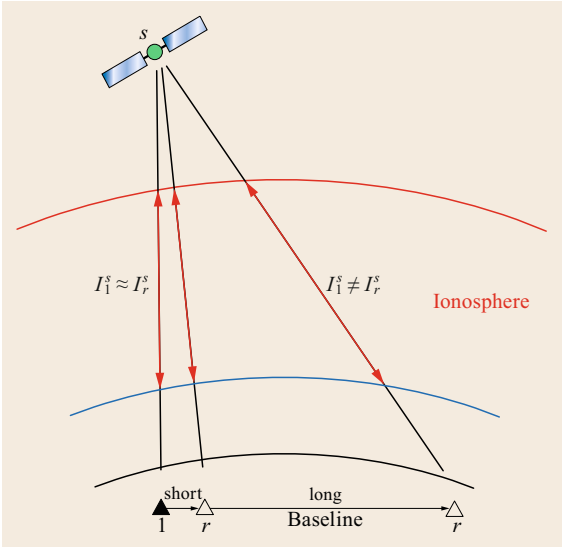

**Fig. 21.7** Visualization of propagation of GNSS signals through the ionosphere. Signals of receivers that are relatively close to each other travel through similar parts of the ionosphere, while more remote receivers experience a more different ionospheric delay

made later on in this chapter. An important advantage of the undifferenced model is that it is more flexible than differenced; this flexibility has been recognized already for a long time [21.18, 61–64]. For example, satellites that are only visible by some of the receivers in the network can still be used, while differencing algorithms can only process those satellites that are in view by *all* receivers. Another important advantage of the undifferenced model is that temporal constraints can be incorporated to parameters that would have been eliminated when differencing, for example, clocks or hardware delays. The undifferenced models that are presented in this section are assumed to be valid for a *network* of $n$ GNSS receivers. By simply setting $n = 2$ the results for a *single-baseline* model are obtained.

### Rank-Deficient Undifferenced Model

As with the undifferenced models for point positioning (Sect. 21.3), also for the relative positioning model based on undifferenced observations it is not possible to estimate all parameters uniquely because the system of observation equations is rank deficient. To overcome this rank deficiency, as in the case of the point positioning models, we apply the theory of S-systems (Chap. 22), resulting in linear combinations of parameters that are estimable. There is, however, not a unique way to choose the estimable linear combinations; in theory there are infinite possibilities. Different choices lead to different *interpretations* of the estimable parameters.

One choice leads to the so-called *distinct clocks* model, for which a receiver clock as well as a satellite clock parameter becomes estimable for each frequency for all code and phase data [21.18, 65]. Another choice results in a full-rank undifferenced model in which common receiver clock and satellite clock parameters become estimable. This is the so-called *common clocks* model [21.66, 67]. This model is reviewed here, as its estimable parameters have a clear link with those presented in the previous sections for SPP and PPP. The common clocks model as presented here applies to a general case of $f \geq 2$ frequencies.

### Regional Networks

For distances between the receivers that are smaller than about 500 km usually not the position and ZTD of all receivers are estimated in absolute sense by means of relative models, as the LOS vectors of the different receivers with respect to the same satellite become close to parallel, resulting in poorly estimable absolute positions and ZTDs [21.68]. In the extreme case, if the LOS vectors are assumed to be equivalent for the different receivers, that is, $\boldsymbol{g}_1^s(t) = \cdots = \boldsymbol{g}_n^s(t) \doteq \boldsymbol{g}^s(t)$ (21.72), this causes an additional rank deficiency in the network model. A common procedure to overcome this additional rank deficiency is to estimate the position and ZTD of all receivers relative to that of one of receivers (i. e., the so-called *pivot receiver*).

### Common Clocks Undifferenced Model

The estimable parameter functions corresponding to the common clocks model have been derived in [21.69] and are presented in Table 21.4. To differentiate the estimable parameters from their original counterparts, the estimable ones are denoted using a *tilde*. Concerning the interpretation, it can first of all be seen that all estimable parameters are a function of their original parameter, but biased by one or more other parameters. These other parameters are frequently the parameters corresponding to the pivot receiver and/or pivot satellite (for both we selected the first receiver and first satellite, denoted using a 1 subscript or superscript, but this could be any other receiver and satellite in the network).

The estimable receiver/ZTD parameters ($\tilde{\boldsymbol{x}}_r(t)$) are absolutely estimable for global networks and relatively estimable in case of a regional network. Absolutely is put between quotes here, as the receiver positions are still relative with respect to the satellite positions that are held fixed. The presence of the pivot receiver's position+ZTD is however *compensated* by their presence in the estimable satellite clock ($\tilde{dt}^s(t)$) from a regional network. This compensation holds for all biases present in a certain estimable parameter. Note that the estimable satellite clock can be written as a combination of ionosphere-free satellite clock, minus the ionosphere-free clock of the pivot receiver, plus (in case of a regional network) the pivot receiver's position and/or ZTD.

If the ionosphere is assumed to be *float* instead of fixed/weighted, this causes an additional rank deficiency, which leads to differences in interpretation of the estimable receiver clock ($\tilde{dt}_r(t)$), receiver phase and code delay ($\tilde{\delta}_{r,j}$ and $\tilde{d}_{r,j}$, respectively), as well as the estimable ionospheric delay ($\tilde{I}_r^s(t)$). Note the subtle difference in the interpretation of the estimable ionospheric delay between the ionosphere-weighted and ionosphere-float models: in the first case the DCB of the pivot receiver appears (i. e., $\mathrm{DCB}_{1,12}$), while in the second case it is the DCB corresponding to the receiver for which the ionospheric delay parameter is considered (i. e., $\mathrm{DCB}_{r,12}$). Furthermore, note that the interpretation of the ionospheric delay in case the ionosphere is float is exactly the same as the estimable ionospheric delay parameter of the dual-frequency PPP model in Table 21.3, if no satellite DCB corrections are applied.

Special attention needs the estimable satellite code delay parameter ($\tilde{d}_j^s$). From Table 21.4 it follows that it is estimable as a modernized DCB (i. e., frequency $j$ relative to frequency 1), however, with respect to the (traditional) DCB between the first two frequencies.

**Table 21.4** Estimable undifferenced parameters for the common clocks relative positioning model. Note: the (modernized) receiver DCB is defined as $\mathrm{DCB}_{r,1j}(t) = d_{r,1}(t) - d_{r,j}(t)$, while the (modernized) satellite DCB is defined as $\mathrm{DCB}^s_{1j}(t) = d^s_1(t) - d^s_j(t)$

| Estimable parameter | Notation and interpretation | Conditions |
|---|---|---|
| Receiver position/ZTD | $\tilde{\boldsymbol{x}}_r(t) = \boldsymbol{x}_r(t) \quad \underbrace{-\boldsymbol{x}_1(t)}_{\text{if regional network}}$ | $r \geq 1$ ($r \geq 2$ reg. net) |
| Receiver clock | $d\tilde{t}_r(t) = [dt_r(t) + d_{r,1}] - [dt_1(t) + d_{1,1}] \underbrace{+ \frac{\mu_1}{\mu_2 - \mu_1}[\mathrm{DCB}_{r,12} - \mathrm{DCB}_{1,12}]}_{\text{if ionosphere float}}$ | $r \geq 2$ |
| Receiver-phase delay | $\tilde{\delta}_{r,j} = \left[\delta_{r,j} - d_{r,1} + \frac{\lambda_j}{c} N^1_{r,j}\right] - \left[\delta_{1,j} - d_{1,1} + \frac{\lambda_j}{c} N^1_{1,j}\right] \underbrace{- \frac{\mu_j + \mu_1}{\mu_2 - \mu_1}[\mathrm{DCB}_{r,12} - \mathrm{DCB}_{1,12}]}_{\text{if ionosphere float}}$ | $r \geq 2\, j \geq 1$ |
| Receiver-code delay | $\tilde{d}_{r,j} = -[\mathrm{DCB}_{r,1j} - \mathrm{DCB}_{1,1j}] \underbrace{+ \frac{\mu_j - \mu_1}{\mu_2 - \mu_1}[\mathrm{DCB}_{r,12} - \mathrm{DCB}_{1,12}]}_{\text{if ionosphere float}}$ | $r \geq 2\, j \geq 2$ ($j \geq 3$ iono float) |
| Satellite clock | $d\tilde{t}^s(t) = \left[dt^s(t) - d^s_{\mathrm{IF}}\right] - [dt_1(t) + d_{1,\mathrm{IF}}] \underbrace{- [\boldsymbol{g}^s(t)]^\top \boldsymbol{x}_1(t)}_{\text{if regional network}}$ | $s \geq 1$ |
| Satellite-phase delay | $\tilde{\delta}^s_j = \left[\delta^s_j - d^s_{\mathrm{IF}} - \frac{\mu_j}{\mu_2 - \mu_1}\mathrm{DCB}^s_{12} + \frac{\lambda_j}{c} N^s_{1,j}\right] + \left[\delta_{1,j} - d_{1,\mathrm{IF}} - \frac{\mu_j}{\mu_2 - \mu_1}\mathrm{DCB}_{1,12}\right]$ | $s \geq 1\, j \geq 1$ |
| Satellite-code delay | $\tilde{d}^s_j = -\left[\mathrm{DCB}^s_{1j} - \frac{\mu_j - \mu_1}{\mu_2 - \mu_1}\mathrm{DCB}^s_{12}\right] - \left[\mathrm{DCB}_{1,1j} - \frac{\mu_j - \mu_1}{\mu_2 - \mu_1}\mathrm{DCB}_{1,12}\right]$ | $s \geq 1\, j \geq 3$ |
| Ionospheric delay | $\tilde{I}^s_r(t) = \begin{cases} I^s(t) - \frac{1}{\mu_2 - \mu_1} c\left[\mathrm{DCB}^s_{12} + \mathrm{DCB}_{1,12}\right] & \text{if ionosphere-fixed} \\ I^s_r(t) - \frac{1}{\mu_2 - \mu_1} c\left[\mathrm{DCB}^s_{12} + \mathrm{DCB}_{1,12}\right] & \text{if ionosphere-weighted } (r \geq 1) \\ I^s_r(t) - \frac{1}{\mu_2 - \mu_1} c\left[\mathrm{DCB}^s_{12} + \mathrm{DCB}_{r,12}\right] & \text{if ionosphere-float } (r \geq 1) \end{cases}$ | $s \geq 1$ |
| Phase ambiguities | $\tilde{N}^s_{r,j} = \left[N^s_{r,j} - N^s_{1,j}\right] - \left[N^1_{r,j} - N^1_{1,j}\right]$ | $r \geq 2\, s \geq 2\, j \geq 1$ |

This whole satellite-dependent DCB term is also relative to a similar DCB term, but then for the pivot receiver. As a consequence, satellite code parameters are only estimable when *at least three frequencies* are used (i. e., if $j \geq 3$, thus for example not in the legacy dual-frequency GPS case).

Concerning the phase ambiguities ($\tilde{N}^s_{r,j}$), they are estimable as *double-differenced* (DD) parameters, and thus integer valued, with respect to the network's pivot receiver and pivot satellite. By means of integer ambiguity resolution (Chap. 23), the network parameters can be estimated with the highest possible precision.

Based on the estimable undifferenced parameter functions, the system of *full-rank* GNSS network observation equations can be given as follows

$$
\begin{aligned}
E(\triangle p^s_{r,j}(t)) &= \boldsymbol{g}^s_{[r]}(t)^\top \tilde{\boldsymbol{x}}_r(t) + c[d\tilde{t}_r(t) + \tilde{d}_{r,j}] \\
&\quad - c[d\tilde{t}^s(t) - \tilde{d}^s_j] + \mu_j \tilde{I}^s_r(t), \quad r \geq 1\,, \\
E\left(\triangle \varphi^s_{r,j}(t)\right) &= \boldsymbol{g}^s_{[r]}(t)^\top \tilde{\boldsymbol{x}}_r(t) + c[d\tilde{t}_r(t) + \tilde{\delta}_{r,j}] \\
&\quad - c\left[d\tilde{t}^s(t) - \tilde{\delta}^s_j\right] - \mu_j \tilde{I}^s_r(t) + \lambda_j \tilde{N}^s_{r,j}\,, \\
r \geq 1\,, \quad &\left[E\left(I^s_r(t) - I^s_1(t)\right) = \tilde{I}^s_r(t) - \tilde{I}^s_1(t), r \geq 2\right].
\end{aligned}
\tag{21.85}
$$

Note that the between-receiver ionospheric constraints, which are included in the form of pseudo observation equations, only appear in case the ionosphere is weighted (that is why we denote them using square brackets).

The *redundancy* of the undifferenced network model reads in the ionosphere-fixed/weighted cases $(n-1)f(m-1) - 4n + (k-1)[n(2fm-1) - (2m-1) - 4n]$, where the 4 reflects the estimation of both positions and ZTD parameters in the network. In case of a regional network, the $4n$ is to be replaced by $4(n-1)$. In the ionosphere-float case it reads $(n-1)(f-1)(m-1) - 4n + (k-1)[n(\{2f-1\}m-1) - (m-1) - 4n]$, requiring one more frequency.

### 21.4.5 PPP-RTK Models

As discussed in Sect. 21.3.7, (standard) PPP is possible by applying satellite positions and clocks that are determined by a (global) reference network (and satellite DCBs in case of single-frequency PPP). This information is not sufficient for the single-receiver GNSS user to resolve the ambiguities in his carrier-phase observations to integer values, which is needed for high-precision PPP based on short convergence times.

The information that is lacking for integer ambiguity resolution enabled PPP (PPP-RTK or PPP-AR) are corrections for satellite phase and code biases, since these parameters hamper the estimable PPP ambiguities from being integer (Table 21.3).

If the reference network adopts an undifferenced model formulation, the crucial satellite phase and code bias information is among the estimable parameters. We emphasize that the choice of a common clocks network model (as done in the previous subsection) is not a prerequisite for PPP-RTK; the network may also adopt another S-system. In fact, the user does not even need to know the S-system of the network as he can equally apply corrections determined by networks that are based on different S-systems [21.69]. However, if the reference network adopts the common clocks model, the estimable satellite clocks are ionosphere-free parameters and this allows a direct comparison with the clocks of, for example, the IGS.

In the literature, other network models can be found that serve as basis for the generation of PPP-RTK corrections [21.35, 70–72]. Usually these network models are not based on strictly undifferenced observables, but on linear combinations between observables, of which the *ionosphere-free* and *Melbourne–Wübbena* combinations (Chap. 20) are frequently used. Consequently the hardware delay and ambiguity parameters estimated using these linear combinations of observables are in the form of *wide-lane* and *narrow-lane* combinations. One-to-one transformation formulas between the corrections of various PPP-RTK approaches are presented in [21.73].

As with the discussion of the models for PPP, in the following we make a distinction between PPP-RTK models without ionospheric corrections (ionosphere-float PPP-RTK model) and those including ionospheric corrections (ionosphere-corrected PPP-RTK model).

### Ionosphere-Float PPP-RTK Model

In the absence of ionospheric corrections, the PPP-RTK corrections for code and phase are the satellite clock as well as satellite code and phase-delay parameters from the common clocks network (and tropospheric and other corrections)

$$o_{p^s_{r,j}}(t) = c\left[d\tilde{t}^s(t) - \tilde{d}^s_j\right] - T^s_{r,0}(t)\,,$$
$$o_{\varphi^s_{r,j}}(t) = c\left[d\tilde{t}^s(t) - \tilde{\delta}^s_j\right] - T^s_{\mathrm{r},0}(t)\,. \qquad (21.86)$$

Here $\tilde{d}^s_j$ is only applied in case $j \geq 3$, that is, for code observations at a third or higher frequency. Thus, in the legacy dual-frequency GPS case it is not applied, but it is for the third frequency observations transmitted by the Block IIF GPS satellites.

If the PPP-RTK user adopts – like the network – a common clocks model, the estimable user parameters plus their interpretation automatically follow from Table 21.4 by regarding receiver $r$ to be the user receiver, instead of a network receiver. The difference is that there are no satellite clock as well as satellite phase and code bias parameters for the user, as these are corrected for. However, the interpretation of the estimable user's position+ZTD, receiver clock, phase delay, code delay, ionospheric delay, and ambiguity parameters is as given in the table, for the case the ionosphere is float. The only difference in the interpretation of the user parameters may be the pivot satellite, showing up in the estimable phase delays and ambiguities. It is namely not needed that the user should adopt the *same* pivot satellite as the network; this can be any of the satellites he has in view.

For the PPP-RTK user's position and ZTD it means that in case of a regional network they are – like for the network receivers – estimable relative to those of the pivot receiver in the network. In case the network pivot receiver's position is held fixed in the processing (a usual assumption in case of CORS networks, i. e., $\triangle r_1(t) = 0$), the estimable user's position is not relative to the network's pivot receiver; however the user's estimable ZTD parameter still is, that is,

$$\tilde{T}^z_r(t) = T^z_r(t) - T^z_1(t)\,.$$

The estimable PPP-RTK user's ambiguity is also relative, with respect to the network pivot receiver's ambiguity and with respect to an arbitrarily chosen pivot satellite $p$

$$\tilde{N}^s_{r,j} = \left[N^s_{r,j} - N^s_{1,j}\right] - \left[N^p_{r,j} - N^p_{1,j}\right]\,, \qquad (21.87)$$

for $s \neq p$ and $j \geq 1$. It is estimable as a double-differenced ambiguity and thus standard ambiguity resolution (LAMBDA) is applied to estimate the integer PPP-RTK ambiguities. Usually a three-step-procedure is followed to solve the position based on the integer ambiguities (Chap. 23).

If the (corrected) pseudorange and carrier-phase observables of, in general, $f$ frequencies are denoted as vectors $\triangle\tilde{\boldsymbol{p}}_r(t)$ and $\triangle\tilde{\boldsymbol{\varphi}}_r(t)$, respectively, the full-rank undifferenced, multifrequency PPP-RTK model is given in Table 21.5 (*second row*). It is emphasized that the receiver code bias parameters ($\tilde{d}_{r,j}$) only show up in case of triple- or higher frequency (i. e., $j \geq 3$) and are absent in a dual-frequency case.

### Ionosphere-Corrected PPP-RTK Model

The ionosphere-float PPP-RTK approach of which the model was presented in the previous section requires

**Table 21.5** Full-rank undifferenced multifrequency (MF) PPP-RTK models

MF PPP-RTK (ionosphere-corrected; $f \geq 1$):

$$E\left(\begin{bmatrix} \triangle\tilde{\boldsymbol{p}}_{r,1}(t) \\ \triangle\tilde{\boldsymbol{p}}_{r,2}(t) \\ \vdots \\ \triangle\tilde{\boldsymbol{p}}_{r,\mathrm{f}}(t) \\ \hline \triangle\tilde{\boldsymbol{\varphi}}_{r,1}(t) \\ \vdots \\ \triangle\tilde{\boldsymbol{\varphi}}_{r,\mathrm{f}}(t) \end{bmatrix}\right) = \left[\begin{array}{ccccccccccc} \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{G}_r(t) & \boldsymbol{u}_m & \boldsymbol{u}_m & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \vdots & \vdots & & \ddots & & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \hline \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \boldsymbol{u}_m & \dots & \mathbf{0} & \lambda_1\mathbf{C}_m & \dots & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \boldsymbol{u}_m & \mathbf{0} & \dots & \lambda_f\mathbf{C}_m \end{array}\right] \begin{bmatrix} \tilde{\boldsymbol{x}}_r(t) \\ c\tilde{d}\tilde{t}_r(t) \\ \hline c\tilde{d}_{r,2} \\ \vdots \\ c\tilde{d}_{r,\mathrm{f}} \\ \hline c\tilde{\delta}_{r,1} \\ \vdots \\ c\tilde{\delta}_{r,\mathrm{f}} \\ \hline \tilde{\boldsymbol{N}}_{r,1} \\ \vdots \\ \tilde{\boldsymbol{N}}_{r,\mathrm{f}} \end{bmatrix}$$

MF PPP-RTK (ionosphere-float; $f \geq 2$)

$$E\left(\begin{bmatrix} \triangle\tilde{\boldsymbol{p}}_{\mathrm{r},1}(t) \\ \triangle\tilde{\boldsymbol{p}}_{\mathrm{r},2}(t) \\ \triangle\tilde{\boldsymbol{p}}_{\mathrm{r},3}(t) \\ \vdots \\ \triangle\tilde{\boldsymbol{p}}_{r,\mathrm{f}}(t) \\ \hline \triangle\boldsymbol{\varphi}_{\mathrm{r},1}(t) \\ \vdots \\ \triangle\boldsymbol{\varphi}_{\mathrm{r},\mathrm{f}}(t) \end{bmatrix}\right) = \left[\begin{array}{ccccccccccc} \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mu_1\mathbf{I}_m & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mu_2\mathbf{I}_m & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{G}_r(t) & \boldsymbol{u}_m & \boldsymbol{u}_m & \dots & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mu_3\mathbf{I}_m & \mathbf{0} & \dots & \mathbf{0} \\ \vdots & \vdots & & \ddots & & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \mu_f\mathbf{I}_m & \mathbf{0} & \dots & \mathbf{0} \\ \hline \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \boldsymbol{u}_m & \dots & \mathbf{0} & -\mu_1\mathbf{I}_m & \lambda_1\mathbf{C}_m & \dots & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{G}_r(t) & \boldsymbol{u}_m & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \dots & \boldsymbol{u}_m & -\mu_f\mathbf{I}_m & \mathbf{0} & \dots & \lambda_f\mathbf{C}_m \end{array}\right] \begin{bmatrix} \tilde{\boldsymbol{x}}_r(t) \\ c\tilde{d}\tilde{t}_r(t) \\ \hline c\tilde{d}_{\mathrm{r},3} \\ \vdots \\ c\tilde{d}_{r,\mathrm{f}} \\ \hline c\tilde{\delta}_{\mathrm{r},1} \\ \vdots \\ c\tilde{\delta}_{r,\mathrm{f}} \\ \hline \tilde{\boldsymbol{I}}_r(t) \\ \hline \tilde{\boldsymbol{N}}_{\mathrm{r},1} \\ \vdots \\ \tilde{\boldsymbol{N}}_{r,\mathrm{f}} \end{bmatrix}$$

a relatively long time before the ambiguities have converged and the integers can be resolved. To speed this up, it is essential to incorporate ionospheric corrections. Global reference networks (such as the IGS network) provide ionospheric corrections in the form of GIMs. Although these global ionospheric corrections may serve standard PPP, for PPP-RTK, aiming at centimeter level precision, they are not precise enough. More precise ionospheric corrections can be generated by a *regional* reference network that better captures the spatial variation of the ionospheric delays than a global network.

A way to generate these regional ionospheric corrections is by means of *Kriging interpolation* [21.74] of the estimated ionospheric delays at the network receivers to the approximate location of the user [21.67]. The interpolation, carried out on a satellite-by-satellite basis, can be given as

$$I^s_{\tilde{r}}(t) = \boldsymbol{h}^\top_{\tilde{r}} \left[I^s_1(t), \dots, I^s_n(t)\right]^\top . \tag{21.88}$$

Here $\boldsymbol{h}_{\tilde{r}}$ denotes the $n$-vector performing the interpolation over the $n$ network receivers and $I^s_{\tilde{r}}(t)$ denotes the interpolated ionospheric delay at the (approximate) location of the user. The entries of the interpolation vector depend on the assumed spatial coherence of the ionosphere, as well as on the distances of the PPP-RTK user with respect to the network receivers. A property of the Kriging interpolation vector is that its entries add up to 1 (i. e., $\boldsymbol{h}^\top_{\tilde{r}}\boldsymbol{u}_n = 1$). At first sight there seems to be a problem to perform the interpolation, as it is based on the original, unbiased ionospheric delays, while the ionospheric parameters that are estimable are biased by other parameters. Fortunately this is not a prob-

lem, and the interpolation should simply be based on the estimable biased ionospheric parameters. If the network model is in the ionosphere-float common clocks S-system, the interpolation of the estimated network ionospheric corrections can then be written as

$$\tilde{I}^s_{\bar{r}}(t) = I^s_{\bar{r}}(t) - \frac{1}{\mu_2 - \mu_1} c \left[\mathrm{DCB}^s_{12} + \mathrm{DCB}_{\bar{r},12}\right] . \tag{21.89}$$

Thus, the interpolated ionospheric correction the PPP-RTK user should apply can be interpreted as the interpolated ionospheric delay itself, plus the satellite DCB (the interpolation does not affect this since it is the same for all receivers), minus the interpolated receiver DCB, that is,

$$\mathrm{DCB}_{\bar{r},12} = \boldsymbol{h}^\top_{\bar{r}} \left[\mathrm{DCB}_{1,12}, \ldots, \mathrm{DCB}_{n,12}\right]^\top .$$

The presence of the satellite DCB as a bias of the interpolated ionospheric corrections means that the user does not have to explicitly correct for it, as is the case when, for example, GIM-based ionospheric corrections are used.

The PPP-RTK corrections for code and phase can now be given as

$$\begin{aligned} o_{P^s_{r,j}}(t) &= c\left[d\tilde{t}^s(t) - \tilde{d}^s_j\right] - T^s_{r,0}(t) - \mu_j \tilde{I}^s_{\bar{r}}(t) , \\ o_{\varphi^s_{r,j}}(t) &= c\left[d\tilde{t}^s(t) - \tilde{\delta}^s_j\right] - T^s_{\mathrm{r},0}(t) + \mu_j \tilde{I}^s_{\bar{r}}(t) . \end{aligned} \tag{21.90}$$

It is assumed that the expectation of the user's predicted ionospheric delay corresponds to its true ionospheric delay, that is,

$$E\left(I^s_{\bar{r}}(t)\right) = E\left(I^s_r(t)\right) .$$

Like with the ionosphere-float PPP-RTK model, if in the ionosphere-corrected case the user adopts a common clocks model as well, his estimable position/ZTD, receiver clock, receiver hardware bias, and ambiguity parameters follow from Table 21.4 by regarding receiver $r$ to be the user receiver. Important to emphasize is that the *ionosphere-float* DCB parameters within the estimable receiver clock as well as receiver phase/code delay apply in this case as well, with the difference that $\mathrm{DCB}_{r,12}$ should be replaced by its network-interpolated counterpart $\mathrm{DCB}_{\bar{r},12}$. Important consequence is that the estimable receiver code DCB is already estimable for two frequencies (i. e., $j \geq 2$) instead of three.

The PPP-RTK model for the ionosphere-corrected case is given in Table 21.5 (*first row*). Note that as the ionospheric delays are corrected for there are no ionospheric parameters. Furthermore, the receiver code delays are estimable from the second frequency onward, in contrast to the ionosphere-float PPP-RTK model, where they are estimable only from the third frequency and higher. In the single-frequency ($f = 1$) case, the model reduces to the PPP model given in Table 21.3 (SF-PPP ionospheric-correction).

### 21.4.6 Link Between PPP-RTK and PPP

If the full-rank PPP-RTK design matrix in Table 21.5 is considered for two frequencies (i. e., $f = 2$), such that the part for the receiver code biases disappears, it is exactly *identical* to the full-rank design matrix corresponding to dual-frequency standard PPP (Table 21.3) (*DF PPP iono-float*). Although the interpretation of the parameters differs between PPP and PPP-RTK, the solution of PPP and PPP-RTK with the ambiguities treated as float are identical. Hence, standard PPP can be considered as a *special case* of PPP-RTK. In relation to this, it follows from the interpretations that the satellite phase biases, that is, $\tilde{\delta}^s_j$, exactly correct for the bias that is inside the PPP ambiguities in order to make them become PPP-RTK ambiguities and thus integer. Thus, in general

$$\left[\tilde{N}^s_{r,j}\right]_{\mathrm{PPP}} - \frac{c}{\lambda_j}\left[\tilde{\delta}^s_j - \tilde{\delta}^p_j\right] = \left[\tilde{N}^s_{r,j}\right]_{\mathrm{PPP\text{-}RTK}} . \tag{21.91}$$

Here $[\tilde{N}^s_{r,j}]_{\mathrm{PPP}}$ denotes the estimable PPP ambiguity of which its interpretation is given in Table 21.3 and $[\tilde{N}^s_{r,j}]_{\mathrm{PPP\text{-}RTK}}$ denotes the estimable integer PPP-RTK ambiguity as in (21.87). Thus, when the estimable between-satellite differenced satellite phase bias is subtracted from the estimable PPP ambiguities, the estimable integer PPP-RTK ambiguities are obtained.

## 21.5 Differenced Positioning Models

Differencing techniques are traditionally applied in GNSS processing to reduce the amount of unknowns and observations. However, they may also result in a loss of information, for example, in the multiepoch case incorporating temporal constraints on parameters which would otherwise be eliminated by means of differencing. This section briefly presents the differenced versions of the single-constellation positioning models presented earlier in this chapter. Although not discussed in detail, we mention that differencing causes (mathematical) correlation between the differenced observations and this should be appropriately taken into account through the variance–covariance matrix of the observations.

### 21.5.1 Single Differencing

Differencing the observations with respect to a chosen pivot satellite removes the receiver-dependent parameters from the models (Fig. 21.8a). This section presents the between-satellite differenced versions of the SPP, PPP, and PPP-RTK models.

#### Between-Satellite Differenced SPP Model

Taking the differences of the code observables between satellite $s$ and (pivot) satellite $p$, the single-differenced, single-frequency SPP model (21.50) becomes

$$E\left(\mathbf{D}_m^\top \triangle\tilde{\boldsymbol{p}}_{r,j}(t)\right) = \left[\mathbf{D}_m^\top \mathbf{G}_r(t)\right] \triangle\boldsymbol{r}_r(t)\ . \tag{21.92}$$

Here the $(m-1)\times m$ (transposed) *differencing matrix* is defined as

$$\mathbf{D}_m^\top = \begin{bmatrix} \mathbf{I}_{p-1} & -\boldsymbol{u}_{p-1} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{u}_{m-p} & \mathbf{I}_{m-p} \end{bmatrix}. \tag{21.93}$$

A property of this differencing matrix is that $\mathbf{D}_m^\top \boldsymbol{u}_m = \mathbf{0}$. In the *dual-frequency* case in which atmospheric delays are estimated, see (21.53) for the undifferenced dual-frequency SPP model, its between-satellite differenced counterpart becomes

$$E\left(\begin{bmatrix}\mathbf{D}_m^\top \triangle\tilde{\boldsymbol{p}}_{r,1}(t)\\ \mathbf{D}_m^\top \triangle\tilde{\boldsymbol{p}}_{r,2}(t)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{D}_m^\top \mathbf{G}_r(t) & \mu_1\mathbf{I}_{m-1}\\ \mathbf{D}_m^\top \mathbf{G}_r(t) & \mu_2\mathbf{I}_{m-1}\end{bmatrix}\begin{bmatrix}\triangle\boldsymbol{r}_r(t)\\ \mathbf{D}_m^\top\tilde{\boldsymbol{I}}_r(t)\end{bmatrix}. \tag{21.94}$$

The between-satellite differenced ionospheric delay, which is denoted as vector $\mathbf{D}_m^\top\tilde{\boldsymbol{I}}_r(t)$, is free of the receiver DCB term, which appears in the undifferenced case (21.54).

#### Between-Satellite Differenced Multiconstellation SPP Model

In the presence of observations of two constellations, the SPP model in its undifferenced form was given in (21.59), assuming one frequency per constellation. In this case, the between-satellite differencing can be carried out in different ways. A first way is to choose a pivot satellite for each constellation and difference the observations corresponding to its own constellation-specific pivot satellite. A second way is to difference the observations of both constellations to one *common* pivot satellite.

In the first case, using a pivot satellite for each constellation, the between-satellite differenced model reads simply

$$E\left(\begin{bmatrix}\mathbf{D}_{m_\mathrm{A}}^\top \triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{A}}(t)\\ \mathbf{D}_{m_\mathrm{B}}^\top \triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{B}}(t)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{D}_{m_\mathrm{A}}^\top \mathbf{G}_r^{\mathrm{A}}(t)\\ \mathbf{D}_{m_\mathrm{B}}^\top \mathbf{G}_r^{\mathrm{B}}(t)\triangle\boldsymbol{r}_r(t)\end{bmatrix}. \tag{21.95}$$

Here $m_\mathrm{A}$ and $m_\mathrm{B}$ denote the number of satellites for constellation A and B, respectively. Compared to its undifferenced counterpart in (21.59), the receiver clock common for both constellations, as well as the ISB parameter for the observations of constellation B, have been eliminated. In the second case, where the observations of both are differenced with respect to the pivot satellite selected from constellation A, the between-satellite differenced model reads

$$E\left(\mathbf{D}_{m_\mathrm{A}+m_\mathrm{B}}^\top \begin{bmatrix}\triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{A}}(t)\\ \triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{B}}(t)\end{bmatrix}\right) = \left[\left\{\mathbf{D}_{m_\mathrm{A}+m_\mathrm{B}}^\top \begin{pmatrix}\mathbf{G}_r^{\mathrm{A}}(t)\\ \mathbf{G}_r^{\mathrm{B}}(t)\end{pmatrix}\right\}\begin{pmatrix}\mathbf{0}\\ \boldsymbol{u}_{m_\mathrm{B}}\end{pmatrix}\right]\begin{bmatrix}\triangle\boldsymbol{r}_r(t)\\ c\mathrm{ISB}_{r,j}^{\mathrm{AB}}\end{bmatrix}. \tag{21.96}$$

Here $\mathbf{D}_{m_\mathrm{A}+m_\mathrm{B}}^\top$ denotes the $(m_\mathrm{A}+m_\mathrm{B}-1)\times(m_\mathrm{A}+m_\mathrm{B})$ difference matrix. Due to the differencing between constellations the ISB parameter is not eliminated. Both models (21.95) and (21.96) are however equivalent in terms of redundancy and positioning solution. Although model (21.96) has one parameter more than model (21.95), it has also one more observation. However, the situation changes if the ISB can be assumed known. In that case, the observations of constellation B can be corrected for it such that model (21.96) reduces to

$$E\left(\mathbf{D}_{m_\mathrm{A}+m_\mathrm{B}}^\top \begin{bmatrix}\triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{A}}(t)\\ \triangle\tilde{\boldsymbol{p}}_{r,j}^{\mathrm{B}}(t)'\end{bmatrix}\right) = \left[\mathbf{D}_{m_\mathrm{A}+m_\mathrm{B}}^\top \begin{pmatrix}\mathbf{G}_r^{\mathrm{A}}(t)\\ \mathbf{G}_r^{\mathrm{B}}(t)\end{pmatrix}\right]\triangle\boldsymbol{r}_r(t)\ . \tag{21.97}$$

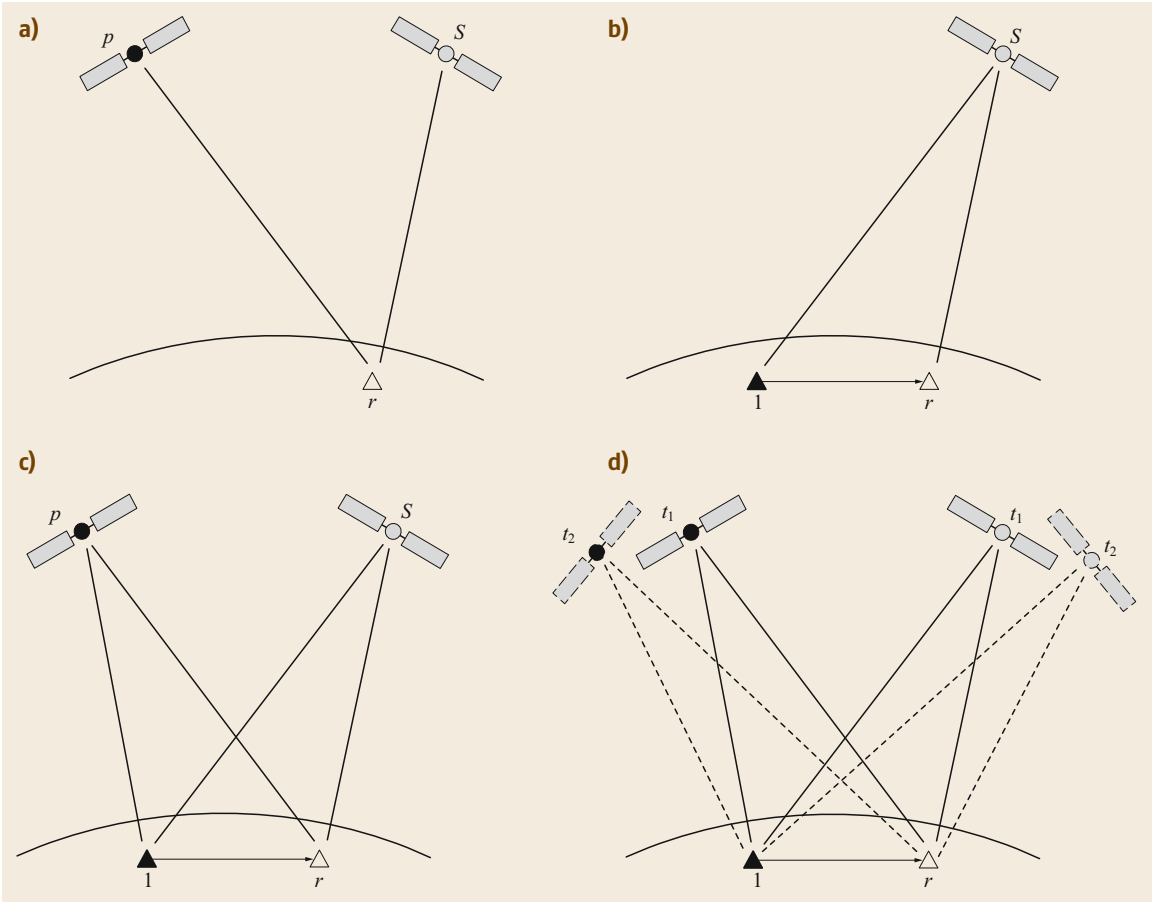

**Fig. 21.8a–d** Various differencing strategies: **(a)** between-satellite single differencing; **(b)** between-receiver single differencing; **(c)** double differencing; **(d)** triple differencing

As a consequence, the above ISB-corrected model can be considered as a *single-constellation model*, similar to (21.92), but now with $m_A + m_B$ satellites.

#### Between-Satellite Differenced PPP(-RTK) Model

In case of single-constellation, single-frequency (ionosphere-corrected) PPP(-RTK), between-satellite differencing results in the following observation (Table 21.3)

$$E\left(\begin{bmatrix}\mathbf{D}_m^\top \triangle\tilde{\boldsymbol{p}}_{r,j}(t)\\ \mathbf{D}_m^\top \triangle\tilde{\boldsymbol{\varphi}}_{r,j}(t)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{D}_m^\top \mathbf{G}_r(t) & \mathbf{0}\\ \mathbf{D}_m^\top \mathbf{G}_r(t) & \lambda_j \mathbf{I}_{m-1}\end{bmatrix}\begin{bmatrix}\boldsymbol{x}_r(t)\\ \tilde{\boldsymbol{N}}_{r,j}\end{bmatrix} . \quad (21.98)$$

Here use is made of the property that $\mathbf{D}_m^\top \mathbf{C}_m = \mathbf{I}_{m-1}$. We remark that the interpretation of the estimable ambiguity parameters does not change as a consequence of the between-satellite differencing, because in the undifferenced model they are already estimable as between-satellite differences, see Table 21.3 in case of PPP and (21.87) in case of PPP-RTK.

In the multifrequency case, with the ionospheric delays as unknown parameters, the between-satellite differencing applied to the PPP-RTK model in Table 21.5 results in the model presented in Table 21.6.

### 21.5.2 Double and Triple Differencing

#### Double-Differenced Relative Positioning Model

For the Relative Positioning models, as discussed in Sect. 21.4, between-satellite differencing can be applied as well, as to remove the receiver-dependent parameters from the models. Alternatively, since multiple receivers are involved that observe the same satellites, one may difference the observations of the same satellite between each receiver and a chosen pivot receiver. This is *between-receiver* differencing (Fig. 21.8b), which

**Table 21.6** Full-rank, between-satellite differenced, ionosphere-float, multifrequency, PPP-RTK model

$$E\left(\begin{bmatrix}\mathbf{D}_m^\top\triangle\tilde{\boldsymbol{p}}_{r,1}(t)\\ \vdots\\ \mathbf{D}_m^\top\triangle\tilde{\boldsymbol{p}}_{r,f}(t)\\ \hline \mathbf{D}_m^\top\triangle\tilde{\boldsymbol{\varphi}}_{r,1}(t)\\ \vdots\\ \mathbf{D}_m^\top\triangle\tilde{\boldsymbol{\varphi}}_{r,f}(t)\end{bmatrix}\right)=\left[\begin{array}{ccccc}\mathbf{D}_m^\top\mathbf{G}_r(t) & \mu_1\mathbf{I}_{m-1} & \mathbf{0} & \dots & \mathbf{0}\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ \mathbf{D}_m^\top\mathbf{G}_r(t) & \mu_f\mathbf{I}_{m-1} & \mathbf{0} & \dots & \mathbf{0}\\ \hline \mathbf{D}_m^\top\mathbf{G}_r(t) & -\mu_1\mathbf{I}_{m-1} & \lambda_1\mathbf{I}_{m-1} & \dots & \mathbf{0}\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ \mathbf{D}_m^\top\mathbf{G}_r(t) & -\mu_f\mathbf{I}_{m-1} & \mathbf{0} & \dots & \lambda_f\mathbf{I}_{m-1}\end{array}\right]\left[\begin{array}{c}\tilde{\boldsymbol{x}}_r(t)\\ \hline \mathbf{D}_m^\top\tilde{\boldsymbol{I}}_r(t)\\ \hline \tilde{\boldsymbol{N}}_{r,1}\\ \vdots\\ \tilde{\boldsymbol{N}}_{r,\mathrm{f}}\end{array}\right]$$

removes the satellite-dependent parameters from the models. This means that both receiver-dependent and satellite-dependent parameters can be eliminated by either taking the between-receiver difference of two between-satellite differences, or taking the between-satellite difference of two between-receiver (Fig. 21.8c). As a consequence one obtains the well-known *double-differenced* positioning model.

In case the ionosphere is float, the double-differenced model has the same structure as the between-satellite differenced PPP-RTK model in Table 21.6, but instead of single-differenced observables the observables are double differenced. In addition, the ionospheric parameters are estimated as double differences as well (the estimable ambiguities are already double differenced in the full-rank between-satellite differenced model). For a double-differenced model, it is implicitly assumed that the network or baseline is of regional size such that the geometry matrices in the design matrix are identical for all receivers, that is, $\mathbf{G}_1(t) = \cdots = \mathbf{G}_n(t) \doteq \mathbf{G}(t)$, and relative position/ZTD parameters are estimated, that is, $\tilde{\boldsymbol{x}}_r(t) = \boldsymbol{x}_r(t) - \boldsymbol{x}_1(t)$.

#### Triple-Differenced Relative Positioning Model

From the double-differenced model, one could go one step further, by taking differences of two double differences in time, so as to eliminate the ambiguity parameters from the relative positioning model (provided that no cycle slips have occurred between the two epochs). As a result one obtains the *triple-differenced* model (Fig. 21.8d). However, triple differencing removes the possibility of taking advantage of the integer nature of these double-differenced ambiguities, which is the key requirement for obtaining high-precision positions. Other drawbacks of triple differencing is that it is only possible to estimate the receiver's position *change in time* and that it creates time correlation between the observations. Therefore it not recommended to base the relative positioning model on triple-differenced observations.

### 21.5.3 Redundancy of the Differenced Models

The *redundancy* (number of observations minus number of estimable parameters) of the differenced models is exactly identical to those of the undifferenced versions of the models, as the models are reduced with the same number of estimable parameters as observations. This, however, only applies to the *single-epoch* case. In the multiepoch case the redundancy of the undifferenced models start to outperform that of the differenced models if temporal constraints on the parameters are included [21.69].

## 21.6 The Positioning Concepts Related

This chapter provided an overview of the models underlying the various positioning concepts. We end this chapter with a summary of how these positioning concepts are related to each other. Figure 21.9 presents in a schematic way the various positioning concepts. They basically differ in the way whether they are dominated by either code data or phase data, and at the scale the correction data are provided by the reference stations.

### 21.6.1 Global Positioning: SPP/PPP

At a *global* scale, *absolute* positioning can be realized by means of SPP or PPP. In case of SPP, based on code observations, global reference network data are employed in the form of the broadcast navigation data. In other words, the orbits, clocks, and atmospheric data that are broadcast by the GNSS satellites are products that are determined by the GNSS ground control network. PPP employs phase observations in addition to code, as well as precise corrections for orbit, clocks,

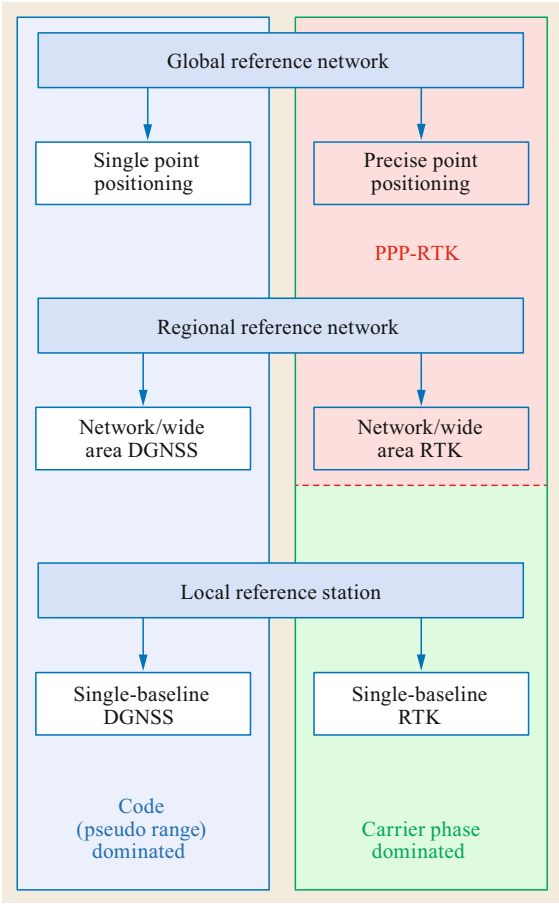

**Fig. 21.9** GNSS-based positioning concepts: SPP versus PPP that are both based on products provided by global reference network data (*top*); network DGNSS versus network RTK that are both based on products provided by regional reference network data (*middle*); single-baseline DGNSS versus single-baseline RTK that are both based on local reference station data (*bottom*). PPP-RTK can be regarded as a method that is conceptually equivalent to PPP, but provides the positioning accuracy of network/wide-area RTK

and ionosphere, which are also products of a global reference network (e.g., the IGS network).

### 21.6.2 Regional Positioning: Network DGNSS/RTK

At a more *regional* scale, covering an area with a radius of typically 500 km or less, we have the code-dominated network DGNSS technique, versus the phase-dominated network RTK technique, where positioning is done relative to a network of reference stations [21.75]. Correction data are determined by the network and transmitted to users operating within the coverage area of the network. Network DGNSS is also known as wide-area DGNSS [21.76]. In case of network RTK the network processing is based on ambiguity resolution (Chap. 23) as to provide the most precise corrections to users, who employ ambiguity resolution themselves as to obtain positions with centimeter level accuracy. In practice several network-RTK implementations exist (Chap. 26). Crucial to the performance of both network DGNSS and network RTK are the (quality of the) corrections for the differential ionospheric delays, which are determined by the network over the coverage area.

### 21.6.3 Local Positioning: Single-Baseline DGNSS/RTK

At a *local* scale, the reference data are provided by a single reference station, located in the vicinity of the user receiver, such that the differential ionospheric delays can be neglected. This leads to code-dominated single-baseline DGNSS, and phase-dominated single-baseline RTK, the latter method relying on phase integer ambiguity resolution. RTK positioning is also referred to as *carrier-phase based DGNSS* for which the differential ionospheric delays may be neglected for baseline lengths up to about 10 km (under average ionospheric conditions). The maximum baseline distance of single-baseline DGNSS, which is at most about 100 km, is longer than for single-baseline RTK, since the noisier code data allow more residual differential ionospheric delays than the precise phase data in case of RTK. Extending the operational distance of single-baseline RTK is possible, up to hundreds of kilometers [21.55], however then the ionospheric delays need to be modeled as unknown parameters, leading to longer convergence times.

### 21.6.4 Global/Regional Positioning: PPP-RTK

PPP-RTK can be considered as a mixture of PPP and RTK: it is conceptually PPP, but based on resolving the integer phase ambiguities as to as to obtain the positioning accuracy of (network) RTK. PPP-RTK can either be based on global or regional network products, where satellite phase bias corrections are crucial for integer ambiguity resolution and therefore centimeter level accuracy. In the absence of these satellite phase biases, PPP-RTK reduces to standard PPP. In a triple- or higher frequency case also satellite code bias corrections are required. Essential to fast integer ambiguity resolution are precise ionospheric corrections. In contrast to network RTK, in case of PPP-RTK the correction infor-

**Table 21.7** Typical values for GPS positioning accuracy, convergence time, and coverage area for different positioning concepts. Note: SF = single-frequency; DF = dual-frequency

| Positioning concept | Accuracy (1-sigma) | Convergence time | Coverage area |
|---|---|---|---|
| SF SPP | < 10 m | Instantaneous | Global |
| SF PPP (GIM-based) | 1–2 dm | < 10 min | Global |
| DF PPP (ionosphere-float) | < 1 dm | 30 min (static)<br>60 min (kin.) | Global |
| Single-baseline (code-based) DGNSS | 1–5 m | Instantaneous | Regional/local |
| Wide area DGNSS | 0.5–2m | Instantaneous | Regional |
| SF RTK-short baseline | < 1 dm | 10 min | Local |
| DF RTK-short baseline | < 1 dm | Instantaneous to few min | Local |
| Network RTK | < 1 dm | < 10 min | Regional |
| SF PPP-RTK (precise iono corrections) | < 1 dm | < 10 min | Regional |
| DF PPP-RTK | < 1 dm | 30 min (static) | Global |
| (ionosphere-float) | < 1 dm | 90 min (kin.) | Regional |

mation is provided to the user in the parameter or state space, whereas in case of network RTK this is in the observation space [21.57]. A drawback of transmitting the corrections in the observation space is that a higher update rate is required than for corrections in the parameter space, as some parameters are (almost) time constant.

### 21.6.5 Accuracy of the Positioning Concepts

The attainable *positioning accuracy* using the concepts in the left column of Fig. 21.9 is driven by the precision of the pseudorange data, while the accuracy of the concepts in the right column is driven by the carrier-phase precision. Table 21.7 summarizes typical values of the accuracy, which can be obtained using the discussed positioning concepts. These numbers hold after a certain (convergence) time that is needed for the position to attain a certain accuracy. The positioning accuracy of single-frequency (GPS) PPP incorporating global ionospheric corrections is typically at decimeter level within a few minutes [21.77]. The positioning accuracy of dual-frequency (GPS) PPP can reach centimeter level however only after a convergence time that may last for more than 30 min [21.52]. Decimeter-level accuracy of dual-frequency (GPS) PPP after a convergence of 40 min was demonstrated for a kinematic receiver in [21.78]. A similar level of accuracy of dual-frequency PPP based on convergence times of 10–30 min was demonstrated by [21.79]. The positioning accuracy of single-baseline DGNSS (DGPS) is 1–5 m and can be obtained instantaneously. With network or wide-area DGPS the accuracy lies in the range 0.5–2 m [21.80]. In case of dual-frequency integer ambiguity resolution enabled PPP centimeter-level accuracy is feasible after about 30 min in case of a static receiver, and about 90 min in case of a kinematic receiver [21.81]. The convergence time of tens of minutes in case of dual-frequency PPP and PPP-RTK is due to the presence of the ambiguities, next to the ionospheric delays.

# 22. Least-Squares Estimation and Kalman Filtering

Sandra Verhagen, Peter J.G. Teunissen

This chapter presents the estimation and filtering principles as used in global navigation satellite system (GNSS) data processing. Estimation and filtering are concerned with retrieving or recovering parameters of interest from noisy measurements. The least-squares (LS) principle is the standard approach for estimating unknown parameters from uncertain data. Various forms of LS estimation, such as partitioned-LS, recursive-LS, constrained-LS, and nonlinear-LS, are discussed.

The parameters of interest, as well as the dominant error sources, are often time varying. If these time variations can be modeled, the parameters can be resolved based on minimum mean squared error prediction, filtering, and smoothing techniques. Of the various such techniques, the Kalman filter is most prominent. It recursively estimates the state of a dynamic system. Different forms of the Kalman filter are discussed, together with its linkage to recursive smoothing techniques. Several GNSS examples are included in support of the general introduction on the principles and properties of LS estimation and Kalman filtering.

## 22.1 Linear Least-Squares Estimation

GNSS observations are, like all empirical data, subject to uncertainty – measurements are never perfect. Moreover, we generally have *redundant* measurements: There are more observations available than strictly needed for estimating the parameters of interest. In this section, we introduce the principle of least-squares (LS) estimation for solving overdetermined systems, that is, estimation problems with redundant measurements. Due to the uncertainty of the measurements, the redundancy generally leads to *inconsistent* systems of equations; estimating the parameters with different subsets of the observations will then lead to different solutions. The LS method ensures that still a unique solution can be obtained by imposing additional criteria. This section explains the LS principle and its properties.

### 22.1.1 Least-Squares Principle

The objective is to obtain estimates of $n$ unknown parameters $x_j, j = 1, \ldots, n$ from a set of $m$ measurements

$y_i, i = 1, \ldots, m$. If there is a linear relationship between the measurements and the unknown parameters, the following linear system of equations is obtained

$$\boldsymbol{y} = \mathbf{A}\boldsymbol{x} \tag{22.1}$$

with the $m$-vector $\boldsymbol{y} = [y_1, \ldots, y_m]^\top$, unknown parameter vector $\boldsymbol{x} = [x_1, \ldots, x_n]^\top$, and an $m \times n$ coefficient matrix $\mathbf{A}$.

In general, the system of equations is overdetermined and

$$m > n = \operatorname{rank}(\mathbf{A}) \,. \tag{22.2}$$

Hence, we assume that the matrix $\mathbf{A}$ is of full column rank.

Due to measurement errors, this generally implies that the system in (22.1) is inconsistent, since it is not possible to find a solution $\boldsymbol{x}$ which exactly reproduces $\boldsymbol{y}$, and consequently we can only have $\boldsymbol{y} \approx \mathbf{A}\boldsymbol{x}$. The LS principle can then be applied to solve this problem. The idea is to explicitly add the measurement error vector $\boldsymbol{e}$ to the system of equations

$$\boldsymbol{y} = \mathbf{A}\boldsymbol{x} + \boldsymbol{e} \,. \tag{22.3}$$

Since the measurement errors are unknown, this leads to a total of $m+n$ unknown parameters in $m$ equations and consequently an infinite number of solutions exists for $\boldsymbol{x}$. The solution of $\boldsymbol{x}$ is selected using the sum of squares of the entries of $\boldsymbol{e}$ as a measure of the discrepancy between $\boldsymbol{y}$ and $\mathbf{A}\boldsymbol{x}$. More specifically, the LS solution $\hat{\boldsymbol{x}}$ of $\boldsymbol{x}$, which minimizes this sum of squares $\boldsymbol{e}^\top\boldsymbol{e} = (\boldsymbol{y} - \mathbf{A}\boldsymbol{x})^\top(\boldsymbol{y} - \mathbf{A}\boldsymbol{x})$ is chosen [22.1, 2]

$$\begin{aligned}\hat{\boldsymbol{x}} &= \arg\min_{\boldsymbol{x}\in\mathbb{R}^n} (\boldsymbol{y} - \mathbf{A}\boldsymbol{x})^\top(\boldsymbol{y} - \mathbf{A}\boldsymbol{x}) \\ &= (\mathbf{A}^\top\mathbf{A})^{-1}\mathbf{A}^\top\boldsymbol{y} \,.\end{aligned} \tag{22.4}$$

The difference between $\boldsymbol{y}$ and adjusted $\hat{\boldsymbol{y}} = \mathbf{A}\hat{\boldsymbol{x}}$ is called the vector of LS residuals

$$\hat{\boldsymbol{e}} = \boldsymbol{y} - \mathbf{A}\hat{\boldsymbol{x}} \,. \tag{22.5}$$

In this way, the scalar inconsistency of the LS is measured by $\|\hat{\boldsymbol{e}}\|^2 = \hat{\boldsymbol{e}}^\top\hat{\boldsymbol{e}}$.

It is also possible to give a geometric interpretation to the LS principle. The estimated $\hat{\boldsymbol{y}}$ with parameter vector $\hat{\boldsymbol{x}}$ follows as

$$\hat{\boldsymbol{y}} = \mathbf{A}\hat{\boldsymbol{x}} = \mathbf{A}(\mathbf{A}^\top\mathbf{A})^{-1}\mathbf{A}^\top\boldsymbol{y} = \mathbf{P}_\mathbf{A}\boldsymbol{y} \tag{22.6}$$

with $\mathbf{P}_\mathbf{A}$ being an orthogonal projector. This shows that $\hat{\boldsymbol{y}} = \mathbf{A}\hat{\boldsymbol{x}}$ is the orthogonal projection of $\boldsymbol{y}$ onto the range space of $\mathbf{A}$.

This can also be illustrated as follows. For the observation vector, we have that $\boldsymbol{y} \in \mathbb{R}^m$, but according to our model, $\mathbf{A}\boldsymbol{x}$ must be in the range space $R(\mathbf{A})$ spanned by the columns of $\mathbf{A}$. Therefore, for the solution $\hat{\boldsymbol{x}}$ it is required that $\mathbf{A}\hat{\boldsymbol{x}} \in R(\mathbf{A})$, and with LS the solution with the shortest distance to $\boldsymbol{y}$ is selected. This implies that it is the orthogonal projection of $\boldsymbol{y}$ onto $R(\mathbf{A})$, as illustrated in Fig. 22.1.

### 22.1.2 Weighted Least-Squares

In practice it might be that not all observations $y_i$ have the same precision, and then it makes sense to give more weight to observations with higher precision. The principle of weighted least-squares (WLS) allows us to consider different weights by minimizing the weighted sum of squared residuals $\|\boldsymbol{e}\|^2_{\mathbf{W}^{-1}} = \boldsymbol{e}^\top\mathbf{W}\boldsymbol{e}$, where $\mathbf{W}$ is the weight matrix with the weights $w_{ii} > 0, i = 1, \ldots, m$ as diagonal elements. The weight matrix must be positive definite, but is not necessarily a diagonal matrix.

The WLS solution equals

$$\begin{aligned}\hat{\boldsymbol{x}} &= \arg\min_{\boldsymbol{x}\in\mathbb{R}^n} (\boldsymbol{y} - \mathbf{A}\boldsymbol{x})^\top\mathbf{W}(\boldsymbol{y} - \mathbf{A}\boldsymbol{x}) \\ &= (\mathbf{A}^\top\mathbf{W}\mathbf{A})^{-1}\mathbf{A}^\top\mathbf{W}\boldsymbol{y} \,.\end{aligned} \tag{22.7}$$

A logical choice for the weight matrix is $\mathbf{W} = \mathbf{Q}_{yy}^{-1}$ with $\mathbf{Q}_{yy}$ being the variance–covariance matrix of the observables. The reason is that it makes sense to give a larger weight to more precise measurements, and a smaller weight to less precise measurements.

### 22.1.3 Computation of LS Solution

The WLS problem is to solve the system of normal equations

$$\mathbf{A}^\top\mathbf{W}\mathbf{A}\hat{\boldsymbol{x}} = \mathbf{A}^\top\mathbf{W}\boldsymbol{y} \tag{22.8}$$

with normal matrix $\mathbf{N} = \mathbf{A}^\top\mathbf{W}\mathbf{A}$. The right-hand side will be denoted as $\boldsymbol{r} = \mathbf{A}^\top\mathbf{W}\boldsymbol{y}$. The WLS solution can be computed by inverting the normal equations

$$\hat{\boldsymbol{x}} = \mathbf{N}^{-1}\boldsymbol{r} \,. \tag{22.9}$$

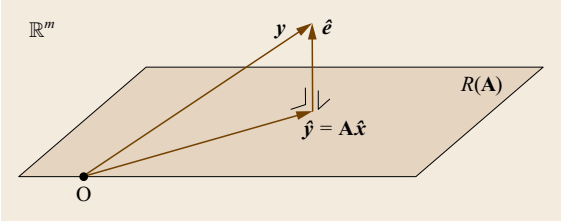

**Fig. 22.1** Geometry of least-squares: $\boldsymbol{y} = \mathbf{A}\hat{\boldsymbol{x}} + \hat{\boldsymbol{e}}$ (after [22.2])

This, however, is not advisable from a numerical point of view, since the explicit computation of the inverse of the normal matrix can be time-consuming and prone to round-off errors. A better alternative is to work with the *Cholesky* decomposition of the positive-definite normal matrix $\mathbf{N}$, $\mathbf{N} = \mathbf{G}\mathbf{G}^\top$, [22.3].

Solving the normal equations with the Cholesky decomposition starts with splitting the original system into two systems

$$\mathbf{G}\hat{\boldsymbol{g}} = \boldsymbol{r} \quad \text{and} \quad \mathbf{G}^\top\hat{\boldsymbol{x}} = \hat{\boldsymbol{g}}\,, \tag{22.10}$$

where $\mathbf{G}$ is the lower triangular matrix or Cholesky factor. First, forward substitution is applied to compute the entries of $\hat{\boldsymbol{g}}$ starting with the first entry $\hat{g}_1 = r_1/G_{11}$, then $\hat{g}_2 = (r_2 - G_{21}\hat{g}_1)/G_{22}$, etc. (where $G_{ij}$ is entry $(i,j)$ from matrix $\mathbf{G}$). Once $\hat{\boldsymbol{g}}$ has been computed, backward substitution is applied to compute the entries of $\hat{\boldsymbol{x}}$ in a similar fashion using the right-hand side of (22.10), but then starting with the last entry since $\mathbf{G}^\top$ is an upper triangular matrix.

Alternative methods for computing the LS solution make use of different matrix decompositions, such as the orthogonal QR factorization, $\mathbf{A} = \mathbf{Q}\mathbf{R}$, or the singular value decomposition (SVD), $\mathbf{A} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^\top$. For a discussion on their principles and properties, see [22.3–5].

### 22.1.4 Statistical Properties

In order to be able to solve the inconsistent linear system of equations $\boldsymbol{y} = \mathbf{A}\boldsymbol{x}$, the measurement error vector $\boldsymbol{e}$ was introduced. The WLS solution is obtained by minimizing the weighted squared norm $\boldsymbol{e}^\top\mathbf{W}\boldsymbol{e}$. In general, it is assumed that the measurement errors are random and zero on average. In other words, if the measurements were to be repeated many times under similar circumstances, the mean errors would become zero. The mean or mathematical expectation $E(.)$ of $\boldsymbol{e}$ is thus assumed to be zero, $E(\boldsymbol{e}) = \mathbf{0}$. Consequently, the mean of $\boldsymbol{y}$ becomes

$$E(\boldsymbol{y}) = E(\mathbf{A}\boldsymbol{x} + \boldsymbol{e}) = \mathbf{A}\boldsymbol{x}, \tag{22.11}$$

since $\boldsymbol{x}$ is the deterministic vector with unknown parameters. The means of the WLS estimators follow as

$$E(\hat{\boldsymbol{x}}) = (\mathbf{A}^\top\mathbf{W}\mathbf{A})^{-1}\mathbf{A}^\top\mathbf{W}E(\boldsymbol{y}) = \boldsymbol{x}\,, \tag{22.12}$$

$$E(\hat{\boldsymbol{y}}) = \mathbf{A}E(\hat{\boldsymbol{x}}) = \mathbf{A}\boldsymbol{x}\,, \tag{22.13}$$

$$E(\hat{\boldsymbol{e}}) = E(\boldsymbol{y}) - E(\hat{\boldsymbol{y}}) = \mathbf{0}\,. \tag{22.14}$$

This shows that WLS provides *unbiased* estimators.

In the consistent linear system of equations $\boldsymbol{y} = \mathbf{A}\boldsymbol{x} + \boldsymbol{e}$, $\boldsymbol{y}$ and $\boldsymbol{e}$ are the random vectors whereas $\boldsymbol{x}$ is deterministic. This implies that $\mathbf{Q}_{yy} = \mathbf{Q}_{ee}$. By application of the variance propagation law [22.2], the variance–covariance matrices of the WLS estimators can be derived as

$$\mathbf{Q}_{\hat{x}\hat{x}} = (\mathbf{A}^\top\mathbf{W}\mathbf{A})^{-1}\mathbf{A}^\top\mathbf{W}\mathbf{Q}_{yy}\mathbf{W}\mathbf{A}(\mathbf{A}^\top\mathbf{W}\mathbf{A})^{-1}, \tag{22.15}$$

$$\mathbf{Q}_{\hat{y}\hat{y}} = \mathbf{A}\mathbf{Q}_{\hat{x}\hat{x}}\mathbf{A}^\top = \mathbf{P}_\mathbf{A}\mathbf{Q}_{yy}\mathbf{P}_\mathbf{A}^\top\,, \tag{22.16}$$

$$\mathbf{Q}_{\hat{e}\hat{e}} = \mathbf{P}_\mathbf{A}^\perp\mathbf{Q}_{yy}\mathbf{P}_\mathbf{A}^{\perp\top}\,, \tag{22.17}$$

with orthogonal projector

$$\mathbf{P}_\mathbf{A}^\perp = \mathbf{I}_m - \mathbf{P}_\mathbf{A} \quad \text{and} \quad \mathbf{P}_\mathbf{A} = \mathbf{A}(\mathbf{A}^\top\mathbf{W}\mathbf{A})^{-1}\mathbf{A}^\top\mathbf{W}\,.$$

The variance–covariance matrices describe the precision of the WLS estimators.

## 22.2 Optimal Estimation

### 22.2.1 Best Linear Unbiased Estimation

The principle of *best linear unbiased estimation* (BLUE) is based on the following requirements for the estimator [22.2, 6]. First, the estimator must be *unbiased*, implying that $E(\hat{\boldsymbol{x}}) = \boldsymbol{x}$. Furthermore, the condition that the estimator must be *linear* means that the estimator $\hat{\boldsymbol{x}}$ is a linear function of $\boldsymbol{y}$. This can be further generalized by considering the situation where the actual parameters of interest are a linear function of $\boldsymbol{x}$, say

$$\boldsymbol{z} = \mathbf{F}^\top\boldsymbol{x} + \boldsymbol{f}\,. \tag{22.18}$$

The estimator $\hat{\boldsymbol{z}}$ is called a *linear unbiased* estimator if it is unbiased and a linear function of the observations $\boldsymbol{y}$ as well

$$E(\hat{\boldsymbol{z}}) = \boldsymbol{z} \quad \text{and} \quad \hat{\boldsymbol{z}} = \mathbf{L}^\top\boldsymbol{y} + \boldsymbol{l}\,. \tag{22.19}$$

The linear unbiased estimator $\hat{\boldsymbol{z}}$ is called *best* if it has the smallest variance of all linear unbiased estimators. In Sect. 22.1.2, it was already argued that $\mathbf{W} = \mathbf{Q}_{yy}^{-1}$ would be a good choice for the weight matrix. And indeed, it can be proven that the WLS estimator becomes the BLUE when the weight matrix is chosen equal to the inverse variance–covariance matrix of the observables.

Thus, the BLUE of $z = \mathbf{F}^\top \boldsymbol{x} + \boldsymbol{f}$ becomes

$$\hat{z} = \mathbf{F}^\top \hat{\boldsymbol{x}} + \boldsymbol{f} \tag{22.20}$$

with the BLUE of $\boldsymbol{x}$ given as

$$\hat{\boldsymbol{x}} = \left(\mathbf{A}^\top \mathbf{Q}_{yy}^{-1} \mathbf{A}\right)^{-1} \mathbf{A}^\top \mathbf{Q}_{yy}^{-1} \boldsymbol{y} \,. \tag{22.21}$$

WLS estimation and BLUE are thus identical when $\mathbf{W} = \mathbf{Q}_{yy}^{-1}$. The variance–covariance matrices of $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{e}}$ from (22.15) and (22.17) become then

$$\mathbf{Q}_{\hat{x}\hat{x}} = \left(\mathbf{A}^\top \mathbf{Q}_{yy}^{-1} \mathbf{A}\right)^{-1} \,, \tag{22.22}$$

$$\mathbf{Q}_{\hat{e}\hat{e}} = \mathbf{Q}_{yy} - \mathbf{Q}_{\hat{y}\hat{y}} \,. \tag{22.23}$$

As it is common practice to assume the measurements to be normally distributed, $\boldsymbol{y} \sim \mathrm{N}(\mathbf{A}\boldsymbol{x}, \mathbf{Q}_{yy})$, the estimators, being linear functions of $\boldsymbol{y}$, will then also be normally distributed

$$\hat{\boldsymbol{x}} \sim \mathrm{N}(\boldsymbol{x}, \mathbf{Q}_{\hat{x}\hat{x}}) \,, \tag{22.24}$$

$$\hat{\boldsymbol{y}} \sim \mathrm{N}(\mathbf{A}\boldsymbol{x}, \mathbf{Q}_{\hat{y}\hat{y}}) \,, \tag{22.25}$$

$$\hat{\boldsymbol{e}} \sim \mathrm{N}(\boldsymbol{0}, \mathbf{Q}_{\hat{e}\hat{e}}) \,. \tag{22.26}$$

Summarizing, BLUE thus has various optimality properties. First, it minimizes the weighted sum of squared residuals. Second, it has the best precision, that is, smallest variance, of all linear unbiased estimators. Moreover, if in addition the model is a Gaussian linear model $\boldsymbol{y} \sim \mathrm{N}(\mathbf{A}\boldsymbol{x}, \mathbf{Q}_{yy})$, BLUE will also maximize the likelihood as will be discussed in the next subsection.

### 22.2.2 Maximum Likelihood Estimation

Another estimation principle is *maximum likelihood* estimation (MLE), which is based on maximizing the so-called likelihood function of a given observation vector $\boldsymbol{y}$. For this purpose, the general structure of the probability density function (PDF) of $\boldsymbol{y}$ must be known, except for some $n$ unknown parameters $\boldsymbol{x}$. The PDF is denoted as $f_y(\cdot|\boldsymbol{x})$, and it will change depending on the choice for $\boldsymbol{x}$. As such, there is a whole family of PDFs, and it is not known to which PDF the observed $\boldsymbol{y}$ belongs.

The idea is then to select from this family of PDFs, the one which best supports the observed data by considering $f_y(\boldsymbol{y}|\boldsymbol{x})$ as function of $\boldsymbol{x}$. The likelihood function is now given by a function of $\boldsymbol{x}$ producing the corresponding probability densities of all PDFs for the same sample $\boldsymbol{y}$. The vector $\boldsymbol{x}$ is then chosen as the one which maximizes the likelihood function

$$\hat{\boldsymbol{x}} = \arg\max_{\boldsymbol{x} \in \mathbb{R}^n} f_y(\boldsymbol{y}|\boldsymbol{x}) \,. \tag{22.27}$$

This is the maximum likelihood estimator of $\boldsymbol{x}$. The principle is illustrated in Fig. 22.2.

MLE is a very general estimation principle, which relies on the knowledge of the structure of the PDF (in contrast to WLS and BLUE). In case of the Gaussian linear model, the PDF is given as $f_y(\boldsymbol{y}|\boldsymbol{x}) \propto \exp(-\frac{1}{2}\|\boldsymbol{y} - \mathbf{A}\boldsymbol{x}\|^2_{\mathbf{Q}_{yy}})$. In that case the MLE of $\boldsymbol{x}$ becomes identical to the BLUE given in (22.21).

### 22.2.3 Confidence Regions

In Sect. 22.2.1, the variance–covariance matrices of the estimators were presented. These matrices contain all information regarding the precision – the variances on the diagonal – and the correlation between the estimated parameters – by means of the covariances. However, the variance (or its square root, the standard deviation) of

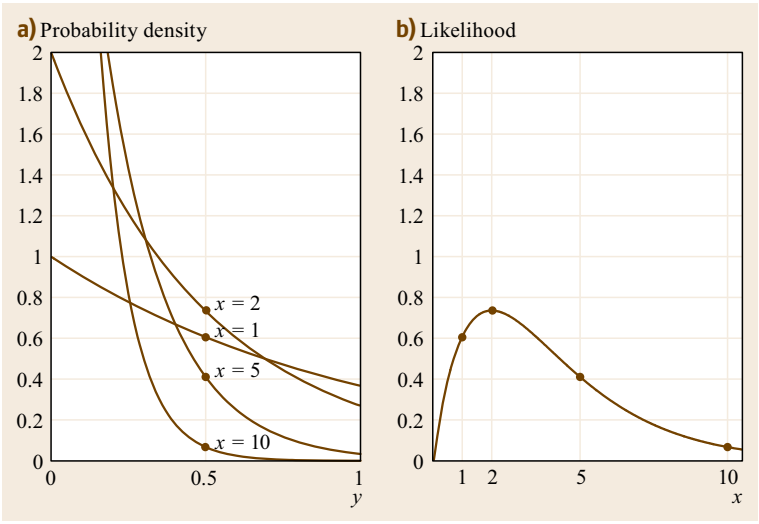

**Fig. 22.2a,b** PDF and likelihood for exponential distribution. **(a)** Family of PDFs $f_y(y|x) = x\exp(-xy)$ with $y \geq 0$, $0 < x < \infty$, for different parameter values $x$; **(b)** corresponding likelihood function for $y = 0.5$. The maximum likelihood estimate in this case is equal to $\hat{x} = 2$

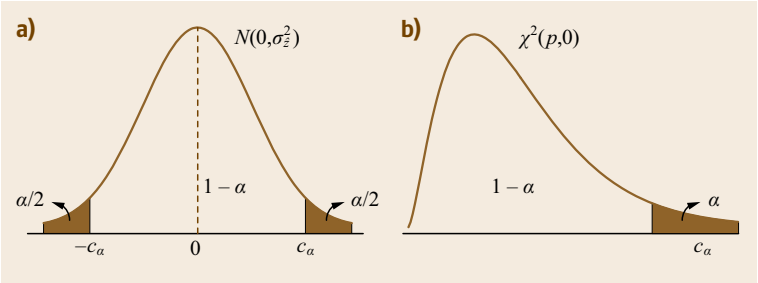

**Fig. 22.3** **(a)** PDF of $N(0,\sigma_{\hat{z}}^2)$ with confidence interval $[-c_\alpha, c_\alpha]$; **(b)** PDF of $\chi^2(p,0)$ with confidence interval $[0, c_\alpha]$. The confidence level in **(a)** and **(b)** is equal to $1-\alpha$

an estimator does not directly provide information on the probability that the estimation error is smaller than a certain value. Therefore, the concept of *confidence regions* can be used. Starting with the estimation error $\hat{z}-z$ of a single parameter, the $100(1-\alpha)\%$ confidence interval is defined as

$$\mathrm{CI}_\alpha = \{z \in \mathbb{R} \,|\, -c_\alpha < \hat{z}-z < c_\alpha\} \ . \tag{22.28}$$

In practice, such a confidence interval is often denoted as $\hat{z} \pm c_\alpha$. It tells you that the estimated value will be within a distance $c_\alpha$ from the true value with a confidence level of $1-\alpha$, that is,

$$P\left(|\hat{z}-z| < c_\alpha\right) = 1-\alpha \ . \tag{22.29}$$

With the assumption that the estimator is normally distributed, it is straightforward to determine $c_\alpha$ for a given choice of $\alpha$, and vice versa. See also Fig. 22.3a. Some common choices are

$$\begin{cases} c_{0.05} &= 1.96\sigma_{\hat{z}} \quad \text{(95\%-confidence level)} \\ c_{0.01} &= 2.58\sigma_{\hat{z}} \quad \text{(99\%-confidence level)} \\ c_{0.001} &= 3.29\sigma_{\hat{z}} \quad \text{(99.9\%-confidence level)} \ . \end{cases}$$

From this, the link with the standard deviation $\sigma_{\hat{z}}$ becomes clear. Here, the confidence interval of an estimator $\hat{z}$ has been presented. However, similarly, the confidence interval of an observation $y$ can be evaluated.

Instead of evaluating the confidence interval of a single variable, it is also possible to evaluate a confidence region of a random vector. Here, only the specific example will be considered that an estimator $\hat{z}$ resides in an ellipsoidal region with its size governed by the confidence coefficient $c_\alpha$. The reason is that

$$\|\hat{z}-z\|^2_{\mathbf{Q}_{\hat{z}\hat{z}}} = c_\alpha$$

is the equation of an hyper-ellipsoid and if

$$\hat{z} \sim \mathrm{N}(z, \mathbf{Q}_{\hat{z}\hat{z}}) \ ,$$

then

$$\|\hat{z}-z\|^2_{\mathbf{Q}_{\hat{z}\hat{z}}} \sim \chi^2(p,0) \ , \tag{22.30}$$

where $\chi^2(p,0)$ denotes the central chi-square distribution with $p$ degrees of freedom, and $p$ is the dimension of vector $\hat{z}$. This allows to evaluate the probability

$$P\left(\|\hat{z}-z\|^2_{\mathbf{Q}_{\hat{z}\hat{z}}} < c_\alpha\right) = 1-\alpha \tag{22.31}$$

and again $c_\alpha$ can be determined for a given choice of $\alpha$ (Fig. 22.3b).

### *Example 22.1 Confidence Ellipse for Horizontal Positioning*

With GNSS positioning, the main parameters of interest are usually the position coordinates. It can then be particularly useful to consider the ellipsoidal confidence region as presented here. See the example in Fig. 22.4, where only the horizontal positioning errors are considered.

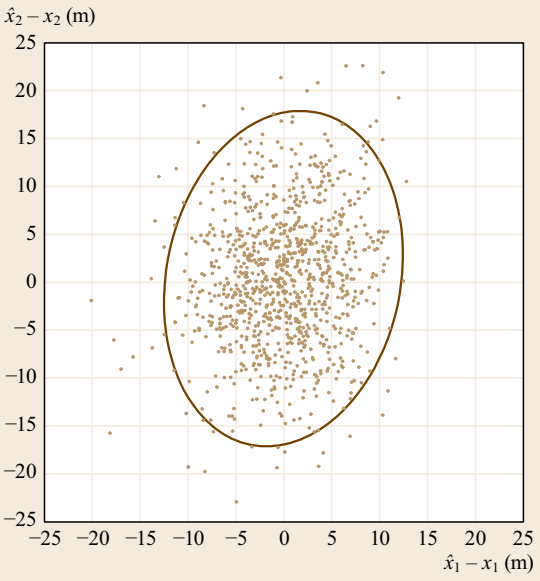

**Fig. 22.4** 95%-confidence ellipse for the horizontal positioning errors, where $x_1$ is the true east coordinate, and $x_2$ the true north coordinate. The *brown dots* represent the actual errors based on 1000 estimated positions (simulated)

## 22.3 Special Forms of Least Squares

In this section, several special forms of LS estimation will be discussed [22.2]. First, various partitioned models and their solutions are reviewed. In the special case that certain constraints on the unknown parameters can be applied, the problem of constrained LS estimation arises, which is the topic of Sect. 22.3.4. The problem of rank-deficiency, causing the solution to be nonunique, is briefly discussed in Sect. 22.3.5. Finally, the problem of nonlinear LS is addressed in Sect. 22.3.6. Another special form of LS arises for the mixed-integer model (Chap. 23), that is, if a subset of the parameters must fulfill an integer constraint. A well-known example is the GNSS model with integer carrier-phase ambiguities.

### 22.3.1 Recursive Estimation

A common form of a partitioned model is

$$E\begin{pmatrix} \boldsymbol{y}_1 \\ \boldsymbol{y}_2 \\ \vdots \\ \boldsymbol{y}_k \end{pmatrix} = \begin{bmatrix} \mathbf{A}_1 \\ \mathbf{A}_2 \\ \vdots \\ \mathbf{A}_k \end{bmatrix} \boldsymbol{x} \tag{22.32}$$

with

$$\mathbf{Q}_{yy} = \begin{bmatrix} \mathbf{Q}_1 & & & \mathbf{0} \\ & \mathbf{Q}_2 & & \\ & & \ddots & \\ \mathbf{0} & & & \mathbf{Q}_k \end{bmatrix}, \tag{22.33}$$

where the observation vectors $\boldsymbol{y}_i$ correspond to subsequent epochs $i = 1, \ldots, k$.

The BLUE of $\boldsymbol{x}$ using all $k$ epochs of data follows as

$$\hat{\boldsymbol{x}}_{(k)} = \left(\sum_{i=1}^{k} \mathbf{A}_i^\top \mathbf{Q}_i^{-1} \mathbf{A}_i\right)^{-1} \left(\sum_{i=1}^{k} \mathbf{A}_i^\top \mathbf{Q}_i^{-1} \boldsymbol{y}_i\right) . \tag{22.34}$$

The model can be solved recursively, that is, a new solution is computed for every new epoch of data, as follows. At epoch 1, the model $E(\boldsymbol{y}_1) = \mathbf{A}_1 \boldsymbol{x}$ with $\mathbf{Q}_{yy} = \mathbf{Q}_1$ is solved as

$$\begin{aligned} \hat{\boldsymbol{x}}_{(1)} &= \left(\mathbf{A}_1^\top \mathbf{Q}_1^{-1} \mathbf{A}_1\right)^{-1} \mathbf{A}_1^\top \mathbf{Q}_1^{-1} \boldsymbol{y}_1 , \\ \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(1)}} &= \left(\mathbf{A}_1^\top \mathbf{Q}_1^{-1} \mathbf{A}_1\right)^{-1} . \end{aligned} \tag{22.35}$$

In the following epochs, it is not necessary to apply a so-called *batch* LS solution by jointly processing all measurement data up till and including the current epoch. Instead, the following model can be used at epoch $k = 2, 3, \ldots$

$$E\begin{pmatrix} \hat{\boldsymbol{x}}_{(k-1)} \\ \boldsymbol{y}_k \end{pmatrix} = \begin{bmatrix} \mathbf{I} \\ \mathbf{A}_k \end{bmatrix} \boldsymbol{x}; \begin{bmatrix} \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} & \\ & \mathbf{Q}_k \end{bmatrix} \tag{22.36}$$

with solution

$$\hat{\boldsymbol{x}}_{(k)} = \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k)}} \left(\mathbf{Q}^{-1}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} \hat{\boldsymbol{x}}_{(k-1)} + \mathbf{A}_k^\top \mathbf{Q}_k^{-1} \boldsymbol{y}_k\right) \tag{22.37}$$

and

$$\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k)}} = \left(\mathbf{Q}^{-1}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} + \mathbf{A}_k^\top \mathbf{Q}_k^{-1} \mathbf{A}_k\right)^{-1}$$

with

$$\mathbf{Q}^{-1}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} = \sum_{i=1}^{k-1} \mathbf{A}_i^\top \mathbf{Q}_i^{-1} \mathbf{A}_i .$$

The recursive BLUE solution of (22.37) can also be written as

$$\hat{\boldsymbol{x}}_{(k)} = \hat{\boldsymbol{x}}_{(k-1)} + \mathbf{K}_k \left(\boldsymbol{y}_k - \mathbf{A}_k \hat{\boldsymbol{x}}_{(k-1)}\right) , \; k > 1 \tag{22.38}$$

with gain matrix

$$\mathbf{K}_k = \left(\mathbf{Q}^{-1}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} + \mathbf{A}_k^\top \mathbf{Q}_k^{-1} \mathbf{A}_k\right)^{-1} \mathbf{A}_k^\top \mathbf{Q}_k^{-1} . \tag{22.39}$$

Equation (22.38) is referred to as the *measurement update* (MU), since the right-hand side of this equation comprises of the estimator based on all previous epochs, $\hat{\boldsymbol{x}}_{(k-1)}$, plus the term $\mathbf{K}_k(\boldsymbol{y}_k - \mathbf{A}_k \hat{\boldsymbol{x}}_{(k-1)})$ in which $\mathbf{A}_k \hat{\boldsymbol{x}}_{(k-1)}$ can be interpreted as the prediction of $\boldsymbol{y}_k$. The difference $\boldsymbol{v}_k = \boldsymbol{y}_k - \mathbf{A}_k \hat{\boldsymbol{x}}_{(k-1)}$ is consequently called the *predicted residual*. Matrix $\mathbf{K}_k$ is called the gain matrix, since the gain experienced by the new data $\boldsymbol{y}_k$ is determined by $\mathbf{K}_k \boldsymbol{v}_k$.

An alternative form of the gain matrix is

$$\mathbf{K}_k = \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} \mathbf{A}_k^\top \left(\mathbf{Q}_k + \mathbf{A}_k \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} \mathbf{A}_k^\top\right)^{-1} . \tag{22.40}$$

Based on this form, the variance–covariance matrix can be calculated with

$$\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k)}} = (\mathbf{I} - \mathbf{K}_k \mathbf{A}_k) \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}_{(k-1)}} . \tag{22.41}$$

The results obtained with (22.39) and (22.40) will be identical. Preference for one of the two expressions may be based on the dimensions of the inverse matrices. If the number of observations $m_k$ is small compared to

the state vector dimension $n$, one may prefer (22.40) over (22.39).

Recursive estimation can be applied in real-time estimation problems, providing new estimates at every measurement epoch using the information of subsequent epochs. For post-processing applications, the data collected over a longer time period can alternatively be jointly processed with batch LS to find the estimates that provide the best fit to the entire set of measurements.

*Example 22.2 (Single Point Positioning)*

An example is shown in Fig. 22.5. The solutions based on single epoch processing, that is, not using data from previous epochs, are shown as dots for a single point positioning model (Sect. 21.3). The recursive LS solution is shown with the solid lines. It can be seen that the solution, especially for the horizontal position, converges quite fast, whereas the precision of the single epoch solutions is much poorer (larger spread in outcomes). Note that the batch solution based on all epochs is identical to the recursive solution at the last epoch.

In Sect. 22.5, another step, namely a time update, will be included to account for a kinematic or dynamic model, that is, with $\boldsymbol{x}$ not being constant in time.

*Example 22.3 (Recursive Phase-Smoothed Pseudorange)*

The phase-smoothed pseudorange algorithm is a single-channel recursive algorithm that uses the high-precision carrier-phase data $\phi_k$ to *smooth* the relatively high noise of the pseudorange data $p_k$. The smoothed pseudorange $\hat{p}_{k|k}$ is obtained from $\phi_k$ and $p_k$ as [22.7, 8]

$$\hat{p}_{k|k-1} = \hat{p}_{k-1|k-1} + [\phi_k - \phi_{k-1}] \,,$$
$$\hat{p}_{k|k} = \hat{p}_{k|k-1} + \frac{1}{k}[p_k - \hat{p}_{k|k-1}] \,. \qquad (22.42)$$

The algorithm is initialized with $\hat{p}_{1|1} = p_1$. The two equations can be combined to give

$$\hat{p}_{k|k} = \frac{1}{k} p_k + \frac{k-1}{k}\left[\hat{p}_{k-1|k-1} + (\phi_k - \phi_{k-1})\right] \,. \qquad (22.43)$$

This equation shows that the *smoothed* pseudorange is a linear combination of the pseudorange, with weight $1/k$, and the *predicted* pseudorange, with weight $k - 1/k$. Figure 22.6 shows a time series of the noise of $p_k$ and $\hat{p}_{k|k}$, respectively.

The following example shows how the smoothed pseudorange algorithm is linked to recursive LS estimation.

*Example 22.4 (Recursive Phase-Adjusted Pseudorange)*

Let the multi-epoch, kinematic GNSS model of observation equations be given as

$$E\begin{pmatrix} \boldsymbol{p}_1 \\ \boldsymbol{\phi}_1 \\ \boldsymbol{p}_2 \\ \boldsymbol{\phi}_2 \\ \vdots \\ \boldsymbol{p}_k \\ \boldsymbol{\phi}_k \end{pmatrix} = \begin{bmatrix} \mathbf{A}_1 & & & & \mathbf{0} \\ \mathbf{A}_1 & & & & \mathbf{I} \\ & \mathbf{A}_2 & & & \mathbf{0} \\ & \mathbf{A}_2 & & & \mathbf{I} \\ & & \ddots & & \vdots \\ & & & \mathbf{A}_k & \mathbf{0} \\ & & & \mathbf{A}_k & \mathbf{I} \end{bmatrix} \begin{pmatrix} \boldsymbol{x}_1 \\ \boldsymbol{x}_2 \\ \vdots \\ \boldsymbol{x}_k \\ a \end{pmatrix} \qquad (22.44)$$

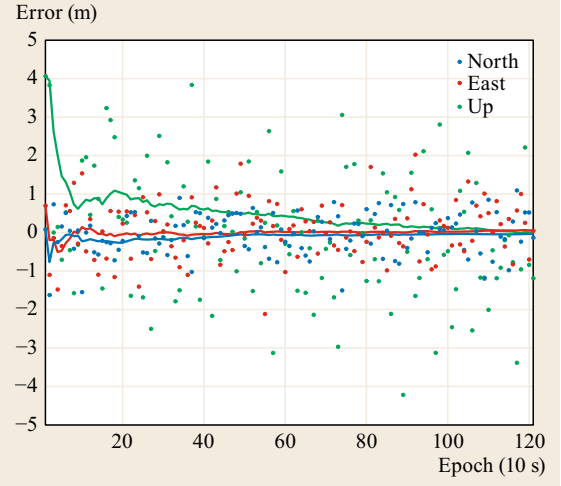

**Fig. 22.5** Single epoch (*dots*) and recursive least-squares (*lines*) solutions with single point poistioning

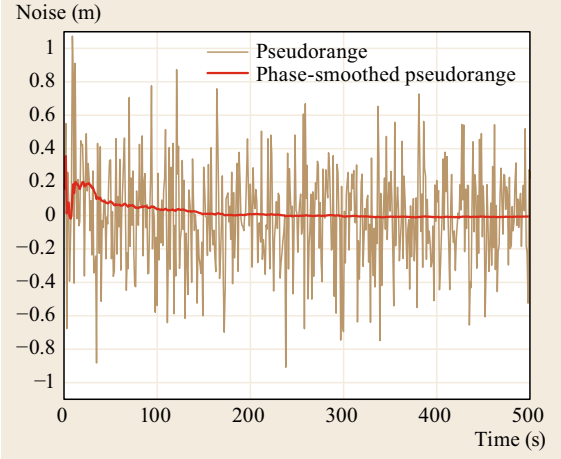

**Fig. 22.6** Noise on pseudorange observation $p_k$ (*brown*) and phase-smoothed pseudorange observation $\hat{p}_{k|k}$ (*red*)

with $\boldsymbol{p}_i$ and $\boldsymbol{\phi}_i$ the vectors of (observed minus computed) pseudorange and phase observables at epoch $i$, respectively; $\boldsymbol{x}_i$ the vector of (increment) position coordinates, clock errors, and $\boldsymbol{a}$ the unknown ambiguities (in meters), which are assumed to be constant in time in the absence of cycle slips. The atmospheric delays are assumed corrected for and/or cancelled by means of using atmosphere-free observables.

The recursive LS solution of model (22.44) is given as [22.9]

$$\begin{aligned}\hat{\boldsymbol{x}}_k &= \mathbf{Q}_{\hat{x}_k\hat{x}_k}\mathbf{A}_k^\top\left(\mathbf{Q}_{p_kp_k}^{-1}\boldsymbol{p}_k + \mathbf{Q}_{\bar{p}_k\bar{p}_k}^{-1}\bar{\boldsymbol{p}}_k\right)\\ \boldsymbol{a}_{(k)} &= \hat{\boldsymbol{a}}_{(k-1)} + \mathbf{Q}_{\hat{a}\hat{a}_{(k-1)}}\mathbf{Q}_{\bar{p}_k\bar{p}_k}^{-1}\left(\bar{\boldsymbol{p}}_k - \mathbf{A}_k\hat{\boldsymbol{x}}_k\right)\end{aligned} \tag{22.45}$$

with

$$\begin{aligned}\mathbf{Q}_{\hat{x}_k\hat{x}_k} &= \left(\mathbf{A}_k^\top\left(\mathbf{Q}_{p_kp_k}^{-1} + \mathbf{Q}_{\bar{p}_k\bar{p}_k}^{-1}\right)\mathbf{A}_k\right)^{-1},\\ \bar{\boldsymbol{p}}_k &= \boldsymbol{\phi}_k - \hat{\boldsymbol{a}}_{(k-1)}, \quad \mathbf{Q}_{\bar{p}_k\bar{p}_k} = \mathbf{Q}_{\phi_k\phi_k} + \mathbf{Q}_{\hat{a}\hat{a}_{(k-1)}}.\end{aligned}$$

The phase-adjusted pseudorange estimator is given by $\mathbf{A}_k\hat{\boldsymbol{x}}_k$.

If we now make the simplifying assumption that $\mathbf{Q}_{\phi_k\phi_k} = 0$, then $\mathbf{Q}_{\bar{p}_k\bar{p}_k} = \mathbf{Q}_{\hat{a}\hat{a}_{(k-1)}}$ and $\hat{\boldsymbol{a}}_{(k)} = \boldsymbol{\phi}_k - \mathbf{A}_k\hat{\boldsymbol{x}}_k$, from which it follows that (22.45) simplifies to

$$\hat{\boldsymbol{x}}_k = \mathbf{K}_k\boldsymbol{p}_k + \mathbf{L}_k\left[\mathbf{A}_{k-1}\hat{\boldsymbol{x}}_{k-1} + (\boldsymbol{\phi}_k - \boldsymbol{\phi}_{k-1})\right] \tag{22.46}$$

with $\mathbf{K}_k = \mathbf{Q}_{\hat{x}_k\hat{x}_k}\mathbf{A}_k^\top\mathbf{Q}_{p_kp_k}^{-1}$, $\mathbf{L}_k = \mathbf{Q}_{\hat{x}_k\hat{x}_k}\mathbf{A}_k^\top\mathbf{Q}_{\hat{a}_k\hat{a}_k}^{-1}$. Compare (22.46) with (22.43). The result (22.46) becomes even identical to (22.43) in case of single-channel processing. Then, the relative-receiver satellite geometry is absent from the model and thus $\mathbf{A}_k = \mathbf{I}$, from which it follows that $\mathbf{K}_k = \frac{1}{k}\mathbf{I}$ and $\mathbf{L}_k = \frac{k-1}{k}\mathbf{I}$. The phase-smoothed pseudorange estimator thus becomes a LS estimator when the phase noise is neglected and the processing is restricted to single-channel processing.

The phase-adjusted pseudorange estimator, being a BLUE, has a better precision than that of the phase-smoothed estimator. The difference in precision between the two estimators, that is, their variance difference, is given in [22.9] as

$$\frac{(k-1)\sigma_\phi^2/\sigma_p^2}{k\left(1+\sigma_\phi^2/\sigma_p^2\right)}\sigma_\phi^2. \tag{22.47}$$

This difference is zero at initialization ($k = 1$) and nonzero but very small otherwise ($\sigma_\phi^2 << \sigma_p^2$). Hence, when restricted to single-channel processing, the phase-smoothed pseudorange is very close to the optimal phase-adjusted pseudorange estimator.

### 22.3.2 Estimation with Partitioned Parameter Vector

The model with the unknown parameter vector $\boldsymbol{x}$ partitioned can be written as

$$E(\boldsymbol{y}) = \begin{bmatrix}\mathbf{A}_1 & \mathbf{A}_2\end{bmatrix}\begin{pmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{pmatrix}. \tag{22.48}$$

This partitioning can be relevant in case one is interested in only a subset of the unknown parameters. The BLUE of, for example, the subset $\boldsymbol{x}_1$ equals

$$\hat{\boldsymbol{x}}_1 = \underbrace{\left(\bar{\mathbf{A}}_1^\top\mathbf{Q}_{yy}^{-1}\bar{\mathbf{A}}_1\right)}_{\mathbf{N}_{\text{red}}}{}^{-1}\bar{\mathbf{A}}_1^\top\mathbf{Q}_{yy}^{-1}\boldsymbol{y} \tag{22.49}$$

with $\mathbf{N}_{\text{red}}$ the *reduced* normal matrix, reduced for $\boldsymbol{x}_2$, and

$$\mathbf{Q}_{\hat{x}_1\hat{x}_1} = \mathbf{N}_{\text{red}}^{-1} \tag{22.50}$$

with $\bar{\mathbf{A}}_1 = \mathbf{P}_{\mathbf{A}_2}^{\perp}\mathbf{A}_1$.

Once $\hat{\boldsymbol{x}}_1$ is known, it is possible to find $\hat{\boldsymbol{x}}_2$ using

$$\hat{\boldsymbol{x}}_2 = \left(\mathbf{A}_2^\top\mathbf{Q}_{yy}^{-1}\mathbf{A}_2\right)^{-1}\mathbf{A}_2^\top\mathbf{Q}_{yy}^{-1}(\boldsymbol{y} - \mathbf{A}_1\hat{\boldsymbol{x}}_1) \tag{22.51}$$

and

$$\begin{aligned}\mathbf{Q}_{\hat{x}_2\hat{x}_2} &= \left(\mathbf{A}_2^\top\mathbf{Q}_{yy}^{-1}\mathbf{A}_2\right)^{-1}\\ &\times\left(\mathbf{I} + \mathbf{A}_2^\top\mathbf{Q}_{yy}^{-1}\mathbf{A}_1\mathbf{Q}_{\hat{x}_1\hat{x}_1}\mathbf{A}_1^\top\mathbf{Q}_{yy}^{-1}\mathbf{A}_2\left(\mathbf{A}_2^\top\mathbf{Q}_{yy}^{-1}\mathbf{A}_2\right)^{-1}\right).\end{aligned} \tag{22.52}$$

The roles of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ can of course be interchanged in (22.49)–(22.52).

*Example 22.5 (Time-Varying and Time-Constant Parameters)*

An example when the partitioned model (22.48) applies is for GNSS models comprising time-varying and time-constant parameters. For instance, for a static positioning application, the observations of $k$ epochs are collected; the position and possibly ambiguity parameters remain constant in time and are parameterized in vector $\boldsymbol{x}_1$, whereas the clock and atmospheric parameters are time-varying and parameterized in vector $\boldsymbol{x}_2$. The structure of matrices $\mathbf{A}_1$ and $\mathbf{A}_2$ is then

$$\mathbf{A}_1 = \begin{bmatrix}\mathbf{A}_{11}\\ \vdots\\ \mathbf{A}_{1k}\end{bmatrix}, \quad \mathbf{A}_2 = \begin{bmatrix}\mathbf{A}_{21} & & \\ & \ddots & \\ & & \mathbf{A}_{2k}\end{bmatrix}. \tag{22.53}$$

### 22.3.3 Block Estimation

A partitioned model often arising when observations from many stations or two or more (geodetic) networks, campaigns, or sessions are combined as

$$E\begin{pmatrix}\boldsymbol{y}_1\\ \boldsymbol{y}_2\\ \vdots\\ \boldsymbol{y}_k\end{pmatrix} = \begin{bmatrix}\mathbf{A}_{11} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{A}_{1g}\\ \mathbf{0} & \mathbf{A}_{22} & & \vdots & \mathbf{A}_{2g}\\ \vdots & & \ddots & \mathbf{0} & \vdots\\ \mathbf{0} & \cdots & \mathbf{0} & \mathbf{A}_{kk} & \mathbf{A}_{kg}\end{bmatrix}\begin{pmatrix}\boldsymbol{x}_1\\ \vdots\\ \boldsymbol{x}_k\\ \boldsymbol{x}_g\end{pmatrix}, \quad (22.54)$$

where $k$ is the number of, for example, stations/networks. The vector $\boldsymbol{x}_g$ contains the global parameters (related to all $\boldsymbol{y}_i$), and $\boldsymbol{x}_i$ $(i = 1, \ldots, k)$ the local parameter vector related to observations $\boldsymbol{y}_i$ only. The observations $\boldsymbol{y}_i$ are assumed to be mutually independent

$$\mathbf{Q}_{yy} = \begin{bmatrix}\mathbf{Q}_1 & & & \mathbf{0}\\ & \mathbf{Q}_2 & & \\ & & \ddots & \\ \mathbf{0} & & & \mathbf{Q}_k\end{bmatrix}. \quad (22.55)$$

The solution can be obtained with the *Helmert block method* [22.2, 10]. First, the global parameters are estimated as

$$\hat{\boldsymbol{x}}_g = \underbrace{\left(\sum_{i=1}^{k}\bar{\mathbf{A}}_{ig}^{\top}\mathbf{Q}_i^{-1}\bar{\mathbf{A}}_{ig}\right)}_{\mathbf{N}_{red}}{}^{-1}\left(\sum_{i=1}^{k}\bar{\mathbf{A}}_{ig}^{\top}\mathbf{Q}_i^{-1}\boldsymbol{y}_i\right). \quad (22.56)$$

$\mathbf{N}_{red}$ is the reduced normal matrix, since $\boldsymbol{x}_i$ are reduced, with

$$\bar{\mathbf{A}}_{ig} = \mathbf{P}^{\perp}_{\mathbf{A}_{ii}}\mathbf{A}_{ig}, \quad (22.57)$$

and the orthogonal projector is given as $\mathbf{P}^{\perp}_{\mathbf{A}_{ii}} = \mathbf{I} - \mathbf{P}_{\mathbf{A}_{ii}}$ and $\mathbf{P}_{\mathbf{A}_{ii}} = \mathbf{A}_{ii}(\mathbf{A}_{ii}^{\top}\mathbf{Q}_i^{-1}\mathbf{A}_{ii})^{-1}\mathbf{A}_{ii}^{\top}\mathbf{Q}_i^{-1}$. Using this solution, the local parameters can be estimated

$$\hat{\boldsymbol{x}}_i = \left(\mathbf{A}_{ii}^{\top}\mathbf{Q}_i^{-1}\mathbf{A}_{ii}\right)^{-1}\mathbf{A}_{ii}^{\top}\mathbf{Q}_i^{-1}\left(\boldsymbol{y}_i - \mathbf{A}_{ig}\hat{\boldsymbol{x}}_g\right). \quad (22.58)$$

*Example 22.6 (Large GNSS Network)*
Rigorous LS estimation of precise orbits and clocks based on observations from around 20 000 GNSS receivers is hampered by the processing capacity of the IGS analysis centers [22.11]. The Helmert block method can be applied to deal with this problem. In this case, the vectors $\boldsymbol{y}_i$ refer to the observation vectors from the individual GNSS stations. The global parameters $\boldsymbol{x}_g$ are the satellite orbit and clock parameters, and Earth rotation parameters. The local parameters $\boldsymbol{x}_i$ are the station coordinates, atmospheric delays, and receiver clock errors per station $i$.

Similar applications of the Helmert block method are described in [22.12, 13]. An application for the readjustment of a large national geodetic network is described in [22.14].

### 22.3.4 Constrained Least-Squares

So far we discussed the unconstrained linear model $E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x}$. Another formulation is used if certain constraints on the parameters are to be considered

$$E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x} \quad \text{with} \quad \mathbf{C}^{\top}\boldsymbol{x} = \boldsymbol{c}\,. \quad (22.59)$$

This is the constrained linear model. Compared to the unconstrained model, the system of constraints $\mathbf{C}^{\top}\boldsymbol{x} = \boldsymbol{c}$ are added with $n \times d$ matrix $\mathbf{C}$ of rank $d$, and $d$-vector $\boldsymbol{c}$. The redundancy of this model is increased with $d$ compared to the unconstrained model.

In order to solve the model (22.59), first the unconstrained solution, denoted as $\hat{\boldsymbol{x}}$ and $\mathbf{Q}_{\hat{x}\hat{x}}$, is computed. In the second step, the conditioned linear model $\mathbf{C}^{\top}E(\hat{\boldsymbol{x}}) = \boldsymbol{c}$ is solved as

$$\hat{\boldsymbol{x}}_c = \hat{\boldsymbol{x}} - \mathbf{Q}_{\hat{x}\hat{x}}\mathbf{C}\left(\mathbf{C}^{\top}\mathbf{Q}_{\hat{x}\hat{x}}\mathbf{C}\right)^{-1}\left(\mathbf{C}^{\top}\hat{\boldsymbol{x}} - \boldsymbol{c}\right). \quad (22.60)$$

The corresponding variance–covariance matrix is obtained by applying the variance propagation law

$$\mathbf{Q}_{\hat{x}_c\hat{x}_c} = \mathbf{Q}_{\hat{x}\hat{x}} - \mathbf{Q}_{\hat{x}\hat{x}}\mathbf{C}\left(\mathbf{C}^{\top}\mathbf{Q}_{\hat{x}\hat{x}}\mathbf{C}\right)^{-1}\mathbf{C}^{\top}\mathbf{Q}_{\hat{x}\hat{x}}\,. \quad (22.61)$$

### 22.3.5 Rank-Defect Least Squares

No unique LS solution exists if the design matrix $\mathbf{A}$ fails to be of full rank.

Let $\operatorname{rank}(\mathbf{A}) = r < n$. Then, an $n \times (n-r)$ basis matrix $\mathbf{V}$ exists with the property $\mathbf{AV} = \mathbf{0}$. Hence, no unique LS-solution exists then for

$$\min_{\boldsymbol{x}} \|\boldsymbol{y} - \mathbf{A}\boldsymbol{x}\|^2_{\mathbf{Q}_{yy}},$$

since if, say $\hat{\boldsymbol{x}}_s$, is an LS-solution, then so is $\hat{\boldsymbol{x}}_s + \mathbf{V}\boldsymbol{\beta}$ for any $\boldsymbol{\beta} \in \mathbb{R}^{n-r}$.

To determine the general solution of a rank-defect LS problem, we first determine a particular solution. Let $\mathbf{S}$ be a basis matrix of a subspace complementary to the range space of $\mathbf{V}$, that is, $\mathcal{R}(\mathbf{S}) \oplus \mathcal{R}(\mathbf{V}) = \mathbb{R}^n$. Then, $\mathbf{S}$ is of order $n \times r$ and matrix $[\mathbf{S}, \mathbf{V}]$ is invertible. With the reparameterization

$$\boldsymbol{x} = \mathbf{S}\alpha + \mathbf{V}\boldsymbol{\beta} \tag{22.62}$$

the originally rank deficient system is turned into a full rank system

$$E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x} \Rightarrow E(\boldsymbol{y}) = (\mathbf{AS})\boldsymbol{\alpha} \tag{22.63}$$

having the LS-solution

$$\hat{\boldsymbol{\alpha}} = \left[(\mathbf{AS})^\top \mathbf{Q}_{yy}^{-1}(\mathbf{AS})\right]^{-1} (\mathbf{AS})^\top \mathbf{Q}_{yy}^{-1}\boldsymbol{y} \,.$$

Hence, $\hat{\boldsymbol{x}}_\mathrm{s} = \mathbf{S}\hat{\boldsymbol{\alpha}}$ is a particular solution of the rank-defect LS-problem, while its general LS-solution is given by

$$\hat{\boldsymbol{x}} = \hat{\boldsymbol{x}}_\mathrm{s} + \mathbf{V}\boldsymbol{\beta}, \quad \boldsymbol{\beta} \in \mathbb{R}^{n-r} \,. \tag{22.64}$$

Instead of using matrix $\mathbf{S}$ to compute $\hat{\boldsymbol{x}}_\mathrm{s}$, one may also use a computation that makes use of a basis matrix of the orthogonal complement of $\mathcal{R}(\mathbf{S})$. If the $n \times (n-r)$ matrix $\mathbf{S}^\perp$ is such a basis matrix, that is, $\mathcal{R}(\mathbf{S}^\perp) = \mathcal{R}(\mathbf{S})^\perp$, then $\hat{\boldsymbol{x}}_\mathrm{s}$ is the LS-solution of $E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x}$ with constraints $\mathbf{S}^{\perp\top}\boldsymbol{x} = \mathbf{0}$ [22.15].

In decomposition (22.62), $\tilde{\boldsymbol{x}}_\mathrm{s} = \mathbf{S}\boldsymbol{\alpha}$ contains the estimable parameter part, whereas $\boldsymbol{x}_\mathrm{v} = \mathbf{V}\boldsymbol{\beta}$ contains the undetermined or inestimable part (Fig. 22.7)

$$\boldsymbol{x} = \tilde{\boldsymbol{x}}_\mathrm{s} + \boldsymbol{x}_\mathrm{v}, \tilde{\boldsymbol{x}}_\mathrm{s} \in \mathcal{R}(\mathbf{S}), \boldsymbol{x}_\mathrm{v} \in \mathcal{R}(\mathbf{V}) \,. \tag{22.65}$$

Thus, $\hat{\boldsymbol{x}}_\mathrm{s}$ is *not* an unbiased estimator of $\boldsymbol{x}$, $E(\hat{\boldsymbol{x}}_\mathrm{s}) \neq \boldsymbol{x}$, but of $\tilde{\boldsymbol{x}}_\mathrm{s}$ instead, $E(\hat{\boldsymbol{x}}_\mathrm{s}) = \tilde{\boldsymbol{x}}_\mathrm{s}$. To understand what $\hat{\boldsymbol{x}}_\mathrm{s}$ estimates, we need the relation between $\tilde{\boldsymbol{x}}_\mathrm{s}$ and $\boldsymbol{x}$. It is given by

$$\tilde{\boldsymbol{x}}_\mathrm{s} = S\boldsymbol{x}, \quad \text{with} \quad S = \mathbf{I}_n - \mathbf{V}[\mathbf{S}^{\perp\top}\mathbf{V}]^{-1}\mathbf{S}^{\perp\top} \,. \tag{22.66}$$

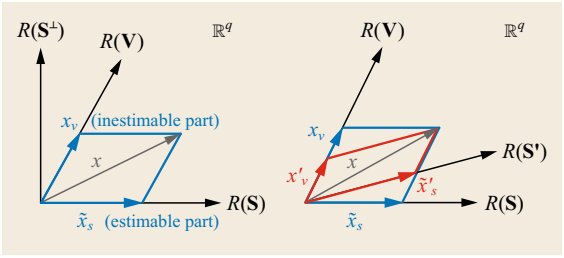

**Fig. 22.7** Two examples of decomposing $\boldsymbol{x}$ in an estimable and inestimable part: $\boldsymbol{x} = \tilde{\boldsymbol{x}}_\mathrm{s} + \boldsymbol{x}_\mathrm{v} = \tilde{\boldsymbol{x}}'_\mathrm{s} + \boldsymbol{x}'_\mathrm{v}$. The $S$-transformation, transforms between solutions: $\tilde{\boldsymbol{x}}_\mathrm{s} = S\tilde{\boldsymbol{x}}'_\mathrm{s}$ (after [22.16])

This relation shows which linear functions of $\boldsymbol{x}$ are estimated by $\hat{\boldsymbol{x}}_\mathrm{s}$. Matrix $\mathbf{S}$, referred to as $S$(ingularity)-transformation, is a projector (i. e., an idempotent matrix) that projects onto $\mathcal{R}(\mathbf{S})$ and along $\mathcal{R}(\mathbf{V})$ [22.15, 17]. This projection is depicted in Fig. 22.7. With the use of the $S$-transformation, one can obtain any particular solution, say $\hat{\boldsymbol{x}}_\mathrm{s}$ and its variance–covariance matrix $\mathbf{Q}_{\hat{\boldsymbol{x}}_\mathrm{s}\hat{\boldsymbol{x}}_\mathrm{s}}$, from any member of the general solution $\hat{\boldsymbol{x}}$ and its variance–covariance matrix, as

$$\hat{\boldsymbol{x}}_\mathrm{s} = S\hat{\boldsymbol{x}} \,, \; \mathbf{Q}_{\hat{\boldsymbol{x}}_\mathrm{s}\hat{\boldsymbol{x}}_\mathrm{s}} = S\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}S^\top \,. \tag{22.67}$$

Hence, one can also transform between different particular solutions by means of an $S$-transformation.

### 22.3.6 Non-Linear Least-Squares

So far only linear LS has been considered. However, the LS principle can also be applied to nonlinear systems of equations. Consider therefore the following inconsistent system of equations

$$y_i \approx a_i(\boldsymbol{x}), \; i = 1, \ldots, m \,, \tag{22.68}$$

where $a_i : \mathbb{R}^n \mapsto \mathbb{R}$ are known but nonlinear functions of the unknown parameter vector $\boldsymbol{x}$. In compact form this is written as

$$\boldsymbol{y} \approx \mathbf{A}(\boldsymbol{x}) = \begin{bmatrix} a_1(\boldsymbol{x}) \\ \vdots \\ a_m(\boldsymbol{x}) \end{bmatrix} . \tag{22.69}$$

The corresponding nonlinear WLS solution reads then

$$\hat{\boldsymbol{x}} = \arg\min_{\boldsymbol{x}\in\mathbb{R}^n} \|\boldsymbol{y} - \mathbf{A}(\boldsymbol{x})\|^2_{\mathbf{W}^{-1}} \,. \tag{22.70}$$

This problem can be solved using an iterative procedure, starting with an initial approximation $\boldsymbol{x}_0$ of the unknown parameters. Successive approximations are made based on the linearized version of $\mathbf{A}(\boldsymbol{x})$.

First, a Taylor series expansion of $a_i(\boldsymbol{x})$ is used

$$\begin{aligned} a_i(\boldsymbol{x}) = a_i(\boldsymbol{x}_0) &+ [\partial_{\boldsymbol{x}} a_i(\boldsymbol{x}_0)]^\top (\boldsymbol{x} - \boldsymbol{x}_0) \\ &+ \frac{1}{2}(\boldsymbol{x} - \boldsymbol{x}_0)^\top \mathbf{H}(\boldsymbol{\theta})(\boldsymbol{x} - \boldsymbol{x}_0) \,, \end{aligned} \tag{22.71}$$

where $a_i : \mathbb{R}^n \mapsto \mathbb{R}$ must have continuous second-order partial derivatives. The gradient vector is given as

$$\partial_{\boldsymbol{x}} a_i(\boldsymbol{x}_0) = \begin{bmatrix} \frac{\partial}{\partial x_1} a_i(\boldsymbol{x}_0) \\ \vdots \\ \frac{\partial}{\partial x_n} a_i(\boldsymbol{x}_0) \end{bmatrix}$$

and the Hessian matrix

$$\mathbf{H}(\boldsymbol{\theta}) = \begin{bmatrix} \frac{\partial^2}{\partial x_1 \partial x_1} a_i(\boldsymbol{\theta}) & \dots & \frac{\partial^2}{\partial x_1 \partial x_n} a_i(\boldsymbol{\theta}) \\ \vdots & & \vdots \\ \frac{\partial^2}{\partial x_n \partial x_1} a_i(\boldsymbol{\theta}) & \dots & \frac{\partial^2}{\partial x_n \partial x_n} a_i(\boldsymbol{\theta}) \end{bmatrix}$$

with $\boldsymbol{\theta}$ in between $\boldsymbol{x}$ and $\boldsymbol{x}_0$. The last term of (22.71) is the second-order remainder and will be ignored, such that the linear approximation

$$a_i(\boldsymbol{x}) \approx a_i(\boldsymbol{x}_0) + [\partial_{\boldsymbol{x}} a_i(\boldsymbol{x}_0)]^\top (\boldsymbol{x} - \boldsymbol{x}_0)$$

is obtained. The vector function $\mathbf{A}(\boldsymbol{x})$ can now be approximated as

$$\mathbf{A}(\boldsymbol{x}) \approx \mathbf{A}(\boldsymbol{x}_0) + \mathbf{J}_0(\boldsymbol{x} - \boldsymbol{x}_0) \tag{22.72}$$

with the Jacobian matrix

$$\mathbf{J}_0 = \begin{bmatrix} [\partial_{\boldsymbol{x}} a_1(\boldsymbol{x}_0)]^\top \\ \vdots \\ [\partial_{\boldsymbol{x}} a_m(\boldsymbol{x}_0)]^\top \end{bmatrix}.$$

The nonlinear system (22.69) can be approximated using (22.72) as

$$\Delta \boldsymbol{y}_0 \approx \mathbf{J}_0 \Delta \boldsymbol{x}_0 \tag{22.73}$$

with $\Delta \boldsymbol{y}_0 = \boldsymbol{y} - \mathbf{A}(\boldsymbol{x}_0)$ and $\Delta \boldsymbol{x}_0 = \boldsymbol{x} - \boldsymbol{x}_0$.

The linearized system of equation in (22.73) can now be solved using the linear WLS principle to obtain the estimator

$$\Delta \hat{\boldsymbol{x}}_0 = \left(\mathbf{J}_0^\top \mathbf{W} \mathbf{J}_0\right)^{-1} \mathbf{J}_0^\top \mathbf{W} \Delta \boldsymbol{y}_0 \,. \tag{22.74}$$

The WLS solution $\hat{\boldsymbol{x}}_0 = \boldsymbol{x}_0 + \Delta \hat{\boldsymbol{x}}_0$ should ideally be closer to $\boldsymbol{x}$ than $\boldsymbol{x}_0$ but is generally not used as the final solution. In the so-called Gauss–Newton iteration scheme, this solution is namely used as a new approximation in order to get a better approximation and continues until the difference between successive approximations becomes small enough. The procedure is thus to take as successive approximations

$$\boldsymbol{x}_i := \boldsymbol{x}_{i-1} + \Delta \hat{\boldsymbol{x}}_{i-1} \tag{22.75}$$

with

$$\Delta \hat{\boldsymbol{x}}_i = \left(\mathbf{J}_i^\top \mathbf{W} \mathbf{J}_i\right)^{-1} \mathbf{J}_i^\top \mathbf{W} \Delta \boldsymbol{y}_i \,, \tag{22.76}$$

where $\mathbf{J}_i$ is the matrix with partial derivatives with respect to $\boldsymbol{x}_i$ and $\Delta \boldsymbol{y}_i = \boldsymbol{y} - \mathbf{A}(\boldsymbol{x}_i)$.

The iteration is terminated when

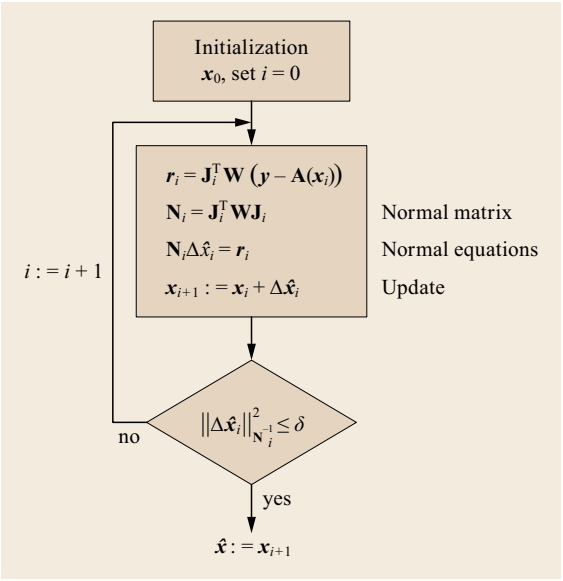

**Fig. 22.8** Gauss–Newton iteration for nonlinear least-squares

$$\|\Delta \hat{\boldsymbol{x}}_i\|^2_{\mathbf{N}_i^{-1}} \le \delta \quad \text{with} \quad \mathbf{N}_i = \mathbf{J}_i^\top \mathbf{W} \mathbf{J}_i$$

and $\delta$ a small user-defined threshold. Once the stop criterion is met, the WLS solution is given by

$$\hat{\boldsymbol{x}} = \boldsymbol{x}_i + \Delta \hat{\boldsymbol{x}}_i \,. \tag{22.77}$$

The complete Gauss–Newton iteration scheme is depicted in Fig. 22.8. For more properties of the Gauss–Newton method and on alternative nonlinear-LS solvers, see [22.18, 19].

The initial approximation $\boldsymbol{x}_0$ has to be obtained depending on the application at hand; it requires insight in the specific problem.

The Gauss–Newton method will converge to the LS solution in the absence of severe nonlinearity and large measurement errors. However, it should be noted that the nonlinear WLS estimator is not unbiased and is not normally distributed even if the measurements and random errors are. Diagnostic measures to test for the significance of these nonlinearity effects on the mean and variance–covariance matrix are given in [22.20]. If the second- and higher order terms in the Taylor series expansion are negligibly small, the distribution of the nonlinear WLS estimator will be very close to the normal distribution with negligible bias. The variance–covariance matrix $\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}$ can then be approximated by

$$\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}} \approx \left(\mathbf{J}_i^\top \mathbf{Q}_{\boldsymbol{y}\boldsymbol{y}}^{-1} \mathbf{J}_i\right)^{-1} , \tag{22.78}$$

where $\mathbf{A}$ in (22.22) is replaced by the Jacobian $\mathbf{J}_i$ (from the last iteration).

## 22.4 Prediction and Filtering

In most GNSS applications, the parameters of interest are time-varying. This is obvious for a moving platform, for which we are interested in its position and sometimes also its attitude (Chaps. 27 and 28). Also, with GNSS deformation measurements of the Earth's surface or man-made structures we are dealing with time-variable parameters. Another example is when we are interested in the troposphere and ionosphere delays, as well as instrumental parameters such as clock drifts and biases.

In Sect. 22.3.1, we have already seen how recursive estimation can be applied in case of constant model parameters with sequentially collected data. Recursive or sequential estimation is very suitable for real-time estimation problems, but also for offline processing in order to reduce the number of parameters to be simultaneously estimated. In the following, three types of estimation problems for sequentially collected data will be discussed. The estimation problem arising for real-time applications is referred to as *filtering*: The measurements up till and including the current epoch are used to estimate the current state. This is the topic of Sect. 22.5. There, also *smoothing* will be discussed. This is the problem where the time of interest falls within the time span of collected data. In the current chapter, the focus will be on *prediction*, this is when we are interested in a future state. Figure 22.9 illustrates the three problems.

### 22.4.1 Prediction Problem

Prediction may refer to predicting the model parameters in time; however, it may also refer to predicting, or interpolating the parameters in space. Moreover, not necessarily, the model parameters are to be predicted; also the observations themselves or the signal and noise affecting the measurements may have to be predicted. In all cases, the idea is that an observable random vector $\boldsymbol{y}$ is used to guess the outcome of another random vector, which is not observable. Note the difference with the estimation problem, where the random $\boldsymbol{y}$ was used to find the best matching unknown but *deterministic* parameters according to a given relationship.

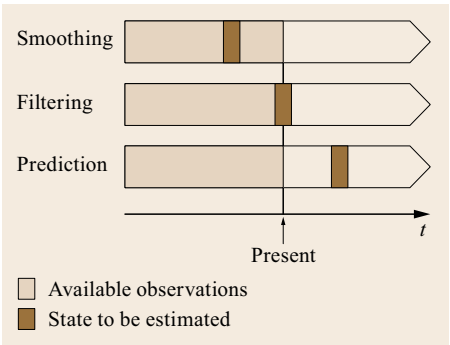

**Fig. 22.9** The concept of smoothing, filtering, and prediction

All prediction problems mentioned above can be written in a similar form as (22.3) [22.21]

$$\begin{pmatrix} \boldsymbol{y} \\ \boldsymbol{p} \end{pmatrix} = \begin{bmatrix} \mathbf{A} \\ \mathbf{A}_p \end{bmatrix} \boldsymbol{x} + \begin{pmatrix} \boldsymbol{e} \\ \boldsymbol{e}_p \end{pmatrix} \tag{22.79}$$

but now with $\boldsymbol{p}$ being an unobserved random vector of which the outcome needs to be predicted. As before, the unknown parameter vector $\boldsymbol{x}$ is deterministic, $\mathbf{A}_p$ is the given $m_p \times n$ coefficient matrix of $\boldsymbol{p}$, and $\boldsymbol{e}_p$ is a zero-mean random vector. The variance–covariance matrix of $\boldsymbol{y}$ and $\boldsymbol{p}$

$$\begin{bmatrix} \mathbf{Q}_{yy} & \mathbf{Q}_{yp} \\ \mathbf{Q}_{py} & \mathbf{Q}_{pp} \end{bmatrix}$$

is assumed given.

Some typical examples to which the above formulation applies are:

*Example 22.7 Recovery of Undifferenced Residuals*

Let $\boldsymbol{e}$ in $\boldsymbol{y} = \mathbf{A}\boldsymbol{x} + \boldsymbol{e}$ be given as $\boldsymbol{e} = \mathbf{D}^\top \boldsymbol{u}$, with matrix $\mathbf{D}$ known and where $\boldsymbol{u}$ is a zero-mean random vector with known variance–covariance matrix $\mathbf{Q}_{uu}$. If $\boldsymbol{y}$ is the vector of differenced GNSS observables and $\mathbf{D}^\top$ the differencing operator, then $\boldsymbol{u}$ is the vector of undifferenced residuals. If the undifferenced GNSS residual vector $\boldsymbol{u}$ is to be predicted, then (22.79) takes the form

$$\begin{pmatrix} \boldsymbol{y} \\ \boldsymbol{u} \end{pmatrix} = \begin{bmatrix} \mathbf{A} \\ \mathbf{0} \end{bmatrix} \boldsymbol{x} + \begin{pmatrix} \boldsymbol{e} \\ \boldsymbol{u} \end{pmatrix} \tag{22.80}$$

with variance–covariance matrix

$$\begin{bmatrix} \mathbf{D}^\top \mathbf{Q}_{uu} \mathbf{D} & \mathbf{D}^\top \mathbf{Q}_{uu} \\ \mathbf{Q}_{uu} \mathbf{D} & \mathbf{Q}_{uu} \end{bmatrix}.$$

A typical GNSS example where the method of recovering undifferenced residuals from double-differenced data is applied is in the creation of CORS multipath maps [22.22, 23].

*Example 22.8 Separation of Trend, Signal, and Noise*

For the trend-signal-noise model, we have

$$\boldsymbol{y} = \mathbf{A}\boldsymbol{x} + \boldsymbol{s} + \boldsymbol{n}\,, \tag{22.81}$$

where $\mathbf{A}\boldsymbol{x}$ is the deterministic *trend* with unknown $\boldsymbol{x}$, $\boldsymbol{s}$ is a zero-mean random *signal*, and $\boldsymbol{n}$ is the zero-mean random *noise*. In this case, the goal is to predict $\boldsymbol{s}$ and $\boldsymbol{n}$, and model (22.79) becomes

$$\begin{pmatrix} \boldsymbol{y} \\ \boldsymbol{s} \\ \boldsymbol{n} \end{pmatrix} = \begin{bmatrix} \mathbf{A} \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix} \boldsymbol{x} + \begin{pmatrix} \boldsymbol{s}+\boldsymbol{n} \\ \boldsymbol{s} \\ \boldsymbol{n} \end{pmatrix} . \tag{22.82}$$

Alternatively, the trend-signal-noise model can be applied to predict a function of the same type, say $\boldsymbol{y}_p = \mathbf{A}_p\boldsymbol{x} + \boldsymbol{s}_p$, at another *time* and/or *location*, which means interpolation or extrapolation. For instance, in the case of ionospheric interpolation from network-derived ionospheric delays, $\boldsymbol{x}$ contains the ionospheric trend parameters, the signals $\boldsymbol{s}$ and $\boldsymbol{s}_p$ the spatiotemporal variability of the ionosphere, and $\boldsymbol{n}$ the GNSS observational measurement noise. In that case the prediction model becomes

$$\begin{pmatrix} \boldsymbol{y} \\ \boldsymbol{y}_p \end{pmatrix} = \begin{bmatrix} \mathbf{A} \\ \mathbf{A}_p \end{bmatrix} \boldsymbol{x} + \begin{pmatrix} \boldsymbol{s}+\boldsymbol{n} \\ \boldsymbol{s}_p \end{pmatrix} , \tag{22.83}$$

which is again of a form similar as (22.79).

In this section, the principle and properties of minimum mean squared error (MMSE) prediction will be presented in order to solve the prediction problems described here. The solution will be presented based on the model of (22.79).

### 22.4.2 Minimum Mean Squared Error Prediction

#### Best Predictor (BP)

Let the predictor of $\boldsymbol{p}$ be given by a function $G(\boldsymbol{y})$. The prediction error in model (22.79) will then be equal to

$$\boldsymbol{p} - G(\boldsymbol{y}) . \tag{22.84}$$

A predictor is considered best if it has the smallest mean square prediction error. The BP $\hat{G}(\boldsymbol{y})$ from a certain class $\Omega$ of predictors should thus fulfill according to the MMSE criterion

$$E\left( \|\boldsymbol{p} - \hat{G}(\boldsymbol{y})\|^2_{\mathbf{W}^{-1}} \right) = \min_{G\in\Omega} E\left( \|\boldsymbol{p} - G(\boldsymbol{y})\|^2_{\mathbf{W}^{-1}} \right) . \tag{22.85}$$

If no restrictions are placed on the class of predictors, the best predictor of $\boldsymbol{p}$ is equal to the conditional mean

$$\hat{\boldsymbol{p}}_{\mathrm{BP}} = E(\boldsymbol{p}|\boldsymbol{y}) = \int \boldsymbol{\alpha} f_{\boldsymbol{p}|\boldsymbol{y}}(\boldsymbol{\alpha}|\boldsymbol{y}) \mathrm{d}\boldsymbol{\alpha} \tag{22.86}$$

with $f_{\boldsymbol{p}|\boldsymbol{y}}(\cdot)$ the conditional PDF of $\boldsymbol{p}$.

#### Best Linear Predictor (BLP)

If it is required that the predictor $G$ is of a linear form

$$G(\boldsymbol{y}) = \mathbf{L}\boldsymbol{y} + \boldsymbol{l} , \tag{22.87}$$

then the best linear predictor (BLP) takes the form

$$\hat{\boldsymbol{p}}_{\mathrm{BLP}} = \bar{\boldsymbol{p}} + \mathbf{Q}_{\boldsymbol{p}\boldsymbol{y}}\mathbf{Q}_{\boldsymbol{y}\boldsymbol{y}}^{-1}(\boldsymbol{y} - \bar{\boldsymbol{y}}) \tag{22.88}$$

with $\bar{\boldsymbol{p}} = E(\boldsymbol{p})$ and $\bar{\boldsymbol{y}} = E(\boldsymbol{y})$. Note that the BLP does not need complete information about the PDF, this in contrast with the BP. For the BLP, only the first two moments, the mean and the variance, need to be known. The two predictors, BP and BLP, become identical in the Gaussian case, that is, when $\boldsymbol{y}$ and $\boldsymbol{p}$ are normally distributed.

#### Best Linear Unbiased Prediction (BLUP)

Although the BLP only needs knowledge about the first two moments, the need to know the mean is still impractical for many applications. As can be seen from (22.79), since $\boldsymbol{x}$ is unknown, also the means $\bar{\boldsymbol{p}}$ and $\bar{\boldsymbol{y}}$ in (22.88) are unknown. What is known, however, is that their means are linearly related as

$$E\begin{pmatrix} \boldsymbol{y} \\ \boldsymbol{p} \end{pmatrix} = \begin{bmatrix} \mathbf{A} \\ \mathbf{A}_p \end{bmatrix} \boldsymbol{x} . \tag{22.89}$$

If we include this relation into the minimization of the mean squared prediction error over the class of linear unbiased predictors, one obtains the best linear unbiased predictor as

$$\hat{\boldsymbol{p}}_{\mathrm{BLUP}} = \mathbf{A}_p\hat{\boldsymbol{x}} + \mathbf{Q}_{\boldsymbol{p}\boldsymbol{y}}\mathbf{Q}_{\boldsymbol{y}\boldsymbol{y}}^{-1}(\boldsymbol{y} - \mathbf{A}\hat{\boldsymbol{x}}) , \tag{22.90}$$

in which $\hat{\boldsymbol{x}}$ is the BLUE of $\boldsymbol{x}$ from (22.21). Hence, the BLUP (22.90) follows from the BP (22.88) by replacing the means $\bar{\boldsymbol{p}}$ and $\bar{\boldsymbol{y}}$ by their BLUEs.

*Example 22.9 Recovery of Undifferenced Residuals (Continued)*

If we apply the above prediction formula (22.90) to determine the BLUP of the undifferenced GNSS residual $\boldsymbol{u}$ of (22.80), we obtain

$$\hat{\boldsymbol{u}} = \mathbf{Q}_{\boldsymbol{u}\boldsymbol{u}}\mathbf{D}\left(\mathbf{D}^\top\mathbf{Q}_{\boldsymbol{u}\boldsymbol{u}}\mathbf{D}\right)^{-1}\hat{\boldsymbol{e}} \tag{22.91}$$

with $\hat{\boldsymbol{e}} = \boldsymbol{y} - \mathbf{A}\hat{\boldsymbol{x}}$. This result shows how the undifferenced GNSS residual $\hat{\boldsymbol{u}}$ can be obtained from the differenced GNSS residual $\hat{\boldsymbol{e}}$ [22.22, 23].

*Example 22.10 Example of Trend–Signal–Noise*

Consider a random vector function $\boldsymbol{z}(t)$ (Fig. 22.10). We assume that $\boldsymbol{z}(t)$ can be written as the sum of a deterministic, but unknown trend $\mathbf{A}_t\boldsymbol{x}$, and a zero-mean random signal $\boldsymbol{s}(t)$

$$\boldsymbol{z}(t) = \mathbf{A}_t\boldsymbol{x} + \boldsymbol{s}(t) \,, \tag{22.92}$$

where $\mathbf{A}_t$ is a known $k \times n$ matrix and $\boldsymbol{x}$ is an unknown parameter vector. The random function is observed at $t_1 \ldots, t_m$,

$$\boldsymbol{y}(t_i) = \boldsymbol{z}(t_i) + \boldsymbol{n}(t_i), \quad i = 1, \ldots, m \,, \tag{22.93}$$

where $\boldsymbol{n}(t_i)$ is the zero-mean random measurement noise. The measurement noise is assumed to be uncorrelated with the signal, $\mathbf{C}(\boldsymbol{s}(t), \boldsymbol{n}(t_i)) = 0$, and the covariance matrices of the signal and the measurement noise are assumed to be given as

$$\mathbf{C}(\boldsymbol{s}(t_i), \boldsymbol{s}(t_j)) = \mathbf{Q}_{s(t_i)s(t_j)} \quad \text{and}$$
$$\mathbf{C}(\boldsymbol{n}(t_i), \boldsymbol{n}(t_j)) = \mathbf{Q}_{n(t_i)n(t_j)},$$

respectively. If we combine the above equations, we may write in compact vector–matrix form

$$\boldsymbol{y} = \mathbf{A}\boldsymbol{x} + \boldsymbol{s} + \boldsymbol{n} \,, \tag{22.94}$$

where

$$\boldsymbol{y} = \left[\boldsymbol{y}(t_1)^\top, \ldots, \boldsymbol{y}(t_m)^\top\right]^\top \,,$$
$$\mathbf{A} = \left[\mathbf{A}_{t_1}^\top \ldots, \mathbf{A}_{t_m}^\top\right]^\top \,,$$
$$\boldsymbol{s} = \left[\boldsymbol{s}(t_1)^\top, \ldots, \boldsymbol{s}(t_m)^\top\right]^\top \quad \text{and}$$
$$\boldsymbol{n} = \left[\boldsymbol{n}(t_1)^\top, \ldots, \boldsymbol{n}(t_m)^\top\right]^\top \,.$$

We now have all the ingredients available for estimating the trend $\mathbf{A}_t\boldsymbol{x}$ and predicting the signal $\boldsymbol{s}(t)$, the noise $\boldsymbol{n}(t_i)$, and the function $\boldsymbol{z}(t)$.

### Trend

Let $\boldsymbol{e} = \boldsymbol{s} + \boldsymbol{n}$. Then, $\boldsymbol{y} = \mathbf{A}\boldsymbol{x} + \boldsymbol{e}$ is in the form of a linear model with deterministic parameters, where $E(\boldsymbol{e}) = 0$ and $D(\boldsymbol{y}) = D(\boldsymbol{e}) = \mathbf{Q}_{ss} + \mathbf{Q}_{nn}$, since $\mathbf{Q}_{sn} = 0$. Hence, the BLUE of $\boldsymbol{x}$ is

$$\hat{\boldsymbol{x}} = \left(\mathbf{A}^\top(\mathbf{Q}_{ss} + \mathbf{Q}_{nn})^{-1}\mathbf{A}\right)^{-1} \times \mathbf{A}^\top(\mathbf{Q}_{ss} + \mathbf{Q}_{nn})^{-1}\boldsymbol{y} \,. \tag{22.95}$$

Since the trend of the random function is given by its mean, $E(\boldsymbol{z}(t)) = \mathbf{A}_t\boldsymbol{x}$, the BLUE of the trend follows as $\mathbf{A}_t\hat{\boldsymbol{x}}$.

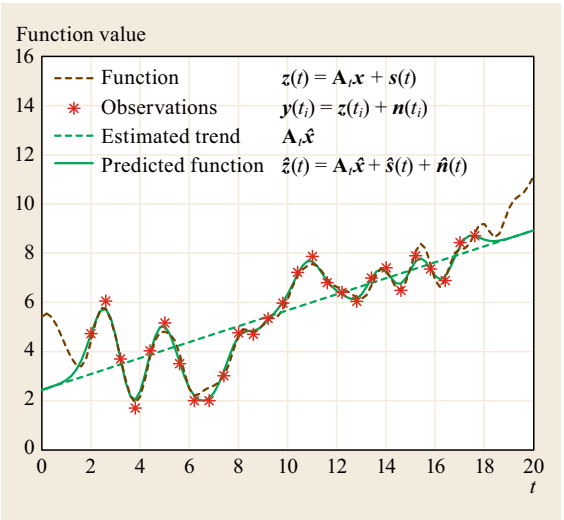

**Fig. 22.10** BLUE of the trend $\mathbf{A}_t\hat{\boldsymbol{x}}$ and BLUP of the random function $\hat{\boldsymbol{z}}(t)$. Observation values $\mathbf{y}(t_i)$, and the random function $\boldsymbol{z}(t)$ are shown as well

### Signal

The zero-mean random signal $\boldsymbol{s}(t)$ is the difference between the random function $\boldsymbol{z}(t)$ and its mean $\mathbf{A}_t\boldsymbol{x}$. To predict by how much the random function differs from its mean, we need the BLUP of $\boldsymbol{s}(t)$. Since $E(\boldsymbol{s}(t)) = 0$ and $\mathbf{C}(\boldsymbol{s}(t), \boldsymbol{n}) = 0$, the BLUP of $\boldsymbol{s}(t)$ is given as

$$\hat{\boldsymbol{s}}(t) = \mathbf{Q}_{s(t)s}(\mathbf{Q}_{ss} + \mathbf{Q}_{nn})^{-1}(\boldsymbol{y} - \mathbf{A}\hat{\boldsymbol{x}}) \,. \tag{22.96}$$

### Noise

Similar to the prediction of the signal, we can predict the measurement noise $\boldsymbol{n}(t_i)$. We have

$$\hat{\boldsymbol{n}}(t_i) = \mathbf{Q}_{n(t_i)n}(\mathbf{Q}_{ss} + \mathbf{Q}_{nn})^{-1}(\boldsymbol{y} - \mathbf{A}\hat{\boldsymbol{x}}) \,. \tag{22.97}$$

Note, since

$$(\mathbf{Q}_{s(t_i)s} + \mathbf{Q}_{n(t_i)n})(\mathbf{Q}_{ss} + \mathbf{Q}_{nn})^{-1} = [\mathbf{0}, \ldots, \mathbf{I}_k, \ldots, \mathbf{0}] \,,$$

that the predicted signal $\hat{\boldsymbol{s}}(t_i)$ and the predicted noise $\hat{\boldsymbol{n}}(t_i)$ add up to the BLUP of $\boldsymbol{e}(t_i) = \boldsymbol{s}(t_i) + \boldsymbol{n}(t_i)$, $\hat{\boldsymbol{e}}(t_i) = \hat{\boldsymbol{s}}(t_i) + \hat{\boldsymbol{n}}(t_i) = \boldsymbol{y}(t_i) - \mathbf{A}(t_i)\hat{\boldsymbol{x}}$.

### Function

The BLUP of the random function $\boldsymbol{z}(t)$ itself follows as the sum of the BLUE of the trend and the BLUP of the signal

$$\hat{\boldsymbol{z}}(t) = \mathbf{A}_t\hat{\boldsymbol{x}} + \hat{\boldsymbol{s}}(t) \,. \tag{22.98}$$

Note, since

$$\hat{\boldsymbol{s}}(t_i) + \hat{\boldsymbol{n}}(t_i) = \boldsymbol{y}(t_i) - \mathbf{A}(t_i)\hat{\boldsymbol{x}} \,,$$

that

$$\boldsymbol{y}(t_i) = \hat{\boldsymbol{z}}(t_i) + \hat{\boldsymbol{n}}(t_i) = \mathbf{A}(t_i)\hat{\boldsymbol{x}} + \hat{\boldsymbol{s}}(t_i) + \hat{\boldsymbol{n}}(t_i)\,,$$

which shows that the observable is its own best predictor.

Figure 22.10 shows the function $\boldsymbol{z}(t)$, as well as the BLUE of its trend and its BLUP. In Fig. 22.11, it is shown that the predicted signal $\hat{\boldsymbol{s}}(t_i)$ and the predicted noise $\hat{\boldsymbol{n}}(t_i)$ indeed add up to $\hat{\boldsymbol{e}}(t_i)$. In the figure, this is demonstrated for the BLUP of the random function from Fig. 22.10 at observation instant $t_2$.

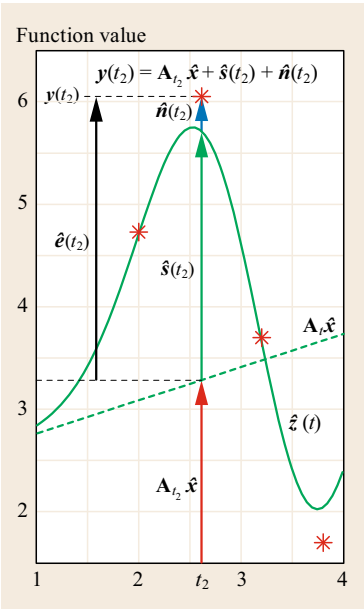

**Fig. 22.11**
Portion of Fig. 22.10, showing that $\hat{\boldsymbol{e}}(t_2) = \hat{\boldsymbol{s}}(t_2) + \hat{\boldsymbol{n}}(t_2) = \boldsymbol{y}(t_2) - \mathbf{A}_{t_2}\hat{\boldsymbol{x}}$

### 22.4.3 Properties of MMSE Prediction

The MMSE predictors as discussed in the previous section are all unbiased predictors. Hence, they have a zero-mean prediction error

$$E(\hat{\boldsymbol{e}}_p) = E(\boldsymbol{p} - \hat{\mathbf{G}}(\boldsymbol{y})) = \mathbf{0}\,. \tag{22.99}$$

The variance matrices of the BLP and BLUP prediction errors are given as [22.21]

$$\begin{aligned}\mathbf{Q}^{\text{BLUP}}_{\hat{\boldsymbol{e}}_p\hat{\boldsymbol{e}}_p} &= \mathbf{Q}^{\text{BLP}}_{\hat{\boldsymbol{e}}_p\hat{\boldsymbol{e}}_p} + \mathbf{A}_{p|\boldsymbol{y}}\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}\mathbf{A}^{\top}_{p|\boldsymbol{y}}\\ \mathbf{Q}^{\text{BLP}}_{\hat{\boldsymbol{e}}_p\hat{\boldsymbol{e}}_p} &= \mathbf{Q}_{\boldsymbol{pp}} - \mathbf{Q}_{\boldsymbol{py}}\mathbf{Q}^{-1}_{\boldsymbol{yy}}\mathbf{Q}_{\boldsymbol{yp}}\end{aligned} \tag{22.100}$$

with

$$\mathbf{A}_{p|\boldsymbol{y}} = \mathbf{A}_p - \mathbf{Q}_{\boldsymbol{py}}\mathbf{Q}^{-1}_{\boldsymbol{yy}}\mathbf{A}\,.$$

Note that

$$\mathbf{Q}^{\text{BLUP}}_{\hat{\boldsymbol{e}}_p\hat{\boldsymbol{e}}_p} \geq \mathbf{Q}^{\text{BLP}}_{\hat{\boldsymbol{e}}_p\hat{\boldsymbol{e}}_p}\,,$$

that is, the BLUP prediction error is never more precise than that of the BLP. This is due to additional uncertainty that enters by having to estimate $\boldsymbol{x}$ as well.

The variance–covariance matrix of the prediction error, also referred to as *error variance matrix*, should not be confused with the variance–covariance matrix of the predictor itself, which in case of BLUP is given as

$$\mathbf{Q}^{\text{BLUP}}_{\hat{\boldsymbol{p}}\hat{\boldsymbol{p}}} = \mathbf{Q}^{\text{BLUE}}_{\hat{\boldsymbol{p}}\hat{\boldsymbol{p}}} + \mathbf{Q}_{\boldsymbol{py}}\mathbf{Q}^{-1}_{\boldsymbol{yy}}\mathbf{Q}_{\hat{\boldsymbol{e}}\hat{\boldsymbol{e}}}\mathbf{Q}^{-1}_{\boldsymbol{yy}}\mathbf{Q}_{\boldsymbol{yp}} \tag{22.101}$$

with

$$\mathbf{Q}^{\text{BLUE}}_{\hat{\boldsymbol{p}}\hat{\boldsymbol{p}}} = \mathbf{A}_p\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}\mathbf{A}^{\top}_p\,.$$

## 22.5 Kalman Filtering

The Kalman filter is a recursive method to estimate the random states of a dynamic system in a way that minimizes the mean squared prediction error. After its initialization, the Kalman filter follows a recursive two-step procedure of time- and measurement-updates. In the time-update (TU), information of the dynamic model is used to predict the system state, and its error-variance matrix, ahead in time, thus, giving $\hat{\boldsymbol{x}}_{k|k-1}$ and its error variance matrix $\mathbf{P}_{k|k-1}$. In the measurement-update (MU), the newly arrived measurements $\boldsymbol{y}_k$ are combined, in a MMSE-sense, with the predicted state $\hat{\boldsymbol{x}}_{k|k-1}$ to obtain the filtered state $\hat{\boldsymbol{x}}_{k|k}$ and its error variance matrix $\mathbf{P}_{k|k}$ (Fig. 22.12).

### 22.5.1 Model Assumptions

First, we state the assumptions on which the Kalman filter is based. They concern the measurement model and the dynamic model.

#### The Measurement Model

The link between the random vector of observables $\boldsymbol{y}_i$ and the random state-vector $\boldsymbol{x}_i$ is assumed given as

$$\boldsymbol{y}_i = \mathbf{A}_i\boldsymbol{x}_i + \boldsymbol{n}_i,\ i = 0, 1, \ldots, t \tag{22.102}$$

together with

$$E(\boldsymbol{x}_0) = \bar{\boldsymbol{x}}_0, \quad E(\boldsymbol{n}_i) = \mathbf{0} \tag{22.103}$$

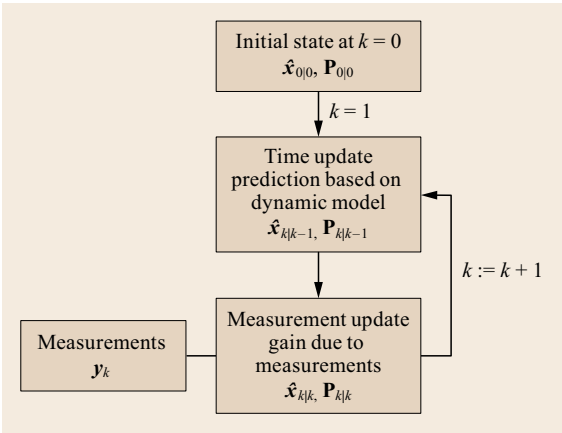

**Fig. 22.12** Kalman filter recursion with time-update (TU) and measurement-update (MU)

and

$$\mathbf{C}(\boldsymbol{x}_0, \boldsymbol{n}_i) = \mathbf{0}, \quad \mathbf{C}(\boldsymbol{n}_i, \boldsymbol{n}_j) = \mathbf{R}_i \delta_{i,j}\,, \quad i = 0, 1, \ldots, t\,, \tag{22.104}$$

where $\mathbf{C}(\boldsymbol{u}, \boldsymbol{v})$ denotes the covariance between two random vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ and $\delta_{i,j}$ is the Kronecker delta. Thus, the zero-mean measurement noise $\boldsymbol{n}_i$ is assumed to be uncorrelated in time and to be uncorrelated with the initial state-vector $\boldsymbol{x}_0$.

### The Dynamic Model

The linear dynamic model, describing the time-evolution of the random state-vector $\boldsymbol{x}_i$, is given as

$$\boldsymbol{x}_i = \boldsymbol{\Phi}_{i,i-1}\boldsymbol{x}_{i-1} + \boldsymbol{d}_i, \; i = 1, 2, \ldots, t \tag{22.105}$$

with

$$E(\boldsymbol{d}_i) = \mathbf{0}, \; \mathbf{C}(\boldsymbol{x}_0, \boldsymbol{d}_i) = \mathbf{0}\,, \tag{22.106}$$

$$\mathbf{C}(\boldsymbol{d}_i, \boldsymbol{n}_j) = \mathbf{0}, \; \mathbf{C}(\boldsymbol{d}_i, \boldsymbol{d}_j) = \mathbf{S}_i \delta_{i,j}\,, \quad i, j = 1, 2, \ldots, t\,, \tag{22.107}$$

where $\boldsymbol{\Phi}_{i,i-1}$ denotes the transition matrix and the random vector $\boldsymbol{d}_i$ is the system noise. The system noise $\boldsymbol{d}_i$ is thus also assumed to have a zero mean, to be uncorrelated in time and to be uncorrelated with the initial state-vector and the measurement noise. Note that the transition matrix from epoch $j$ to $i$ is denoted as $\boldsymbol{\Phi}_{i,j}$. Thus, $\boldsymbol{\Phi}_{i,j}^{-1} = \boldsymbol{\Phi}_{j,i}$.

The dynamic model (22.105) and its transition matrix can be obtained from solving the dynamic system's first-order vectorial differential equation. For instance, if the dynamic system is described by a first-order linearized time-varying system of differential equations, $\dot{\boldsymbol{x}}_t = \mathbf{F}_t \boldsymbol{x}_t + \mathbf{G}_t \boldsymbol{u}_t$, then

$$\boldsymbol{x}_t = \boldsymbol{\Phi}_{t,t_0}\boldsymbol{x}_{t_0} + \int_{t_0}^{t} \boldsymbol{\Phi}_{t,\tau}\mathbf{G}_\tau \boldsymbol{u}_\tau \,\mathrm{d}\tau \tag{22.108}$$

with the transition matrix being the solution of [22.24, 25]

$$\frac{\partial \boldsymbol{\Phi}_{t,t_0}}{\partial t} = \mathbf{F}_t \boldsymbol{\Phi}_{t,t_0}, \boldsymbol{\Phi}_{t,t_0} = \mathbf{I}_n\,.$$

Methods for its numerical integration can be found in, for example, [22.26]. For the case matrix $\mathbf{F}_t$ is time-invariant, the solution is given by the matrix exponential $\boldsymbol{\Phi}_{t,t_0} = \exp(\mathbf{F}(t-t_0))$. Methods of evaluating the matrix exponential are given in [22.27].

## 22.5.2 The Kalman Filter Recursion

The Kalman filter is usually derived as either a recursive BP (Gaussian case) or as a recursive BLP, [22.28–31]. Both these predictors require that the mean of the random state vector, $E(\boldsymbol{x}_i)$, is known. This is why in the derivation of the Kalman filter one usually assumes the mean of the random initial state-vector $\bar{\boldsymbol{x}}_0$ (22.103) to be known [22.32–35]. Such derivation of the Kalman filter is however not appropriate in case the mean of the random state vector is unknown, a situation that applies to most engineering applications. In the following, we will therefore assume $E(\boldsymbol{x}_0) = \bar{\boldsymbol{x}}_0$ unknown and present the results obtained when applying the recursive BLUP principle. We start with the initialization and then present the TU and MU.

### Initialization

The initial state and its error-variance matrix are given as

$$\hat{\boldsymbol{x}}_{0|0} = (\mathbf{A}^\top \mathbf{R}_0^{-1}\mathbf{A})^{-1}\mathbf{A}^\top \mathbf{R}_0^{-1}\boldsymbol{y}_0$$
$$\mathbf{P}_{0|0} = (\mathbf{A}^\top \mathbf{R}_0^{-1}\mathbf{A})^{-1}\,. \tag{22.109}$$

Note that $\mathbf{P}_{0|0}$ is *not* the variance–covariance matrix of $\hat{\boldsymbol{x}}_{0|0}$. If $\mathbf{Q}_{x_0x_0}$ is the variance–covariance matrix of the random state vector $\boldsymbol{x}_0$, then the sum $\mathbf{Q}_{x_0x_0} + \mathbf{P}_{0|0}$ is the variance–covariance matrix of $\hat{\boldsymbol{x}}_{0|0}$. Would one assume that the mean of the random state vector is known, then the initialization would be given as $\hat{\boldsymbol{x}}_{0|0} = \bar{\boldsymbol{x}}_0$, with error-variance matrix $\mathbf{P}_{0|0} = \mathbf{Q}_{x_0x_0}$.

### Time Update (TU)

The time-updated state vector and its error-variance matrix are given as

$$\hat{\boldsymbol{x}}_{k|k-1} = \boldsymbol{\Phi}_{k,k-1}\hat{\boldsymbol{x}}_{k-1|k-1}$$
$$\mathbf{P}_{k|k-1} = \boldsymbol{\Phi}_{k,k-1}\mathbf{P}_{k-1|k-1}\boldsymbol{\Phi}_{k,k-1}^\top + \mathbf{S}_k\,, \tag{22.110}$$

for $k = 1, \ldots, t$.

### Measurement-Update (MU)

In the MU, it is the predicted residual that is used to correct the predicted state. The predicted residual (sometimes also referred to as *innovation*) and its variance–covariance matrix are given as

$$\begin{aligned} \boldsymbol{v}_k &= \boldsymbol{y}_k - \mathbf{A}_k \hat{\boldsymbol{x}}_{k|k-1} \\ \mathbf{Q}_{\boldsymbol{v}_k \boldsymbol{v}_k} &= \mathbf{R}_k + \mathbf{A}_k \mathbf{P}_{k|k-1} \mathbf{A}_k^\top \,. \end{aligned} \tag{22.111}$$

The predicted residuals have the important property that they are zero-mean and uncorrelated in time

$$E(\boldsymbol{v}_k) = \mathbf{0}\,,\; \mathbf{C}(\boldsymbol{v}_k, \boldsymbol{v}_l) = \mathbf{Q}_{\boldsymbol{v}_k \boldsymbol{v}_k} \delta_{k,l}\,. \tag{22.112}$$

This property forms the basis for performing recursive quality control and hypotheses testing (Chap. 24).

Using the predicted residual vector, the filtered state and its error-variance matrix are given as

$$\begin{aligned} \hat{\boldsymbol{x}}_{k|k} &= \hat{\boldsymbol{x}}_{k|k-1} + \mathbf{K}_k \boldsymbol{v}_k \\ \mathbf{P}_{k|k} &= (\mathbf{I}_n - \mathbf{K}_k \mathbf{A}_k) \mathbf{P}_{k|k-1} \end{aligned} \tag{22.113}$$

with the Kalman gain matrix given as

$$\mathbf{K}_k = \mathbf{P}_{k|k-1} \mathbf{A}_k^\top \mathbf{Q}_{\boldsymbol{v}_k \boldsymbol{v}_k}^{-1}\,. \tag{22.114}$$

An illustration of the contributions of the time update (22.110) and the measurement update (22.113) is shown in Fig. 22.13. The green line shows the actual trajectory $\boldsymbol{x}_t$, not to be confused with the mean trajectory $E(\boldsymbol{x}_t) = \bar{\boldsymbol{x}}_t$. Instead of recovering the actual trajectory, as is done recursively with the Kalman filter, an added objective can be to estimate the unknown mean trajectory $\bar{\boldsymbol{x}}_t$ as well. Also this can be done recursively, thereby making use of the Kalman filter outputs. The corresponding BLUE–BLUP recursion for the recovery of the mean trajectory is given in [22.36]. In the absence of system noise ($\mathbf{S}_k = \mathbf{0}, k = 1, \ldots$), the two solutions, that is, for the mean trajectory and for the actual trajectory, coincide. And, if additionally $\mathbf{\Phi}_{i,i-1} = \mathbf{I}$, then they reduce further to the recursive solution (22.38).

#### *Example 22.11 Ionospheric Delays*

Figure 22.14 presents an example of the filtered solution of the ionospheric delays for a certain satellite; it is based on real data. The observations (shown in gray) are given by a time series of the ionosphere combination of the GPS code observations $p_1$ and $p_2$ on frequencies L1 and L2, respectively

$$\iota_p(t) = \begin{bmatrix} -\frac{f_2^2}{f_1^2 - f_2^2} & \frac{f_2^2}{f_1^2 - f_2^2} \end{bmatrix} \begin{bmatrix} p_1(t) \\ p_2(t) \end{bmatrix}. \tag{22.115}$$

It is assumed that second-order derivative of ionospheric delay is zero mean constant, and the transition matrix

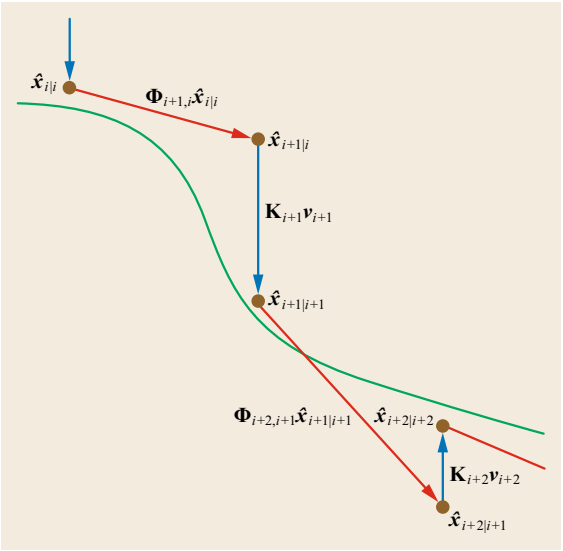

**Fig. 22.13** Contributions of time update and measurement update: actual trajectory $\boldsymbol{x}_t$ is shown in *green*. The predicted states $\hat{\boldsymbol{x}}_{k|k-1}$ based on the time update (*red arrows*), as well as the filtered states $\hat{\boldsymbol{x}}_{k|k}$ after the measurement update (*blue arrows*) are shown

$\mathbf{\Phi}_{k,k-1}$ and system noise $\mathbf{S}_k$ are therefore given as

$$\mathbf{\Phi}_{k,k-1} = \begin{bmatrix} 1 & \Delta t \\ 0 & 1 \end{bmatrix}, \quad \mathbf{S}_k = \sigma_\mathrm{d}^2 \begin{bmatrix} \frac{1}{4}\Delta t^4 & \frac{1}{2}\Delta t^3 \\ \frac{1}{2}\Delta t^3 & \Delta t^2 \end{bmatrix}. \tag{22.116}$$

In this case, $\Delta t$ is 30 s, and $\sigma_\mathrm{d}^2$ is the variance factor of the process noise.

Both the predicted and filtered states as well as their difference are shown in Fig. 22.14. In order to show the effect of the system noise, $\sigma_\mathrm{d}^2$ was reduced by a factor 100, and the corresponding results are shown in the bottom panel. Obviously, the contribution of the observations becomes much smaller, and consequently the difference between predicted and filtered states is smaller as well. The filtered solution is now much smoother, but may deviate considerably from the observed delays.

### 22.5.3 Kalman Filter Information Form

The measurement update equations (22.113) are given in the *variance form*, since they are expressed in terms of the variance–covariance matrices $\mathbf{R}_k$ and $\mathbf{P}_{k|k-1}$. An alternative, the so-called *information form*, is also possible. In the information form, the inverses of $\mathbf{R}_k$ and $\mathbf{P}_{k|k-1}$ are used. The Kalman gain matrix $\mathbf{K}_k$ and error-variance matrix $\mathbf{P}_{k|k}$ can be expressed in $\mathbf{R}_k^{-1}$ and $\mathbf{P}_{k|k-1}^{-1}$

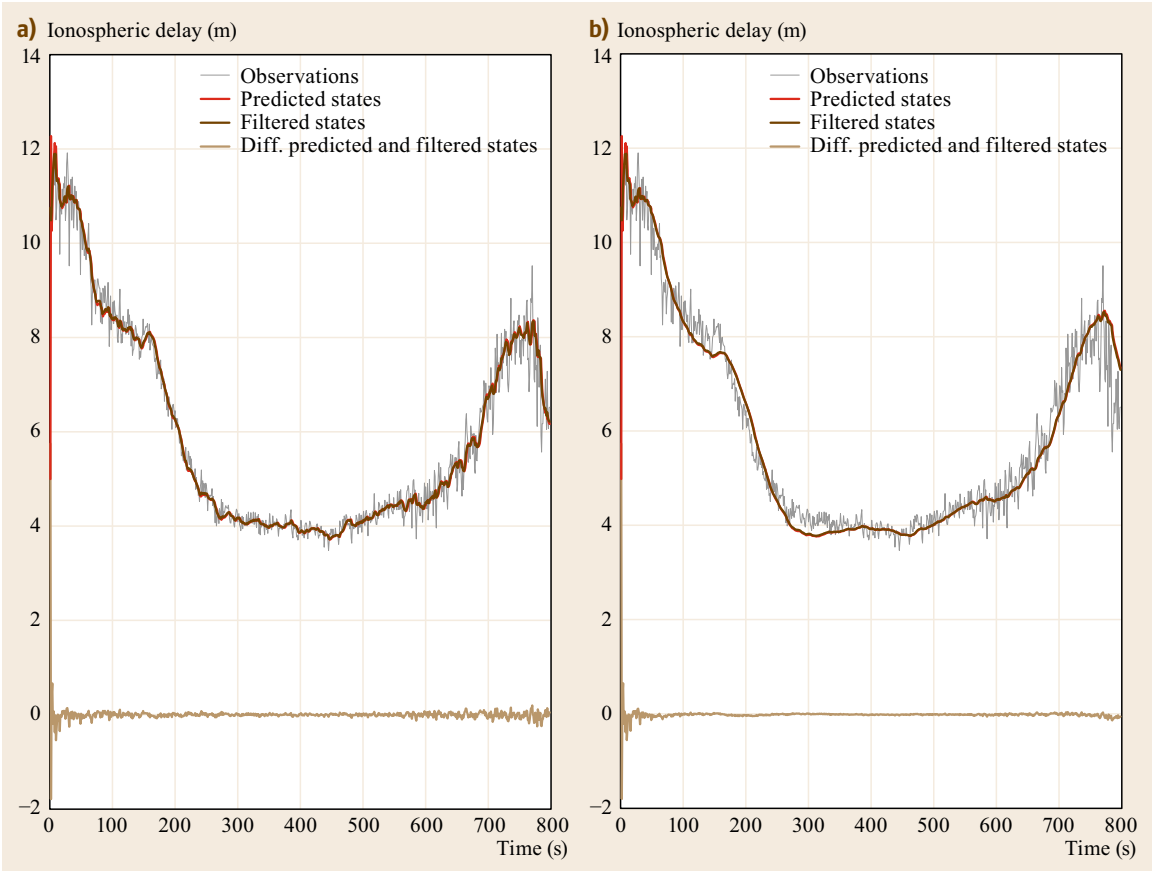

**Fig. 22.14a,b** Observations of ionospheric delays based on ionosphere combination of GPS L1 and L2 code observations, as well as predicted and filtered states from Kalman filtering results. It is assumed that the second-order derivative of the ionospheric delays is a random constant process with zero-mean. **(a)** Realistic $\sigma_d^2$; **(b)** $\sigma_d^2/100$

as

$$\begin{aligned}\mathbf{K}_k &= \mathbf{P}_{k|k}\mathbf{A}_k^\top\mathbf{R}_k^{-1}\\ \mathbf{P}_{k|k} &= (\mathbf{P}_{k|k-1}^{-1}+\mathbf{A}_k^\top\mathbf{R}_k^{-1}\mathbf{A}_k)^{-1}\,.\end{aligned}\tag{22.117}$$

Although the variance form and information form both give identical results, one form may be preferred over the other if one considers the task of matrix inversion. In general, the variance form is preferred over the information form if the dimension of $\boldsymbol{y}_k$ is (much) smaller than that of $\boldsymbol{x}_k$. For instance, in case $\boldsymbol{y}_k$ is a scalar, the variance-form would need the trivial inversion of the scalar $\mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k}$, while the information form would then still need the inversion of $\mathbf{P}_{k|k-1}^{-1}$.

The square root information filter (SRIF) is an efficient mechanization of the Kalman filter [22.37, 38]. Similarly, as in Sect. 22.1.3, it uses a decomposition of the variance–covariance matrices in square root form.

### 22.5.4 Extended Kalman Filter

The Kalman filter applies to models that are linear. In practice, however, measurement and/or dynamic models are often nonlinear. One would then have nonlinear vector functions $\mathbf{A}_k(\cdot)$ and $\boldsymbol{\Phi}_k(\cdot)$, instead of the matrices $\mathbf{A}_k$ and $\boldsymbol{\Phi}_{k,k-1}$ of (22.102) and (22.105), respectively. The extended Kalman filter (EKF) is the Kalman filter applied to the *linearized* versions of such nonlinear measurement and dynamic models [22.29, 35, 39]. Thus, if the nonlinear equations are given as

$$\begin{aligned}\boldsymbol{y}_k &= \mathbf{A}_k(\boldsymbol{x}_k)+\boldsymbol{n}_k\\ \boldsymbol{x}_k &= \boldsymbol{\Phi}_k(\boldsymbol{x}_{k-1})+\boldsymbol{d}_k,\end{aligned}\tag{22.118}$$

the EKF TU is given by

$$\begin{aligned}\hat{\boldsymbol{x}}_{k|k-1} &= \boldsymbol{\Phi}_k(\hat{\boldsymbol{x}}_{k-1|k-1})\\ \mathbf{P}_{k|k-1} &= \mathbf{J}_{\boldsymbol{\Phi}_k}\mathbf{P}_{k-1|k-1}\mathbf{J}_{\boldsymbol{\Phi}_k}^\top+\mathbf{S}_k\end{aligned}\tag{22.119}$$

and the EKF MU by

$$\hat{\boldsymbol{x}}_{k|k} = \hat{\boldsymbol{x}}_{k|k-1} + \mathbf{K}_k(\boldsymbol{y}_k - \mathbf{A}_k(\hat{\boldsymbol{x}}_{k|k-1}))$$
$$\mathbf{P}_{k|k} = (\mathbf{I}_n - \mathbf{K}_k\mathbf{J}_{\mathbf{A}_k})\mathbf{P}_{k|k-1} \qquad (22.120)$$

with the gain matrix given as

$$\mathbf{K}_k = \mathbf{P}_{k|k-1}\mathbf{J}_{\mathbf{A}_k}^{\top}(\mathbf{R}_k + \mathbf{J}_{\mathbf{A}_k}\mathbf{P}_{k|k-1}\mathbf{J}_{\mathbf{A}_k}^{\top})^{-1}\,, \qquad (22.121)$$

where $\mathbf{J}_{\mathbf{A}_k}$ is the Jacobian of $\mathbf{A}_k(.)$ evaluated at $\hat{\boldsymbol{x}}_{k|k-1}$ and $\mathbf{J}_{\boldsymbol{\Phi}_k}$ is the Jacobian of $\boldsymbol{\Phi}_k(.)$ evaluated at $\hat{\boldsymbol{x}}_{k-1|k-1}$. If $\mathbf{A}_k(.)$ is highly nonlinear, a further improvement can be obtained by iterating the solution of the EKF measurement update. This is referred to as the iterated extended Kalman filter (IEKF). As the IEKF can be shown to be a special case of a Gauss–Newton iteration, it also inherits all its convergency properties [22.40].

### 22.5.5 Smoothing

Smoothing filters rely on forward running Kalman filters. They are often used in offline (post-) processing in order to get better estimates of the past states based on all available information, but can also be used parallel to a filter running in realtime. Three types of smoothers are distinguished as follows, where $N$ refers to the length of the interval and $k$ is the instant at which a smoothed estimate is needed.

The first is the *fixed-interval* smoother, also known as the Rauch–Tung–Striebel filter or forward–backward filter. The smoothing interval is fixed to a length $N$, but the time instant $t_k$ for which the smoothed estimate is computed changes. It is based on the Kalman filter solutions up till and including epoch $k < N$, and a backward running filter from epoch $N$ to $k$.

The *fixed-point* smoother is estimating the state at a fixed time instant $t_k$, and this state estimate is updated as more and more observations become available, that is, $N$ is increasing.

Finally, the *fixed-lag* smoother is estimating the states with a fixed lag of $N$ epochs using the observations up till and including current epoch. Hence, the final smoothed state for a given time instant $t_k$ is computed after $N$ epochs and $k+N$ is the last observation epoch that is used.

Figures 22.15–22.17 illustrate the different principles.

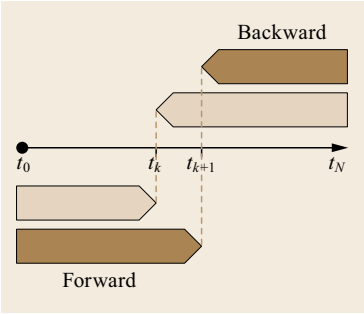

**Fig. 22.15** Fixed-interval smoothing based on forward–backward filtering to estimate the state at any time $t_i$ $(i = 0, \ldots, N)$ using all available observations from $t_0$ till $t_N$. The principle is shown here for times $t_k$ and $t_{k+1}$

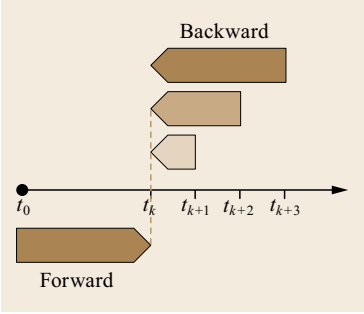

**Fig. 22.16** Fixed-point smoothing to estimate the state at fixed time $t_k$ with increasing smoothing window as more observations become available

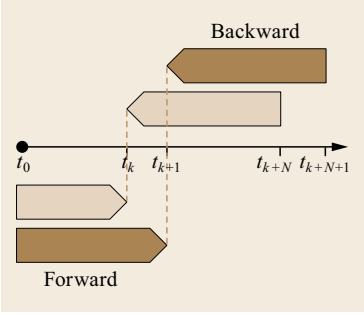

**Fig. 22.17** Fixed-lag smoothing to estimate the state at any time $t_i$ using all available observations from $t_0$ till $t_{i+N}$, that is, with a smoothing interval of fixed length $N$. The principle is shown here for times $t_k$ and $t_{k+1}$

#### Fixed-Interval Smoothing

The *Rauch–Tung–Striebel* smoothing algorithm was proposed in [22.41], and is the fixed-interval smoother that will be discussed here. For each $t_k$ in the interval $[t_0, t_N]$, the state estimate is based on all observations in this interval. The idea is illustrated in Fig. 22.15: The forward filter is the standard Kalman filter to provide the state estimate at an epoch $k$ based on epochs 0 till $k$; the backward filter is applied to obtain a smoothed state using the observations from $k$ till $N$.

From the forward filter, we have the estimated states $\hat{\boldsymbol{x}}_{k|k-1}$ and $\hat{\boldsymbol{x}}_{k|k}$, together with their error variance–covariance matrices $\mathbf{P}_{k|k-1}$ and $\mathbf{P}_{k|k}$.

The backward filter runs recursively with $k = N-1, N-2, \ldots, 0$. The smoothed state estimate and its error variance–covariance matrix equal

$$\hat{\boldsymbol{x}}_{k|N} = \hat{\boldsymbol{x}}_{k|k} + \mathbf{L}_k\left(\hat{\boldsymbol{x}}_{k+1|N} - \hat{\boldsymbol{x}}_{k+1|k}\right) \qquad (22.122)$$
$$\mathbf{P}_{k|N} = \mathbf{P}_{k|k} + \mathbf{L}_k\left(\mathbf{P}_{k+1|N} - \mathbf{P}_{k+1|k}\right)\mathbf{L}_k^{\top}\,, \qquad (22.123)$$

where

$$\mathbf{L}_k = \mathbf{P}_{k|k}\boldsymbol{\Phi}_{k+1,k}^{\top}\mathbf{P}_{k+1|k}^{-1}\,. \qquad (22.124)$$

The fixed-interval smoother is mainly used for offline processing, as storage of all results from the forward filter is required and inversion of $\mathbf{P}_{k+1|k}$ is needed for every recursion.

*Example 22.12 Ionospheric delays (continued)*

For the example of the filtered ionosphere delay solution, presented at the end of Sect. 22.5.2, also the fixed-interval smoother was applied. The complete observation interval is used for smoothing the state at each epoch. Figure 22.18 shows the smoothed states. For comparison, also the filtered states are shown. The effect of the forward–backward filtering is obvious for the whole period, and very pronounced at the start of the observation interval, since the Kalman filter needs to converge.

### Fixed-Point Smoothing

With fixed-point smoothing [22.42], the state estimate for one specific $t_k$ is continuously smoothed as new observations become available, that is, the time window used to estimate the smoothed state becomes much longer. In the following, the superscript s indicates the smoothed state; estimates and variance–covariance matrices without the superscript refer to the standard Kalman filter solutions.

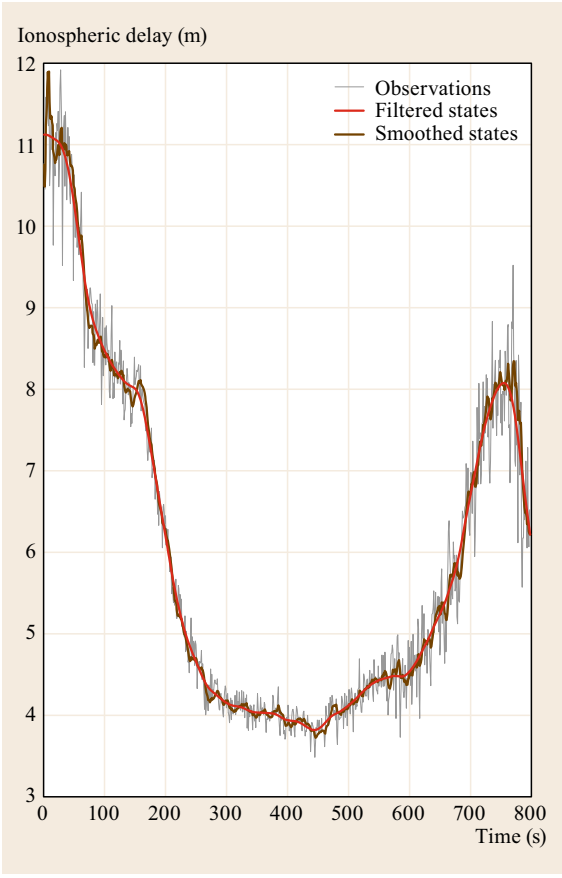

**Fig. 22.18** Observations of ionospheric delays based on ionosphere combination of GPS L1 and L2 code observations, as well as filtered and smoothed states from Kalman filtering and fixed-interval smoothing, respectively. It is assumed that the second-order derivative of the ionospheric delays is a random constant process with zero mean

As initial values, the standard Kalman filter solution is used: $\hat{\boldsymbol{x}}^{\mathrm{s}}_{k|k} = \hat{\boldsymbol{x}}_{k|k}, \mathbf{P}^{\mathrm{s}}_{k|k} = \mathbf{P}_{k|k}$. Then, for $j = k+1, k+2, \ldots$ (and $k$ fixed)

$$\hat{\boldsymbol{x}}^{\mathrm{s}}_{k|j} = \hat{\boldsymbol{x}}^{\mathrm{s}}_{k|j-1} + \mathbf{M}_j\left(\hat{\boldsymbol{x}}_{j|j} - \hat{\boldsymbol{x}}_{j|j-1}\right), \tag{22.125}$$

$$\mathbf{P}^{\mathrm{s}}_{k|j} = \mathbf{P}^{\mathrm{s}}_{k|j-1} + \mathbf{M}_j\left(\mathbf{P}_{j|j} - \mathbf{P}_{j|j-1}\right)\mathbf{M}_j^{\top}, \tag{22.126}$$

where

$$\mathbf{M}_j = \prod_{i=k}^{j-1} \mathbf{L}_i \tag{22.127}$$

with $\mathbf{L}_i$ from (22.124).

### Fixed-Lag Smoothing

Fixed-lag smoothing [22.42] implies that the final smoothed state of a certain epoch is calculated after a fixed lag of $N$ epochs. The smoothed states are obtained by a recursion over $k = 0, 1, 2, \ldots$

$$\hat{\boldsymbol{x}}^{\mathrm{s}}_{k|k+N} = \boldsymbol{p}_1 + \boldsymbol{p}_2 + \boldsymbol{p}_3\,, \tag{22.128}$$

with

$$\boldsymbol{p}_1 = \boldsymbol{\Phi}_{k,k-1}\hat{\boldsymbol{x}}^{\mathrm{s}}_{k-1|k-1+N}$$

$$\boldsymbol{p}_2 = \mathbf{S}_{k-1}\boldsymbol{\Phi}^{-\top}_{k,k-1}\mathbf{P}^{-1}_{k-1|k-1}\left(\hat{\boldsymbol{x}}^{\mathrm{s}}_{k-1|k-1+N} - \hat{\boldsymbol{x}}_{k-1|k-1}\right)$$

$$\boldsymbol{p}_3 = \mathbf{M}_{k+N}\mathbf{K}_{k+N}\boldsymbol{v}_{k+N}\,.$$

The terms $\boldsymbol{p}_1$ and $\boldsymbol{p}_2$ form the prediction based on the *smoothed* state at epoch $k-1$; $\boldsymbol{p}_3$ is the contribution of the new observations at epoch $k+N$.

The error variance–covariance matrix of the smoothed state equals

$$\mathbf{P}^{\mathrm{s}}_{k|k+N} = \boldsymbol{q}_1 + \boldsymbol{q}_2 + \boldsymbol{q}_3\,, \tag{22.129}$$

with

$$\boldsymbol{q}_1 = \mathbf{P}^{\mathrm{s}}_{k|k-1}$$

$$\boldsymbol{q}_2 = -\mathbf{L}^{-1}_{k-1}\left(\mathbf{P}_{k-1|k-1} - \mathbf{P}^{\mathrm{s}}_{k-1|k-1+N}\right)\mathbf{L}^{-\top}_{k-1}$$

$$\boldsymbol{q}_3 = \mathbf{M}_{k+N}\mathbf{K}_{k+N}\mathbf{A}_{k+N}\mathbf{P}_{k+N|k-1+N}\mathbf{M}^{\top}_{k+N}\,.$$

As can be seen from (22.128) and (22.129), the input from a running Kalman filter is required.

The initial conditions $\hat{\boldsymbol{x}}^{\mathrm{s}}_{0|N}$ and $\mathbf{P}^{\mathrm{s}}_{0|N}$ must be determined with the fixed-point smoother.

# 23. Carrier Phase Integer Ambiguity Resolution

Peter J.G. Teunissen

Global Navigation Satellite System (GNSS) carrier-phase integer ambiguity resolution is the process of resolving the carrier-phase ambiguities as integers. It is the key to fast and high-precision GNSS parameter estimation and it applies to a great variety of GNSS models that are currently in use in navigation, surveying, geodesy and geophysics. The theory that underpins GNSS carrier-phase ambiguity resolution is the theory of integer inference. This theory and its practical application is the topic of the present chapter.

Carrier-phase integer ambiguity resolution is the key to fast and high-precision GNSS parameter estimation. It is the process of resolving the unknown cycle ambiguities of the carrier-phase data as integers. Once this has been done successfully, the very precise carrier-phase data will act as very precise pseudorange data, thus making very precise positioning and navigation possible.

GNSS ambiguity resolution applies to a great variety of current and future GNSS models, with applications in surveying, navigation, geodesy and geophysics. These models may differ greatly in complexity and diversity. They range from single-receiver or single-baseline models used for kinematic positioning to multibaseline models used as a tool for studying geodynamic phenomena. The models may or may not have the relative receiver-satellite geometry included. They may also be discriminated as to whether the slave receiver(s) is stationary or in motion, or whether or not the differential atmospheric delays (ionosphere and troposphere) are included as unknowns. An overview of these models can be found in textbooks like [23.1–5] and in the Chaps. 21, 25, and 26 of this Handbook.

The theory that underpins ultraprecise GNSS carrier-phase ambiguity resolution is the theory of integer inference [23.6, 7]. This theory of integer estimation and validation is the topic of the present chapter. Although the theory was originally developed for Global Positioning System (GPS) [23.8–14], the theory has a much wider range of applicability. Next to the regional and global satellite navigation systems, it also applies to other carrier-phase-based interferometric techniques, such as Very Long Baseline Interferometry (VLBI) [23.15], Interferometric Synthetic Aperture Radar (InSAR) [23.16], or underwater acoustic carrier-phase positioning [23.17].

This chapter is organized as follows. In Sect. 23.1, the mixed-integer GNSS model is introduced. It forms the basis of all integer ambiguity resolution methods. An overview of the various ambiguity resolution steps is given, together with an evaluation of their contribution to the overall quality.

In Sect. 23.2, the ambiguity resolution methods of integer rounding (IR) and integer bootstrapping (IB) are presented, together with practical expressions for evaluating their ambiguity success rates. These methods are the simplest methods available, but their performance depends on the chosen ambiguity parametrization.

In Sect. 23.3 it is shown how the performance of rounding and bootstrapping can be improved by using certain ambiguity parametrizations. This includes a description of the decorrelating $Z$-transformation by which these improvements can be realized. Various examples that illustrate the concepts involved are also given.

The method of integer least-squares (ILSs) ambiguity resolution is described in Sect. 23.4. This method is optimal in the sense that it achieves the highest success rate of all ambiguity resolution methods. The method is however also more complex as it requires an integer search over an ambiguity search space. It is shown how to make the method numerically efficient by combining the integer search with ambiguity decorrelation. Methods for computing or bounding the ILS success rate are also given.

The concept of partial ambiguity resolution is presented in Sect. 23.5. It is an alternative to full ambiguity resolution in case the resolution of all ambiguities cannot be done with a sufficiently high success rate.

As wrongly fixed integer ambiguities can result in unacceptably large positioning errors, it is important to have rigorous testing methods in place for accepting or rejecting the computed integer ambiguity solution. These methods and their theoretical foundation are presented in Sect. 23.6.

## 23.1 GNSS Ambiguity Resolution

### 23.1.1 The GNSS Model

To formulate the GNSS model for ambiguity resolution, we start with the observation equations for the pseudorange (code) and carrier-phase observables. If we denote the $j$-frequency pseudorange and carrier-phase for the $r$-$s$ receiver–satellite combination at epoch $t$ as $p^s_{r,j}(t)$ and $\phi^s_{r,j}(t)$ respectively, then their observation equations can be formulated as [23.1–5],

$$\begin{aligned} p^s_{r,j}(t) &= \rho^s_r(t) + T^s_r(t) + I^s_{r,j}(t) \\ &\quad + c\,dt^s_{r,j}(t) + e^s_{r,j}(t)\,, \\ \varphi^s_{r,j}(t) &= \rho^s_r(t) + T^s_r(t) - I^s_{r,j}(t) \\ &\quad + c\,\delta t^s_{r,j}(t) + \lambda_j N^s_{r,j} + \epsilon^s_{r,j}(t)\,, \end{aligned} \tag{23.1}$$

where $\rho^s_r$ is the receiver–satellite range, $T^s_r(t)$ and $I^s_r$ are the tropospheric and ionospheric path delays, $dt^s_{r,j}$ and $\delta t^s_{r,j}$ are the pseudorange and carrier-phase receiver–satellite clock biases, $N^s_{r,j}$ is the time-invariant *integer* carrier-phase ambiguity, $c$ is the speed of light, $\lambda_j$ is the $j$-frequency wavelength, and $e^s_{r,j}$, $\epsilon^s_{r,j}$ are the remaining error terms respectively.

The receiver–satellite range $\rho^s_r$ in (23.1) is usually further linearized in the receiver- or satellite-position coordinates. As a result one obtains linear equations that can be used to form a system of linear equations for solving the unknown parameters of position, atmosphere, clock and ambiguities. Hence, if we assume the error terms $e^s_{r,j}$ and $\epsilon^s_{r,j}$ in (23.1) to be zero-mean random variables, the linear(ized) system of observation equations can be used to set up a linear model in which some of the unknown parameters are reals and others are integer. Such a GNSS model is an example of a mixed-integer linear model.

We now define the general form of the mixed-integer GNSS model.

*Definition 23.1 Mixed-integer GNSS model*

Let $(\mathbf{A}, \mathbf{B})$ be a given $m \times (n+p)$ matrix of full rank and let $\mathbf{Q}_{yy}$ be a given $m \times m$ positive definite matrix. Then

$$\boldsymbol{y} \sim \mathrm{N}(\mathbf{A}\boldsymbol{a} + \mathbf{B}\boldsymbol{b}, \mathbf{Q}_{yy})\,,\ \boldsymbol{a} \in \mathbb{Z}^n\,,\ \boldsymbol{b} \in \mathbb{R}^p \tag{23.2}$$

will be referred to as the mixed-integer GNSS model.

The notation $\sim$ is used to describe *distributed as*. The $m$-vector $\boldsymbol{y}$ contains the pseudorange and carrier-phase observables, the $n$-vector $\boldsymbol{a}$ the integer ambiguities, and the real-valued $p$-vector $\boldsymbol{b}$ the remaining unknown parameters, such as, for example, position coordinates, atmospheric delay parameters (troposphere, ionosphere) and clock parameters. As in most GNSS applications, the underlying probability distribution of the data is assumed to be a multivariate normal distribution.

### 23.1.2 Ambiguity Resolution Steps

The purpose of ambiguity resolution is to exploit the integer constraints, $\boldsymbol{a} \in \mathbb{Z}^n$ in (23.2), so as to get a better estimator of $\boldsymbol{b}$ than otherwise would be the case. The mixed-integer GNSS model (23.2) can be solved in the following steps:

1. *Float Solution*: In the first step, the integer nature of the ambiguities is discarded and a standard least-squares (LS) parameter estimation is performed. As a result, one obtains the so-called float solution, together with its variance-covariance matrix,

$$\begin{bmatrix}\hat{\boldsymbol{a}}\\ \hat{\boldsymbol{b}}\end{bmatrix} \sim \mathrm{N}\left(\begin{bmatrix}\boldsymbol{a}\\ \boldsymbol{b}\end{bmatrix}, \begin{bmatrix}\mathbf{Q}_{\hat{a}\hat{a}} & \mathbf{Q}_{\hat{a}\hat{b}}\\ \mathbf{Q}_{\hat{b}\hat{a}} & \mathbf{Q}_{\hat{b}\hat{b}}\end{bmatrix}\right) . \tag{23.3}$$

   Other forms than batch least-squares – such as recursive LS or Kalman filtering – may also be used to come up with a float solution. Such choices will depend on the application and on the structure of the GNSS model.
2. *Integer Solution*: The purpose of this second step is to take the integer constraints $\boldsymbol{a} \in \mathbb{Z}^n$ (23.2) into account. Hence, a mapping $\mathcal{I} : \mathbb{R}^n \mapsto \mathbb{Z}^n$ is introduced that maps the float ambiguities to corresponding integer values,

$$\check{\boldsymbol{a}} = \mathcal{I}(\hat{\boldsymbol{a}}) . \tag{23.4}$$

   Many such integer mappings $\mathcal{I}$ exist. Popular choices are integer rounding (IR), integer bootstrapping (IB) and integer least-squares (ILS), see Sects. 23.2 and 23.4.
3. *Fixed Solution*: In the final step, once $\check{\boldsymbol{a}}$ is accepted, the ambiguity residual $\hat{\boldsymbol{a}} - \check{\boldsymbol{a}}$ is used to readjust the float estimator $\hat{\boldsymbol{b}}$ to obtain the so-called fixed estimator

$$\check{\boldsymbol{b}} = \hat{\boldsymbol{b}} - \mathbf{Q}_{\hat{b}\hat{a}}\mathbf{Q}_{\hat{a}\hat{a}}^{-1}(\hat{\boldsymbol{a}} - \check{\boldsymbol{a}}) . \tag{23.5}$$

The fixed solution has a quality that is commensurate with the high precision of the phase data, *provided* the probability of $\check{\boldsymbol{a}}$ being the correct integer is sufficiently high. Figure 23.1 illustrates the high gain in positioning precision that can be achieved with successful ambiguity resolution.

### 23.1.3 Ambiguity Resolution Quality

To determine the quality of the fixed solution $\check{\boldsymbol{b}}$ (23.5), we need to propagate the probabilistic properties of its constituents:

1. *Quality of float solution*: The float solution is defined as the minimizer of the unconstrained LS-problem,

$$(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}}) = \arg \min_{\boldsymbol{a}\in\mathbb{R}^n, \boldsymbol{b}\in\mathbb{R}^p} \|\boldsymbol{y} - \mathbf{A}\boldsymbol{a} - \mathbf{B}\boldsymbol{b}\|^2_{\mathbf{Q}_{yy}} \tag{23.6}$$

   the solution of which follows from solving the normal equations

$$\begin{bmatrix}\mathbf{A}^\top\mathbf{Q}_{yy}^{-1}\mathbf{A} & \mathbf{A}^\top\mathbf{Q}_{yy}^{-1}\mathbf{B}\\ \mathbf{B}^\top\mathbf{Q}_{yy}^{-1}\mathbf{A} & \mathbf{B}^\top\mathbf{Q}_{yy}^{-1}\mathbf{B}\end{bmatrix}\begin{bmatrix}\hat{\boldsymbol{a}}\\ \hat{\boldsymbol{b}}\end{bmatrix} = \begin{bmatrix}\mathbf{A}^\top\mathbf{Q}_{yy}^{-1}\boldsymbol{y}\\ \mathbf{B}^\top\mathbf{Q}_{yy}^{-1}\boldsymbol{y}\end{bmatrix} . \tag{23.7}$$

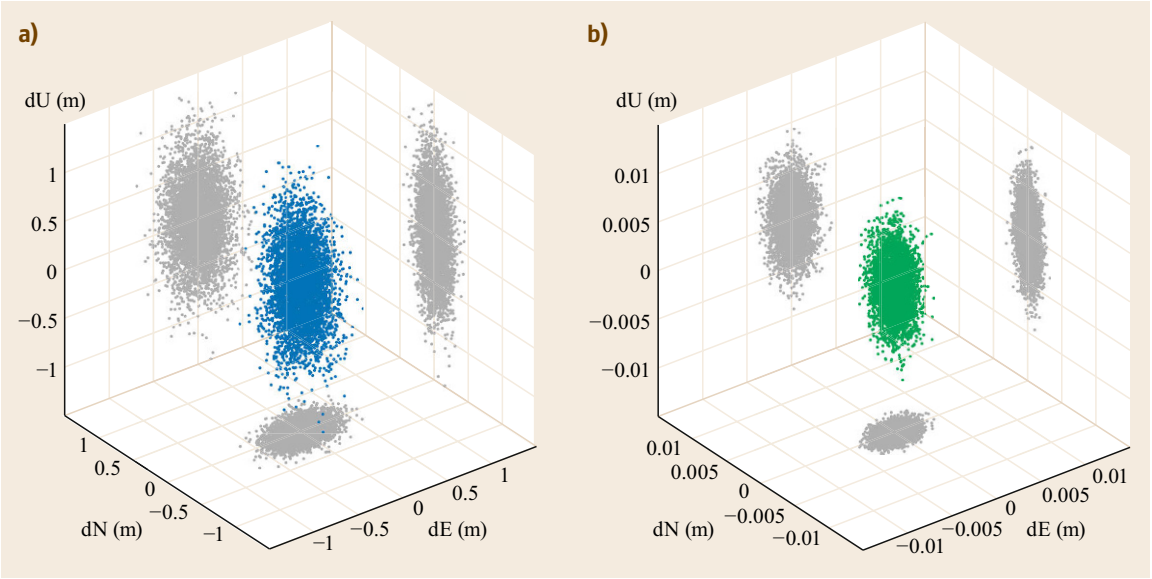

**Fig. 23.1a,b** Three-dimensional scatterplot of GPS position errors for short-baseline, dual-frequency instantaneous ambiguity *float* solutions ((**a**); $\hat{b}$) and corresponding ambiguity *fixed* position solutions ((**b**); $\check{b}$) (after [23.18]). Note the two orders of magnitude difference in scale between the two panels. dE, dN, and dU denote the components of the position errors in north, east and up direction

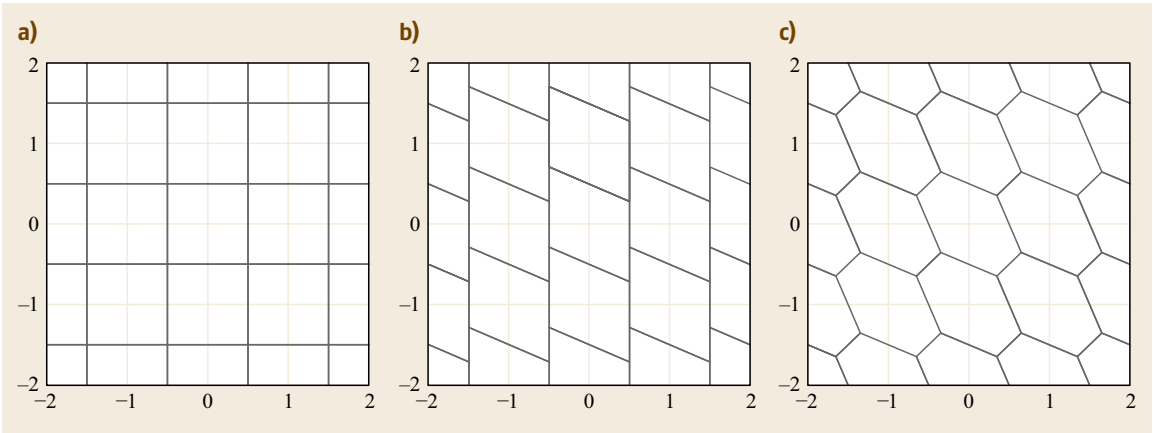

**Fig. 23.2a–c** Two-dimensional pull-in regions of integer rounding **(a)**, integer bootstrapping **(b)**, and integer least-squares **(c)**

This solution is given as

$$\hat{\boldsymbol{a}} = (\bar{\mathbf{A}}^\top \mathbf{Q}_{yy}^{-1} \bar{\mathbf{A}})^{-1} \bar{\mathbf{A}}^\top \mathbf{Q}_{yy}^{-1} \boldsymbol{y}$$
$$\hat{\boldsymbol{b}} = (\mathbf{B}^\top \mathbf{Q}_{yy}^{-1} \mathbf{B})^{-1} \mathbf{B}^\top \mathbf{Q}_{yy}^{-1} (\boldsymbol{y} - \mathbf{A}\hat{\boldsymbol{a}}) \,, \qquad (23.8)$$

where $\bar{\mathbf{A}} = \mathbf{P}_{\mathbf{B}}^{\perp}\mathbf{A}$, with orthogonal projector

$$\mathbf{P}_{\mathbf{B}}^{\perp} = \mathbf{I}_m - \mathbf{B}(\mathbf{B}^\top \mathbf{Q}_{yy}^{-1} \mathbf{B})^{-1} \mathbf{B}^\top \mathbf{Q}_{yy}^{-1} \,.$$

With the distributional assumptions of (23.2), the distribution of the ambiguity float solution follows as the multivariate normal distribution $\hat{\boldsymbol{a}} \sim \mathrm{N}(\boldsymbol{a}, \mathbf{Q}_{\hat{a}\hat{a}})$, with variance matrix

$$\mathbf{Q}_{\hat{a}\hat{a}} = (\bar{\mathbf{A}}^\top \mathbf{Q}_{yy}^{-1} \bar{\mathbf{A}})^{-1} \,. \qquad (23.9)$$

The probability density function (PDF) of $\hat{\boldsymbol{a}}$ is thus given as

$$f_{\hat{a}}(\boldsymbol{x}|\boldsymbol{a}) = \frac{1}{\sqrt{\det(2\pi \mathbf{Q}_{\hat{a}\hat{a}})}} \exp\left(-\frac{1}{2}||\boldsymbol{x}-\boldsymbol{a}||^2_{\mathbf{Q}_{\hat{a}\hat{a}}}\right) . \qquad (23.10)$$

Its shape is completely determined by the ambiguity variance matrix $\mathbf{Q}_{\hat{a}\hat{a}}$, which in its turn is completely determined by the GNSS model's design matrix, $(\mathbf{A}, \mathbf{B})$, and observation variance matrix $\mathbf{Q}_{yy}$. The PDF of $\hat{\boldsymbol{a}}$ is needed to determine the probability mass function (PMF) of $\check{\boldsymbol{a}}$ in step 2.

2. *Quality of integer solution*: Since the integer map of step 2, $\mathcal{I} : \mathbb{R}^n \mapsto \mathbb{Z}^n$, is a many-to-one map, different real-valued vectors will be mapped to one and the same integer vector. One can therefore assign a subset, say $\mathcal{P}_z \subset \mathbb{R}^n$, to each integer vector $\boldsymbol{z} \in \mathbb{Z}^n$,

$$\mathcal{P}_z = \{\boldsymbol{x} \in \mathbb{R}^n \,|\, \boldsymbol{z} = \mathcal{I}(\boldsymbol{x})\}, \quad \boldsymbol{z} \in \mathbb{Z}^n \,. \qquad (23.11)$$

This subset is referred to as the *pull-in region* of $\boldsymbol{z}$. It is the region in which all vectors are pulled to the same integer vector $\boldsymbol{z}$. The pull-in regions are translational invariant over the integers and cover the whole space $\mathbb{R}^n$ without gaps and overlap [23.19]. Two-dimensional examples of pull-in regions are shown in Fig. 23.2. They are the pull-in regions of integer rounding, integer bootstrapping and integer least-squares.

The PMF of $\check{\boldsymbol{a}}$ follows from integrating the PDF of $\hat{\boldsymbol{a}}$ over the pull-in regions. Since $\check{\boldsymbol{a}} = \boldsymbol{z} \in \mathbb{Z}^n$ iff $\hat{\boldsymbol{a}} \in \mathcal{P}_z$, the PMF of $\check{\boldsymbol{a}}$ follows as

$$P(\check{\boldsymbol{a}} = \boldsymbol{z}) = P(\hat{\boldsymbol{a}} \in \mathcal{P}_z) = \int_{\mathcal{P}_z} f_{\hat{a}}(\boldsymbol{x}|\boldsymbol{a}) \mathrm{d}\boldsymbol{x} \,. \qquad (23.12)$$

A two-dimensional example of an ambiguity PDF and corresponding PMF is given in Fig. 23.3a,b.

Of all the probabilities of the PMF, the probability of correct integer estimation, $P(\check{\boldsymbol{a}} = \boldsymbol{a})$, is of particular importance for ambiguity resolution. This probability is referred to as the ambiguity *success rate* and it is given by the integral

$$P_{\mathrm{s}} = P(\check{\boldsymbol{a}} = \boldsymbol{a}) = \int_{\mathcal{P}_a} f_{\hat{a}}(\boldsymbol{x}|\boldsymbol{a}) \mathrm{d}\boldsymbol{x} = \int_{\mathcal{P}_0} f_{\hat{a}}(\boldsymbol{x}|\boldsymbol{0}) \mathrm{d}\boldsymbol{x} \,, \qquad (23.13)$$

where the last line follows from the translational property $f_{\hat{a}}(\boldsymbol{x}+\boldsymbol{a}|\boldsymbol{a}) = f_{\hat{a}}(\boldsymbol{x}|\boldsymbol{0})$ of the multivariate normal distribution.

Note that the success rate $P_{\mathrm{s}}$ depends on the pull-in region $\mathcal{P}_0$ and on the PDF $f_{\hat{a}}(\boldsymbol{x}|\boldsymbol{0})$. Hence, the success rate is determined by the mapping $\mathcal{I} : \mathbb{R}^n \mapsto \mathbb{Z}^n$

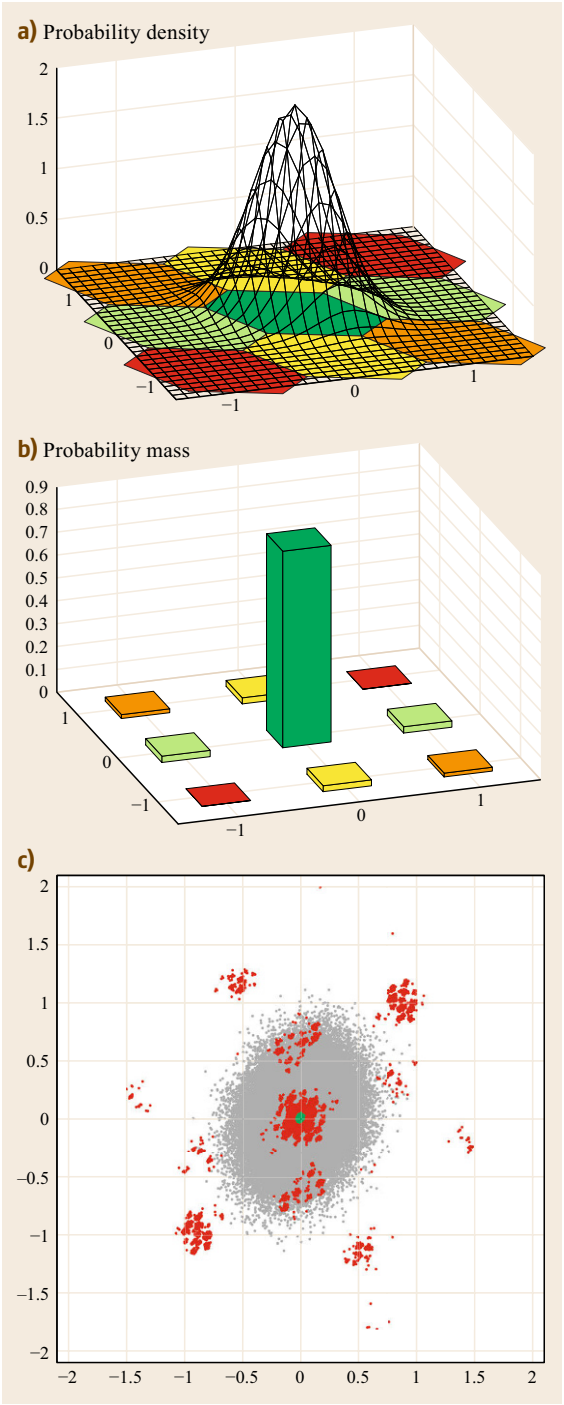

**Fig. 23.3** **(a)** Gaussian probability density function (PDF) $f_{\hat{a}}(\boldsymbol{x}|\boldsymbol{a})$ with 2-D (*hexagon*) ILS pull-in regions. **(b)** Corresponding probability mass function (PMF) $P(\check{\boldsymbol{a}}_{\mathrm{ILS}} = z)$ of ILS estimator. **(c)** Scatterplot of horizontal position errors for float solution (*gray dots*) and corresponding fixed solution (*green* and *red dots*). In this case, 93% of the solutions were correctly fixed (*green dots*), and 7% were wrongly fixed (*red dots*) (after [23.18]) ►

and the ambiguity variance matrix $\mathbf{Q}_{\hat{a}\hat{a}}$, i. e., by the choice of integer estimator and the precision of the float ambiguities.

Due to the shape of the pull-in regions and the nondiagonality of the ambiguity variance matrix, the computation of the ambiguity success rate is nontrivial. The evaluation of the multivariate integral (23.13) can generally be done through Monte Carlo integration [23.20], see also Sect. 23.4.3. For some important integer estimators we also have easy-to-compute expressions and/or sharp (lower and upper) bounds of their success rates available (Sect. 23.2).

3. *Quality of fixed solution*: Once the integer solution is available, the fixed solution is computed as in (23.5). This fixed solution has the *multimodal* PDF [23.21]

$$f_{\check{\boldsymbol{b}}}(\boldsymbol{x}) = \sum_{z\in\mathbb{Z}^n} f_{\hat{\boldsymbol{b}}(z)}(\boldsymbol{x}) P(\check{\boldsymbol{a}} = z) \tag{23.14}$$

in which $f_{\hat{\boldsymbol{b}}(z)}(\boldsymbol{x})$ denotes the PDF of the conditional LS-estimator

$$\hat{\boldsymbol{b}}(z) = \hat{\boldsymbol{b}} - \mathbf{Q}_{\hat{b}\hat{a}}\mathbf{Q}_{\hat{a}\hat{a}}^{-1}(\hat{\boldsymbol{a}} - z),$$

normally distributed with mean and variance matrix,

$$\begin{aligned} \boldsymbol{b}(z) &= \boldsymbol{b} - \mathbf{Q}_{\hat{b}\hat{a}}\mathbf{Q}_{\hat{a}\hat{a}}^{-1}(\boldsymbol{a} - z)\,, \\ \mathbf{Q}_{\hat{\boldsymbol{b}}(z)\hat{\boldsymbol{b}}(z)} &= \mathbf{Q}_{\hat{b}\hat{b}} - \mathbf{Q}_{\hat{b}\hat{a}}\mathbf{Q}_{\hat{a}\hat{a}}^{-1}\mathbf{Q}_{\hat{a}\hat{b}}\,. \end{aligned} \tag{23.15}$$

From (23.14) it follows that

$$f_{\check{\boldsymbol{b}}}(\boldsymbol{x}) \approx f_{\hat{\boldsymbol{b}}(\boldsymbol{a})}(\boldsymbol{x}) \sim \mathrm{N}(\boldsymbol{b}, \mathbf{Q}_{\hat{\boldsymbol{b}}(z)\hat{\boldsymbol{b}}(z)}) \tag{23.16}$$

if

$$P_{\mathrm{s}} = P(\check{\boldsymbol{a}} = \boldsymbol{a}) \approx 1\,. \tag{23.17}$$

Thus if the success rate is sufficiently close to one, the distribution of the fixed solution $\check{\boldsymbol{b}}$ can be approximated by the unimodal normal distribution $\mathrm{N}(\boldsymbol{b}, \mathbf{Q}_{\hat{\boldsymbol{b}}(z)\hat{\boldsymbol{b}}(z)})$ of which the precision is better than that of the float solution $\hat{\boldsymbol{b}}$, $\mathbf{Q}_{\hat{\boldsymbol{b}}(z)\hat{\boldsymbol{b}}(z)} < \mathbf{Q}_{\hat{b}\hat{b}}$.

The relevance of ambiguity resolution and the need to have sufficiently large success rates is illustrated in Fig. 23.3c. It shows scatterplots of float positions (gray scatter) and corresponding fixed positions (green/red scatter). The small size of the green scatter shows

the improvements that can be achieved over the float solution if the ambiguities are correctly fixed. The large red scatter indicates however that in this case the success rate is not large enough ($P_s = 93\%$) to avoid some of the fixed positions being even poorer than the float positions. This underlines the importance of working with sufficiently high success rates only.

## 23.2 Rounding and Bootstrapping

### 23.2.1 Integer Rounding

The simplest integer estimator is *rounding to the nearest integer*. In the scalar case, its pull-in regions (intervals) are given as

$$\mathcal{R}_z = \left\{ x \in \mathbb{R} \;\middle|\; |x - z| \le \frac{1}{2} \right\},\ z \in \mathbb{Z}\,. \tag{23.18}$$

Any outcome of $\hat{a} \sim \mathrm{N}(a \in \mathbb{Z}, \sigma_{\hat{a}}^2)$, that satisfies $|\hat{a} - z| \le 1/2$, will thus be pulled to the integer $z$. We denote the rounding estimator as $\check{a}_\mathrm{R}$ and the operation of integer rounding as $\lceil . \rfloor$. Thus $\check{a}_\mathrm{R} = \lceil \hat{a} \rfloor$ and $\check{a}_\mathrm{R} = z$ if $\hat{a} \in \mathcal{R}_z$.

The PMF of $\check{a}_\mathrm{R} = \lceil \hat{a} \rfloor$ is given as

$$P(\check{a}_\mathrm{R} = z) = \left[ \Phi\left( \frac{1 - 2(a-z)}{2\sigma_{\hat{a}}} \right) + \Phi\left( \frac{1 + 2(a-z)}{2\sigma_{\hat{a}}} \right) - 1 \right], \quad z \in \mathbb{Z}\,, \tag{23.19}$$

where $\Phi(x)$ denotes the normal distribution function,

$$\Phi(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} \exp\left( -\frac{1}{2} v^2 \right) \mathrm{d}v\,.$$

The PMF becomes more peaked when $\sigma_{\hat{a}}$ gets smaller. The success rate of scalar rounding follows from (23.19) by setting $z$ equal to $a$,

$$P(\check{a}_\mathrm{R} = a) = 2\Phi\left( \frac{1}{2\sigma_{\hat{a}}} \right) - 1\,. \tag{23.20}$$

The behavior of the success rate as function of the ambiguity standard deviation $\sigma_{\hat{a}}$ is shown in Fig. 23.4. It shows that a success rate better than 99%, requires $\sigma_{\hat{a}} < 0.20$ cycle.

### 23.2.2 Vectorial Rounding

Scalar rounding is easily generalized to the vectorial case. It is defined as the componentwise rounding of $\hat{\boldsymbol{a}} = (\hat{a}_1, \ldots, \hat{a}_n)^\top$, $\check{\boldsymbol{a}}_\mathrm{R} = (\lceil \hat{a}_1 \rfloor, \lceil \hat{a}_2 \rfloor, \ldots, \lceil \hat{a}_n \rfloor)^\top$. The pull-in regions of vectorial rounding are the multivariate versions of the scalar pull-in intervals,

$$\mathcal{R}_{\boldsymbol{z}} = \left\{ \boldsymbol{x} \in \mathbb{R}^n \;\middle|\; |\boldsymbol{c}_i^\top (\boldsymbol{x} - \boldsymbol{z})| \le \frac{1}{2}\,,\ i = 1, \ldots, n \right\}, \tag{23.21}$$

with $\boldsymbol{z} \in \mathbb{Z}^n$ and where $\boldsymbol{c}_i$ denotes the unit vector having a 1 as its $i$th entry and zeros otherwise. Thus the pull-in regions of rounding are unit-squares in two-dimensional (2-D), unit-cubes in three-dimensional (3-D), and so on (Fig. 23.2).

To determine the joint PMF of the components of $\check{\boldsymbol{a}}_\mathrm{R}$, we have to integrate the PDF of $\hat{\boldsymbol{a}} \sim \mathrm{N}(\boldsymbol{a}, \boldsymbol{Q}_{\hat{a}\hat{a}})$ over the pull-in regions $\mathcal{R}_{\boldsymbol{z}}$. These $n$-fold integrals are difficult to evaluate unless the variance matrix $\boldsymbol{Q}_{\hat{a}\hat{a}}$ is diagonal, in which case the components of $\check{\boldsymbol{a}}_\mathrm{R}$ are independent and their joint PMF follows as the product of the univariate PMFs of the components. The corresponding success rate is then given by the $n$-fold product of the univariate success rates.

In case of GNSS, the variance matrix $\boldsymbol{Q}_{\hat{a}\hat{a}}$ will be fully populated, meaning that one will have to resort to methods of Monte Carlo simulation for computing the joint PMF. For the success rate, one can alternatively make use of the following bounds.

*Theorem 23.1 Rounding success-rate bounds [23.22]*

Let the float ambiguity solution be distributed as $\hat{\boldsymbol{a}} \sim \mathrm{N}(\boldsymbol{a}, \boldsymbol{Q}_{\hat{a}\hat{a}})$, $\boldsymbol{a} \in \mathbb{Z}^n$. Then the rounding success rate can be bounded from below and from above as

$$\mathrm{LB} \le P(\check{\boldsymbol{a}}_\mathrm{R} = \boldsymbol{a}) \le \mathrm{UB}\,, \tag{23.22}$$

where

$$\mathrm{LB} = \prod_{i=1}^{n} \left[ 2\Phi\left( \frac{1}{2\sigma_{\hat{a}_i}} \right) - 1 \right],$$
$$\mathrm{UB} = \left[ 2\Phi\left( \frac{1}{2 \max\limits_{i=1,\ldots,n} \sigma_{\hat{a}_i}} \right) - 1 \right]. \tag{23.23}$$

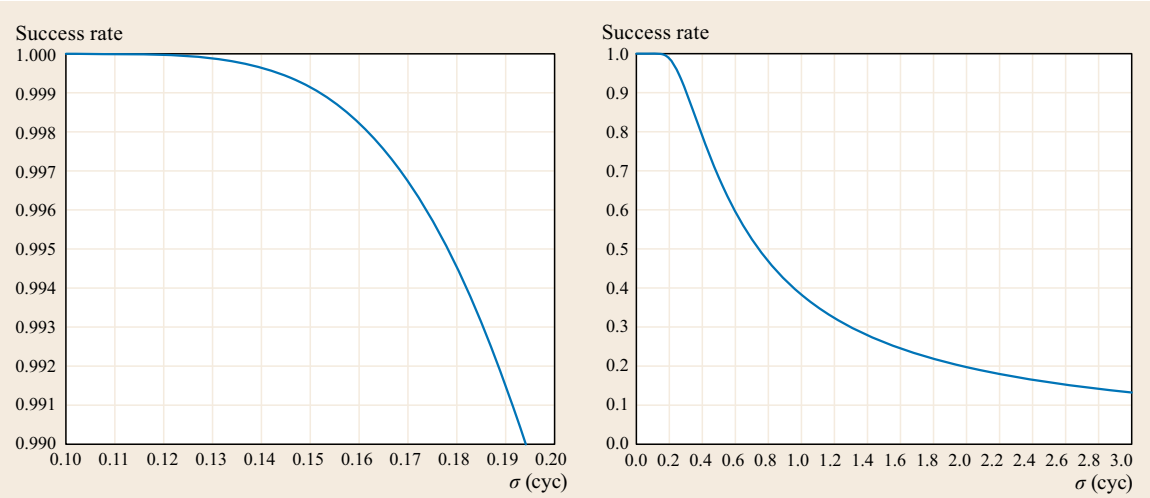

**Fig. 23.4** Scalar rounding success rate versus ambiguity standard deviation $\sigma$ in cycles

These easy-to-compute bounds are very useful for determining the expected success of GNSS ambiguity rounding. The upper bound is useful to quickly decide against such ambiguity resolution. It shows that ambiguity resolution based on vectorial rounding cannot be expected to be successful if already one of the scalar rounding success rates is too low.

The lower bound is useful to quickly decide in favor of vectorial rounding. If the lower bound is sufficiently close to 1, one can be confident that vectorial rounding will produce the correct integer ambiguity vector. Note that this requires each of the individual probabilities in the product of the lower bound to be sufficiently close to 1.

### 23.2.3 Integer Bootstrapping

Integer bootstrapping is a generalization of integer rounding; it combines integer rounding with sequential conditional least-squares estimation and as such takes some of the correlation between the components of the float solution into account. The method goes as follows. If $\hat{\boldsymbol{a}} = (\hat{a}_1, \ldots, \hat{a}_n)^\top$, one starts with $\hat{a}_1$ and as before rounds its value to the nearest integer. Having obtained the integer of the first component, the real-valued estimates of all remaining components are then corrected by virtue of their correlation with $\hat{a}_1$. Then the second, but now corrected, real-valued component is rounded to its nearest integer. Having obtained the integer value of this second component, the real-valued estimates of all remaining $n-2$ components are then again corrected by virtue of their correlation with the second component. This process is continued until all $n$ components are taken care of. We have the following definition.

*Definition 23.2 Integer bootstrapping*

Let $\hat{\boldsymbol{a}} = (\hat{a}_1, \ldots, \hat{a}_n)^\top \in \mathbb{R}^n$ be the float solution and let $\check{\boldsymbol{a}}_\mathrm{B} = (\check{a}_{\mathrm{B},1}, \ldots, \check{a}_{\mathrm{B},n})^\top \in \mathbb{Z}^n$ denote the corresponding integer bootstrapped solution. Then

$$
\begin{aligned}
\check{a}_{\mathrm{B},1} &= \lceil \hat{a}_1 \rfloor \,, \\
\check{a}_{\mathrm{B},2} &= \lceil \hat{a}_{2|1} \rfloor = \lceil \hat{a}_2 - \sigma_{21}\sigma_1^{-2}\,(\hat{a}_1 - \check{a}_{\mathrm{B},1}) \rfloor \,, \\
&\;\;\vdots \\
\check{a}_{\mathrm{B},n} &= \lceil \hat{a}_{n|N} \rfloor = \lceil \hat{a}_n - \sum_{j=1}^{n-1} \sigma_{n,j|J}\sigma_{j|J}^{-2}\,(\hat{a}_{j|J} - \check{a}_{\mathrm{B},j}) \rfloor \,,
\end{aligned}
\tag{23.24}
$$

where $\hat{a}_{i|I}$ is the least-squares estimator of $a_i$ conditioned on the values of the previous $I = \{1, \ldots, (i-1)\}$ sequentially rounded components, $\sigma_{i,j|J}$ is the covariance between $\hat{a}_i$ and $\hat{a}_{j|J}$, and $\sigma^2_{j|J}$ is the variance of $\hat{a}_{j|J}$. For $i = 1$, $\hat{a}_{i|I} = \hat{a}_1$.

As the definition shows, the bootstrapped estimator can be seen as a generalization of integer rounding. The bootstrapped estimator reduces to integer rounding in the case where correlations are absent, i. e., in the case where the variance matrix $Q_{\hat{a}\hat{a}}$ is diagonal.

In vector-matrix form, the bootstrapped estimator (23.24) can shown to be given as [23.23],

$$
\check{\boldsymbol{a}}_\mathrm{B} = \lceil \hat{\boldsymbol{a}} + (\mathbf{L}^{-1} - \mathbf{I}_n)(\hat{\boldsymbol{a}} - \check{\boldsymbol{a}}_\mathrm{B}) \rfloor \,, \tag{23.25}
$$

with $\mathbf{L}$ the unit lower triangular matrix of the triangular decomposition $\mathbf{Q}_{\hat{a}\hat{a}} = \mathbf{L}\mathbf{D}\mathbf{L}^\top$. As the diagonal matrix

$$\mathbf{D} = \mathrm{diag}\left(\sigma^2_{a_1}, \ldots, \sigma^2_{a_{n|N}}\right)$$

is not used in the construction of the bootstrapped estimator, bootstrapping takes only part of the information of the variance matrix into account. Although the diagonal matrix $\mathbf{D}$ is not used in (23.25), it is needed to determine the bootstrapped success rate.

### 23.2.4 Bootstrapped Success Rate

To determine the bootstrapped PMF, we first need the bootstrapped pull-in regions. They are given as

$$\mathcal{B}_z = \left\{ \boldsymbol{x} \in \mathbb{R}^n \mid \mid \boldsymbol{c}_i^\top \mathbf{L}^{-1}(\boldsymbol{x} - z) \mid \leq \frac{1}{2},\ i = 1, \ldots, n \right\}, \tag{23.26}$$

with $z \in \mathbb{Z}^n$ and where $\boldsymbol{c}_i$ denotes the unit vector having a 1 as its $i$th entry and zeros otherwise. They are parallelograms in 2-D (Fig. 23.2).

The bootstrapped PMF follows from integrating the multivariate normal distribution over the bootstrapped pull-in regions. In contrast to the multivariate integral for integer rounding, the multivariate integral for bootstrapping can be simplified considerably. As shown by the following theorem, the bootstrapped PMF can be expressed as a product of univariate integrals.

*Theorem 23.2 Bootstrapped PMF [23.22]*
Let $\hat{\boldsymbol{a}} \sim \mathrm{N}(\boldsymbol{a} \in \mathbb{Z}^n, \mathbf{Q}_{\hat{a}\hat{a}})$ and let $\check{\boldsymbol{a}}_\mathrm{B}$ be the bootstrapped estimator of $\boldsymbol{a}$. Then

$$P(\check{\boldsymbol{a}}_\mathrm{B} = z) = \prod_{i=1}^{n} \left[ \Phi\left( \frac{1 - 2\boldsymbol{l}_i^\top (\boldsymbol{a} - z)}{2\sigma_{\hat{a}_{i|I}}} \right) + \Phi\left( \frac{1 + 2\boldsymbol{l}_i^\top (\boldsymbol{a} - z)}{2\sigma_{\hat{a}_{i|I}}} \right) - 1 \right], \tag{23.27}$$

with $z \in \mathbb{Z}^n$ and where $\boldsymbol{l}_i$ is the $i$th column vector of the unit upper triangular matrix $(\mathbf{L}^{-1})^\top$.

As a direct consequence of the above theorem, we have an exact and easy-to-compute expression for the bootstrapped success rate.

*Corollary 23.1 Bootstrapped success rate*
Let $\hat{\boldsymbol{a}} \sim \mathrm{N}(\boldsymbol{a} \in \mathbb{Z}^n, \mathbf{Q}_{\hat{a}\hat{a}})$. Then the bootstrapped success rate is given as

$$P(\check{\boldsymbol{a}}_\mathrm{B} = \boldsymbol{a}) = \prod_{i=1}^{n} \left[ 2\Phi\left( \frac{1}{2\sigma_{\hat{a}_{i|I}}} \right) - 1 \right]. \tag{23.28}$$

This is an important result as it provides a simple way for evaluating the bootstrapped success rate.

When comparing the performance of bootstrapping with rounding, it can be shown that the success rate of bootstrapping will never be smaller than that of rounding [23.22],

$$P(\check{\boldsymbol{a}}_\mathrm{B} = \boldsymbol{a}) \geq P(\check{\boldsymbol{a}}_\mathrm{R} = \boldsymbol{a})\,. \tag{23.29}$$

Thus bootstrapping is a better integer estimator than rounding.

Despite the fact that we have the above exact and easy-to-compute formula for the bootstrapped success rate, an easy-to-compute upper bound of it would still be useful if it would be $Z$-invariant. Such an upper bound can be constructed when use is made of the $Z$-invariant ADOP (ambiguity dilution of precision).

*Theorem 23.3 Bootstrapped success-rate invariant upper bound [23.24]*
Let $\hat{\boldsymbol{a}} \sim \mathrm{N}(\boldsymbol{a},\ \mathbf{Q}_{\hat{a}\hat{a}})$, $\boldsymbol{a} \in \mathbb{Z}^n$, $\hat{\boldsymbol{z}} = \mathbf{Z}\hat{\boldsymbol{a}}$ and $\mathrm{ADOP} = \det(\mathbf{Q}_{\hat{a}\hat{a}})^{\frac{1}{2n}}$. Then

$$P(\check{\boldsymbol{z}}_\mathrm{B} = z) \leq \left[ 2\Phi\left( \frac{1}{2\mathrm{ADOP}} \right) - 1 \right]^n \tag{23.30}$$

for any admissible $Z$-transformation.

Thus if the upper bound is too small, we can immediately conclude, for *any* ambiguity parametrization, that bootstrapping nor rounding will be successful.

## 23.3 Linear Combinations

### 23.3.1 Z-transformations

Although the integer estimators $\check{\boldsymbol{a}}_{\mathrm{R}}$ and $\check{\boldsymbol{a}}_{\mathrm{B}}$ are easy to compute, they both suffer from a lack of invariance against integer reparametrizations or so-called $Z$-transformations.

*Definition 23.3 Z-transformations [23.25]*
An $n \times n$ matrix $\mathbf{Z}$ is called a $Z$-transformation iff $\mathbf{Z}, \mathbf{Z}^{-1} \in \mathbb{Z}^{n\times n}$, i. e., if the entries of the matrix and its inverse are all integer.

$Z$-transformations leave the integer nature of integer vectors invariant. It can be shown that the two conditions, $\mathbf{Z}, \mathbf{Z}^{-1} \in \mathbb{Z}^{n\times n}$, are equivalent to the two conditions $\mathbf{Z} \in \mathbb{Z}^{n\times n}$ and $\det(\mathbf{Z}) = \pm 1$. Hence, the class of $Z$-transformations can also be defined as

$$\mathcal{Z} = \{\mathbf{Z} \in \mathbb{Z}^{n\times n} \mid |\mathbf{Z}| = \pm 1\} \,. \tag{23.31}$$

Thus, $Z$-transformations are volume-preserving transformations. This implies that the determinant of the ambiguity variance matrix is invariant for $Z$-transformations: $|\mathbf{Q}_{\check{z}\check{z}}| = |\mathbf{Z}\mathbf{Q}_{\hat{a}\hat{a}}\mathbf{Z}^{\top}| = |\mathbf{Q}_{\hat{a}\hat{a}}|$.

By saying that an estimator lacks $Z$-invariance, we mean that if the float solution is $Z$-transformed, the integer solution does not transform accordingly. That is, rounding/bootstrapping and transforming do generally not commute,

$$\check{z}_{\mathrm{R}} \neq \mathbf{Z}\check{\boldsymbol{a}}_{\mathrm{R}} \text{ and } \check{z}_{\mathrm{B}} \neq \mathbf{Z}\check{\boldsymbol{a}}_{\mathrm{B}} \text{ if } \hat{z} = \mathbf{Z}\hat{\boldsymbol{a}} \,. \tag{23.32}$$

This is illustrated in Fig. 23.5 for integer rounding and in Fig. 23.6 for integer bootstrapping. Also the success rates of rounding and bootstrapping lack $Z$-invariance,

$$\begin{aligned} P(\check{z}_{\mathrm{R}} = z) &\neq P(\check{\boldsymbol{a}}_{\mathrm{R}} = \boldsymbol{a}) \,, \\ P(\check{z}_{\mathrm{B}} = z) &\neq P(\check{\boldsymbol{a}}_{\mathrm{B}} = \boldsymbol{a}) \,. \end{aligned} \tag{23.33}$$

This is also very clear from Figs. 23.5 and 23.6. Since the scatterplot of $\hat{\boldsymbol{a}}$ is much more elongated than that of $\hat{z} = \mathbf{Z}\hat{\boldsymbol{a}}$, the rounding pull-in region is a much poorer fit of the original scatterplot than of the transformed scatterplot. This is also true for the bootstrapped pull-in regions, even though the shape of the bootstrapped pull-in region changes with the $Z$-transformation. Note that the two figures also illustrate the workings of inequality (23.29), i. e., that bootstrapping outperforms rounding. The bootstrapped pull-in regions have a better fit of the scatterplot, original as well as transformed, than the pull-in region of rounding.

The question is now whether the above-identified lack of invariance means that rounding and bootstrapping are unfit for GNSS integer ambiguity resolution? The answer is no, by no means. Integer rounding and bootstrapping are valid ambiguity estimators, and they are attractive, because of their computational simplicity. Whether or not they can be successfully applied in any concrete situation, depends solely on the value of their success rates for that particular situation.

### 23.3.2 (Extra) Widelaning

Since the performance of rounding and bootstrapping depends on the chosen ambiguity parameterization, it would be helpful to know how to improve their performance by choosing suitable $Z$-transformations. The simplest such $Z$-transformations are the so-called widelaning transformations. Examples of widelaning trans-

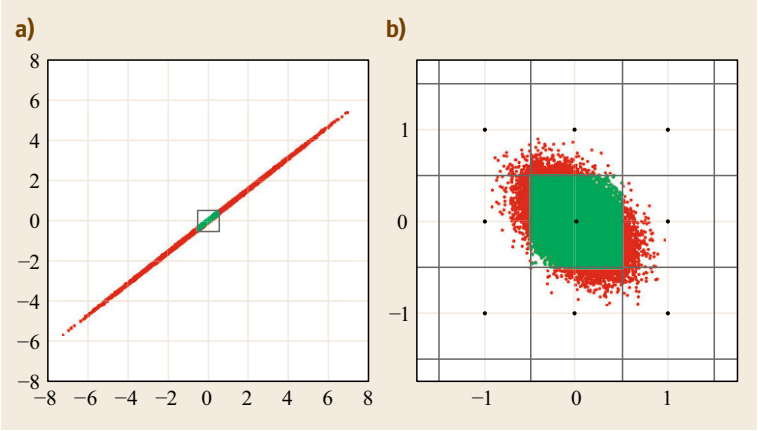

**Fig. 23.5a,b** 2-D IR pull-in regions and 50 000 simulated zero-mean float solutions. **(a)** Original ambiguities $\hat{\boldsymbol{a}}$ [cycles]; **(b)** $Z$-transformed ambiguities $\hat{z} = \mathbf{Z}\hat{\boldsymbol{a}}$ [cycles]. *Red dots* will be pulled to wrong integer solutions, while *green dots* will be pulled to the correct integer solution (after [23.18])

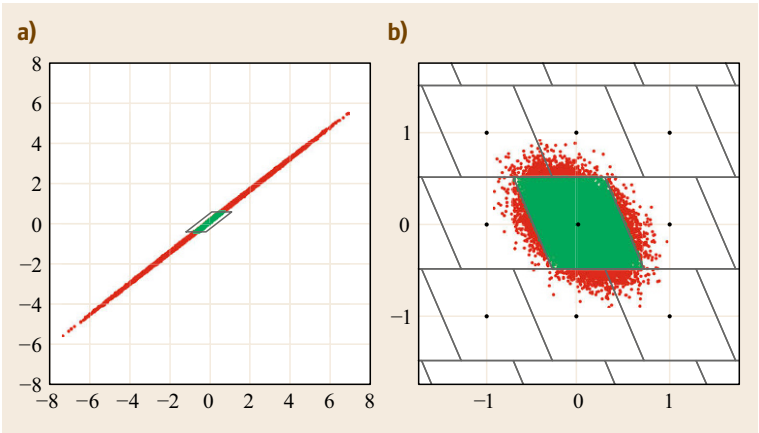

**Fig. 23.6** 2-D IB pull-in regions (original and transformed) and 50 000 simulated zero-mean float solutions. **(a)** Original ambiguities $\hat{\boldsymbol{a}}$ [cycles]; **(b)** $Z$-transformed ambiguities $\hat{\boldsymbol{z}} = \boldsymbol{Z}\hat{\boldsymbol{a}}$ [cycles]. *Red dots* will be pulled to wrong integer solutions, while *green dots* will be pulled to the correct integer solution (after [23.18])

formations are

$$\begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} \tag{23.34}$$

for the dual-frequency case, and

$$\begin{bmatrix} z_1 \\ z_2 \\ z_3 \end{bmatrix} = \begin{bmatrix} 0 & 1 & -1 \\ 1 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} \tag{23.35}$$

for the triple-frequency case. These transformations are referred to as *widelaning*, since they can be interpreted to form carrier-phase observables with long wavelengths. To see this, consider the carrier-phase transformation

$$\bar{\phi}_i = \frac{\sum_{j=1}^{f} Z_{ij}\lambda_j^{-1}\phi_j}{\sum_{j=1}^{f} Z_{ij}\lambda_j^{-1}}\,, \quad i = 1,\ldots,f\,, \tag{23.36}$$

in which $\phi_j$ denotes the double-differenced (DD) carrier-phase observable on frequency $j = 1,\ldots,f$, $\lambda_j$ its wavelength and $Z_{ij}$ the $ij$th-entry of the $Z$-transformation matrix. With this transformation, the system of $f$ DD carrier-phase observation equations

$$\phi_i = \rho - \mu_i I + \lambda_i a_i\,, \quad i = 1,\ldots,f \tag{23.37}$$

transforms to a system with similar structure, namely

$$\bar{\phi}_i = \rho - \bar{\mu}_i I + \bar{\lambda}_i z_i\,, \quad i = 1,\ldots,f\,, \tag{23.38}$$

with $\rho$ the DD nondispersive range plus tropospheric delay, $I$ the DD ionospheric delay on the first frequency, $\mu_i$ and $\bar{\mu}_i$ the original and transformed ionospheric coefficient, $\lambda_i$ and $\bar{\lambda}_i$ the original and transformed wavelength, and $a_i$ and $z_i$ the original and transformed ambiguity.

The relation between the original and transformed wavelengths is given as

$$\bar{\lambda}_i = \left(\sum_{j=1}^{f} Z_{ij}\lambda_j^{-1}\right)^{-1}\,, \quad i = 1,\ldots,f\,. \tag{23.39}$$

If we now substitute the entries of the above widelaning transformation (23.35), together with the wavelengths of GPS (or Galileo or BeiDou), we obtain the values of the transformed wavelengths ($\bar{\lambda}_1 = \lambda_{\mathrm{ew}}, \bar{\lambda}_2 = \lambda_{\mathrm{w}}, \bar{\lambda}_3 = \lambda_3$) as given in Table 23.1, which indeed are larger than the original wavelengths.

The rationale for aiming at longer wavelengths is that a larger ambiguity coefficient $\bar{\lambda}_i$ improves the precision with which the ambiguity $z_i$ can be estimated. However, this reasoning is only valid of course if all other circumstances remain unchanged under the transformation. This is not really the case with the above carrier-phase transformation (23.36), since the variance matrix of $\phi_i$, $i = 1,\ldots,f$, will generally differ from that of the transformed $\bar{\phi}_i$, $i = 1,\ldots,f$. Nevertheless, the above simple widelaning transformations, (23.34) and (23.35), are still useful as they can often be seen as an easy first step in improving the precision of the float ambiguities.

### 23.3.3 Decorrelating Transformation

In general the widelaning approach is quite limited in finding suitable $Z$-transformations. We now describe a general method, due to [23.14], for finding such transformations. The method can be applied to any possible integer GNSS model and it has generally a significantly improved performance over widelaning [23.26–28].

Since it is the ambiguity variance matrix that completely determines the ambiguity success rate (23.13), the method takes the ambiguity variance matrix $\boldsymbol{Q}_{\hat{a}\hat{a}}$

**Table 23.1** GPS, Galileo and BeiDou original, widelane (w) and extra widelane (ew) wavelengths (cm)

| Wavelength | GPS | | Galileo | | BeiDou | |
|---|---|---|---|---|---|---|
| $a_1$ | $L_1$ | 19.0 | $E_1$ | 19.0 | $B_1$ | 19.2 |
| $a_2$ | $L_2$ | 24.4 | $E_6$ | 23.4 | $B_3$ | 23.6 |
| $z_3 = a_3$ | $L_5$ | 25.5 | $E_{5a}$ | 25.5 | $B_2$ | 24.8 |
| $z_2 = a_1 - a_2$ | $L_w$ | 86.2 | $E_w$ | 101.1 | $B_w$ | 102.4 |
| $z_1 = a_2 - a_3$ | $L_{ew}$ | 587.0 | $E_{ew}$ | 292.8 | $B_{ew}$ | 488.9 |

as its point of departure. The aim is to find a $Z$-transformation that decorrelates the ambiguities as much as possible, i. e., that makes the transformed ambiguity variance matrix $\mathbf{Q}_{\hat{z}\hat{z}} = \mathbf{Z}\mathbf{Q}_{\hat{a}\hat{a}}\mathbf{Z}^\top$ as diagonal as possible. The rationale of this approach is that an ambiguity parametrization with diagonal variance matrix is optimal in the sense that then no further success-rate improvements of rounding and bootstrapping are possible through reparametrization.

The degree of decorrelation of a variance matrix is measured by its decorrelation number. Let

$$\mathbf{R}_{\hat{a}\hat{a}} = [\mathrm{diag}(\mathbf{Q}_{\hat{a}\hat{a}})]^{-1/2}\mathbf{Q}_{\hat{a}\hat{a}}[\mathrm{diag}(\mathbf{Q}_{\hat{a}\hat{a}})]^{-1/2}$$

be the correlation matrix of $\mathbf{Q}_{\hat{a}\hat{a}}$. Then the *decorrelation number* is defined as [23.26]

$$r_{\hat{a}} = \sqrt{|\mathbf{R}_{\hat{a}\hat{a}}|} \quad (0 \le r_{\hat{a}} \le 1)\,. \tag{23.40}$$

In two dimensions it reduces to

$$r_{\hat{a}} = \sqrt{(1-\rho_{\hat{a}}^2)}\,,$$

with $\rho_{\hat{a}}$ being the ambiguity correlation coefficient. Hence, a two-dimensional ambiguity variance matrix is diagonal if and only if $r_{\hat{a}} = 1$. It can be shown that this also holds true for the higher-dimensional case. Since $|\mathbf{R}_{\hat{a}\hat{a}}| = |\mathbf{Q}_{\hat{a}\hat{a}}|/(\prod_{i=1}^n \sigma_{\hat{a}_i}^2)|$ and $|\mathbf{Q}_{\hat{z}\hat{z}}| = |\mathbf{Q}_{\hat{a}\hat{a}}|$, we have

$$r_{\hat{z}} \ge r_{\hat{a}} \;\Leftrightarrow\; \sigma_{\hat{z}_1}^2 \ldots \sigma_{\hat{z}_n}^2 \le \sigma_{\hat{a}_1}^2 \ldots \sigma_{\hat{a}_n}^2\,. \tag{23.41}$$

Hence, the ambiguity decorrelation number increases if the product of ambiguity variances decreases. We now show how to construct such decorrelating $Z$-transformation for the two-dimensional case. For the higher-dimensional case, see for example [23.27, 28].

We minimize the product $\sigma_{\hat{a}_1}^2\sigma_{\hat{a}_2}^2$ in an alternating fashion, i. e., we start by keeping the first variance unchanged and reduce the second variance. Then we keep the second, now reduced, variance unchanged and reduce the first variance. This process is continued until no further reduction in the product of variances is possible anymore.

In the sequence of alternating reductions, the following type of transformations are applied

$$\mathbf{\Pi}_2\mathbf{G}_\alpha = \begin{bmatrix}\alpha & 1\\ 1 & 0\end{bmatrix}, \tag{23.42}$$

where

$$\mathbf{G}_\alpha = \begin{bmatrix}1 & 0\\ \alpha & 1\end{bmatrix}, \quad \mathbf{\Pi}_2 = \begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}. \tag{23.43}$$

With $\mathbf{G}_\alpha$, the variance of the second ambiguity is reduced, while with $\mathbf{\Pi}_2$, the order of the two ambiguities is interchanged. Once the order is interchanged, a transformation like $\mathbf{G}_\alpha$ can again be applied to further reduce the product of variances.

The value of $\alpha$ is determined in each step of the sequence as follows. With $\mathbf{G}_\alpha$, the variance of the second ambiguity becomes

$$\begin{aligned}&[\mathbf{G}_\alpha\mathbf{Q}_{\hat{a}\hat{a}}\mathbf{G}_\alpha^\top]_{22}\\ &\quad= \alpha^2\sigma_{\hat{a}_1}^2 + 2\alpha\sigma_{\hat{a}_2\hat{a}_1} + \sigma_{\hat{a}_2}^2\\ &\quad= \sigma_{\hat{a}_2}^2 - \sigma_{\hat{a}_1}^2\left[(\sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2})^2 - (\alpha + \sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2})^2\right].\end{aligned} \tag{23.44}$$

This shows that the variance of the transformed ambiguity is minimal for $\alpha = -\sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2}$. As this is not an integer in general, it would not produce an admissible transformation when substituted into $\mathbf{G}_\alpha$ of (23.43). Therefore, instead of using the real-valued minimizer $-\sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2}$ for $\alpha$ in $\mathbf{G}_\alpha$, its nearest integer is used as approximation, $\alpha = -\lceil\sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2}\rfloor$. This still gives a reduction in the variance of the second ambiguity, since

$$(\sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2})^2 > (\alpha + \sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2})^2$$

if

$$|\sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2}| > \frac{1}{2}\,,$$

i. e., if

$$\lceil\sigma_{\hat{a}_2\hat{a}_1}\sigma_{\hat{a}_1}^{-2}\rfloor \neq 0\,.$$

The construction of the decorrelation transformation is summarized in the following definition [23.26–28].

### *Definition 23.4 Decorrelating Z-transformation*

Let $\mathbf{Q}^{(1)} = \mathbf{Q}_{\hat{a}\hat{a}}$ and $\mathbf{Q}^{(i+1)} = \mathbf{Z}_i\mathbf{Q}^{(i)}\mathbf{Z}_i^\top$, $i = 1, \ldots, k+2$. Then the two-dimensional decorrelating $Z$-transformation is given as the product

$$\mathbf{Z} = \mathbf{Z}_k\mathbf{Z}_{k-1}\ldots\mathbf{Z}_1\,, \tag{23.45}$$

**Table 23.2** 2-D example of rounding and bootstrapping on original and $Z$-transformed ambiguities

| $\mathbf{Z} = \begin{bmatrix} 4 & -3 \\ -1 & 1 \end{bmatrix}$ | $\hat{\boldsymbol{a}} = \begin{bmatrix} 2.23 \\ 2.51 \end{bmatrix}$, $\mathbf{Q}_{\hat{a}\hat{a}} = \begin{bmatrix} 0.1680 & 0.2152 \\ 0.2152 & 0.2767 \end{bmatrix}$ **Original ambiguities, $\rho_{\hat{a}} = 0.96$** | $\hat{\boldsymbol{z}} = \begin{bmatrix} 1.39 \\ 0.28 \end{bmatrix}$, $\mathbf{Q}_{\hat{z}\hat{z}} = \begin{bmatrix} 0.0135 & 0.0043 \\ 0.0043 & 0.0143 \end{bmatrix}$ **Transformed ambiguities, $\rho_{\hat{z}} = 0.31$** |
|---|---|---|
| Rounding | $\check{\boldsymbol{a}}_{\mathrm{R}} = [2,3]^{\top}$ | $\check{\boldsymbol{z}}_{\mathrm{R}} = [1,0]^{\top}$ |
| Bootstrapping | $\check{\boldsymbol{a}}_{\mathrm{B}}^{(1)} = [2,2]^{\top}$, $\check{\boldsymbol{a}}_{\mathrm{B}}^{(2)} = [3,3]^{\top}$ | $\check{\boldsymbol{z}}_{\mathrm{B}}^{(1)} = [1,0]^{\top}$, $\check{\boldsymbol{z}}_{\mathrm{B}}^{(2)} = [1,0]^{\top}$ |

where

$$\mathbf{Z}_i = \begin{bmatrix} \alpha_i & 1 \\ 1 & 0 \end{bmatrix}, \quad \mathbf{Q}^{(i)} = \begin{bmatrix} \sigma_1^2(i) & \sigma_{12}(i) \\ \sigma_{21}(i) & \sigma_2^2(i) \end{bmatrix}$$

and

$$\alpha_i = -\lceil \sigma_{21}(i)\sigma_1^{-2}(i) \rfloor ,$$

with $\alpha_{k+1} = \alpha_{k+2} = 0$.

After the above decorrelating transformation is applied, the correlation coefficient of the transformed ambiguities will never be larger than 0.5 in absolute value. This can be seen as follows. If $\alpha_{k+1} = \alpha_{k+2} = 0$, then $\sigma_{21}(k+2) = \sigma_{21}(k+1)$ and $\sigma_1^2(k+2) = \sigma_2^2(k+1)$, and therefore

$$\rho_{\check{z}}^2 = \frac{\sigma_{21}(k+1)^2}{\sigma_1^2(k+1)\sigma_2^2(k+1)} \leq \frac{1}{4} . \tag{23.46}$$

Geometrically, the above sequence of transformations in the product of $\mathbf{Z}$ (23.45) can be given the following useful interpretation. Consider the confidence ellipse of $\hat{\boldsymbol{a}}$. Its shape and orientation is determined by $\mathbf{Q}_{\hat{a}\hat{a}}$. The part $\mathbf{G}_{\alpha_1}$ of $\mathbf{Z}_1$ then pushes the two horizontal tangents of the ellipse inwards, while at the same time keeping fixed the area of the ellipse and the location of the two vertical tangents. Then $\mathbf{G}_{\alpha_2}\mathbf{\Pi}_2$ of the product $\mathbf{Z}_2\mathbf{Z}_1$ pushes the two vertical tangents of the ellipse inwards, while at the same time keeping fixed the area of the ellipse and the location of the two horizontal tangents. This process is continued until no further reduction is possible. Since the area of ellipse is kept constant at all times ($|\mathbf{Q}_{\hat{a}\hat{a}}| = |\mathbf{Q}_{\hat{z}\hat{z}}|$), whereas the area of the enclosing rectangular box is reduced in each step, it follows that not only the diagonality of the ambiguity variance matrix is reduced, but also that the shape of the ellipse is forced to become more circular.

For further computational details on how such $Z$-transformations can be constructed, we refer to [23.14, 27–29] and the references cited therein. Also see [23.30–34].

### 23.3.4 Numerical Example

The following two-dimensional numerical example compares rounding with bootstrapping and illustrates their dependence on the chosen ambiguity parametrization. The float solution has been computed from a dual-frequency, ionosphere-fixed geometry-free model for two receivers, two satellites, and two epochs, in which an undifferenced phase standard deviation of 3 mm and an undifferenced code standard deviation of 10 cm is assumed.

Hence, the computations are based on the double-differenced (DD) phase- and code-observation equations

$$\begin{aligned} \phi_i(t) &= \rho(t) + \lambda_i a_i + e_{\phi_i}(t) , \\ p_i(t) &= \rho(t) + e_{p_i}(t) , \end{aligned} \tag{23.47}$$

with $i = 1, 2$ and $t = t_1, t_2$.

The original and transformed float solution, $\hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{z}} = \mathbf{Z}\hat{\boldsymbol{a}}$, and their variance matrices, $\mathbf{Q}_{\hat{a}\hat{a}}$ and $\mathbf{Q}_{\hat{z}\hat{z}}$, are given in Table 23.2, together with the decorrelating transformation matrix $\mathbf{Z}$. It is constructed as

$$\mathbf{Z} = \begin{bmatrix} -3 & 1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} -1 & 1 \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} 4 & -3 \\ -1 & 1 \end{bmatrix} . \tag{23.48}$$

This transformation decorrelates ($\rho_{\hat{a}} = 0.96$ versus $\rho_{\hat{z}} = 0.31$) and significantly improves the precision of the ambiguities (Table 23.2). Also note that the first step in the construction of $\mathbf{Z}$ consists of widelaning.

Table 23.2 also contains six integer solutions, two based on rounding and four based on bootstrapping. Rounding of $\hat{\boldsymbol{a}}$ gives

$$\check{\boldsymbol{a}}_{\mathrm{R}} = \begin{bmatrix} \lceil 2.23 \rfloor \\ \lceil 2.51 \rfloor \end{bmatrix} = \begin{bmatrix} 2 \\ 3 \end{bmatrix} ,$$

while bootstrapping of $\hat{\boldsymbol{a}}$ gives

$$\check{\boldsymbol{a}}_{\mathrm{B}}^{(1)} = \begin{bmatrix} \lceil 2.23 \rfloor \\ \lceil 2.51 - \frac{0.2152}{0.1680}(2.23 - 2) \rfloor \end{bmatrix} = \begin{bmatrix} 2 \\ 2 \end{bmatrix} ,$$

when starting from the first ambiguity, and

$$\check{\boldsymbol{a}}_{\mathrm{B}}^{(2)} = \begin{bmatrix} \lceil 2.23 - \frac{0.2152}{0.2767}(2.51 - 3) \rfloor \\ \lceil 2.51 \rfloor \end{bmatrix} = \begin{bmatrix} 3 \\ 3 \end{bmatrix} ,$$

when starting from the second ambiguity. These solutions together with their counterparts in the transformed domain can be found in Table 23.2.

Note that all three solutions in the original domain, $\check{\boldsymbol{a}}_{\mathrm{R}}$, $\check{\boldsymbol{a}}_{\mathrm{B}}^{(1)}$ and $\check{\boldsymbol{a}}_{\mathrm{B}}^{(2)}$, are different, while their counterparts in the transformed domain are the same and all equal to $[1,0]^{\top}$. Also note that when the solution in the transformed domain is back-transformed to the original domain, again a different solution is obtained, namely,

$$\check{\boldsymbol{a}}'_{\mathrm{R}} = \mathbf{Z}^{-1}\check{\boldsymbol{z}}_{\mathrm{R}} = \begin{bmatrix}1\\1\end{bmatrix}. \tag{23.49}$$

In Table 23.3, the success rates of the different solutions are given. Note the big differences between the success rates of the transformed ambiguities and original ambiguities. The success rates of the transformed ambiguities are all very close to 1. This is due to the high precision of the transformed float solution $\hat{\boldsymbol{z}}$ (Table 23.2). Also note that the success rates of $\check{\boldsymbol{a}}_{\mathrm{B}}^{(1)}$ and $\check{\boldsymbol{z}}_{\mathrm{B}}^{(1)}$ are larger than those of their counterparts $\check{\boldsymbol{a}}_{\mathrm{B}}^{(2)}$ and $\check{\boldsymbol{z}}_{\mathrm{B}}^{(2)}$. This is due to the fact that in this example the first ambiguity is more precise than the second ambiguity. Thus bootstrapping should always start with the most precise ambiguity.

**Table 23.3** Bootstrapped success rates and rounding success rate lower bound for the ambiguity solutions of Table 23.2

| Success rate | Original ambiguities | Transformed ambiguities |
|---|---|---|
| Lower bound rounding | 0.51171 | 0.99995 |
| Bootstrapping (1st ambiguity) | 0.77749 | 0.99997 |
| Bootstrapping (2nd ambiguity) | 0.65816 | 0.99996 |

## 23.4 Integer Least-Squares

In this section we discuss the integer least-squares (ILS) ambiguity estimator. It has the best performance of all integer estimators. However, in contrast to rounding and bootstrapping, an integer search is needed for its computation.

### 23.4.1 Mixed Integer Least-Squares

Application of the least-squares principle to model (23.2), but now with the integer ambiguity constraints included, gives

$$(\check{\boldsymbol{a}}_{\mathrm{LS}}, \check{\boldsymbol{b}}_{\mathrm{LS}}) = \arg \min_{\boldsymbol{a}\in\mathbb{Z}^n, \boldsymbol{b}\in\mathbb{R}^p} \| \boldsymbol{y} - \mathbf{A}\boldsymbol{a} - \mathbf{B}\boldsymbol{b} \|^2_{\mathbf{Q}_{yy}} \ . \tag{23.50}$$

This is a nonstandard least-squares problem due to the integer constraints $\boldsymbol{a} \in \mathbb{Z}^n$ [23.14].

To solve (23.50), we start from the orthogonal decomposition

$$\begin{aligned} &||\boldsymbol{y} - \mathbf{A}\boldsymbol{a} - \mathbf{B}\boldsymbol{b}||^2_{\mathbf{Q}_{yy}} = \\ &\quad ||\hat{\boldsymbol{e}}||^2_{\mathbf{Q}_{yy}} + ||\hat{\boldsymbol{a}} - \boldsymbol{a}||^2_{\mathbf{Q}_{\hat{a}\hat{a}}} + ||\hat{\boldsymbol{b}}(\boldsymbol{a}) - \boldsymbol{b}||^2_{\mathbf{Q}_{\hat{b}(a)\hat{b}(a)}} \ , \end{aligned} \tag{23.51}$$

where $\hat{\boldsymbol{e}} = \boldsymbol{y} - \mathbf{A}\hat{\boldsymbol{a}} - \mathbf{B}\hat{\boldsymbol{b}}$, with $\hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{b}}$ the float solution, i. e., the unconstrained least-squares estimators of $\boldsymbol{a}$ and $\boldsymbol{b}$ respectively. Furthermore,

$$\hat{\boldsymbol{b}}(\boldsymbol{a}) = \hat{\boldsymbol{b}} - \mathbf{Q}_{\hat{b}\hat{a}}\mathbf{Q}_{\hat{a}\hat{a}}^{-1}(\hat{\boldsymbol{a}} - \boldsymbol{a}) \ ,$$

and

$$\mathbf{Q}_{\hat{b}(a)\hat{b}(a)} = \mathbf{Q}_{\hat{b}\hat{b}} - \mathbf{Q}_{\hat{b}\hat{a}}\mathbf{Q}_{\hat{a}\hat{a}}^{-1}\mathbf{Q}_{\hat{a}\hat{b}} \ .$$

Note that the first term on the right-hand side of (23.51) is constant and that the third term can be made zero for any $\boldsymbol{a}$ by setting $\boldsymbol{b} = \hat{\boldsymbol{b}}(\boldsymbol{a})$. Hence, the mixed-integer minimizers of (23.50) are given as

$$\begin{aligned} \check{\boldsymbol{a}}_{\mathrm{LS}} &= \arg \min_{z\in\mathbb{Z}^n} ||\hat{\boldsymbol{a}} - z||^2_{\mathbf{Q}_{\hat{a}\hat{a}}} \ , \\ \check{\boldsymbol{b}}_{\mathrm{LS}} &= \hat{\boldsymbol{b}}(\check{\boldsymbol{a}}_{\mathrm{LS}}) = \hat{\boldsymbol{b}} - \mathbf{Q}_{\hat{b}\hat{a}}\mathbf{Q}_{\hat{a}\hat{a}}^{-1}(\hat{\boldsymbol{a}} - \check{\boldsymbol{a}}_{\mathrm{LS}}) \ . \end{aligned} \tag{23.52}$$

In contrast to rounding and bootstrapping, the ILS principle is $Z$-invariant. For $\hat{\boldsymbol{z}} = \mathbf{Z}\hat{\boldsymbol{a}}$, we have

$$\check{\boldsymbol{z}}_{\mathrm{LS}} = \mathbf{Z}\check{\boldsymbol{a}}_{\mathrm{LS}} \ \text{ and } \ \check{\boldsymbol{b}}_{\mathrm{LS}} = \hat{\boldsymbol{b}} - \mathbf{Q}_{\hat{b}\hat{z}}\mathbf{Q}_{\hat{z}\hat{z}}^{-1}(\hat{\boldsymbol{z}} - \check{\boldsymbol{z}}_{\mathrm{LS}}) \ . \tag{23.53}$$

Hence, application of the ILS principle to $\mathbf{Z}\hat{\boldsymbol{a}}$ gives the same result as $\mathbf{Z}$ times the ILS estimator of $\boldsymbol{a}$. Also $\check{\boldsymbol{b}}_{\mathrm{LS}}$ is invariant for the integer reparametrization.

The $Z$-invariance of the ILS principle also implies that the same success rate is obtained, i. e., $P(\check{\boldsymbol{z}}_{\mathrm{LS}} = \boldsymbol{z}) = P(\check{\boldsymbol{a}}_{\mathrm{LS}} = \boldsymbol{a})$. This is illustrated in Fig. 23.7. The number of green dots in the original scatterplot is exactly the same as the number of green dots in the transformed scatterplot.

When we compare Fig. 23.7 with Figs. 23.5 and 23.6, we note that the ILS pull-in region gives a better fit to the scatterplot than those of rounding and bootstrapping, thus indicating that ILS has a higher success rate. And indeed we have the following optimality property of the ILS estimator.

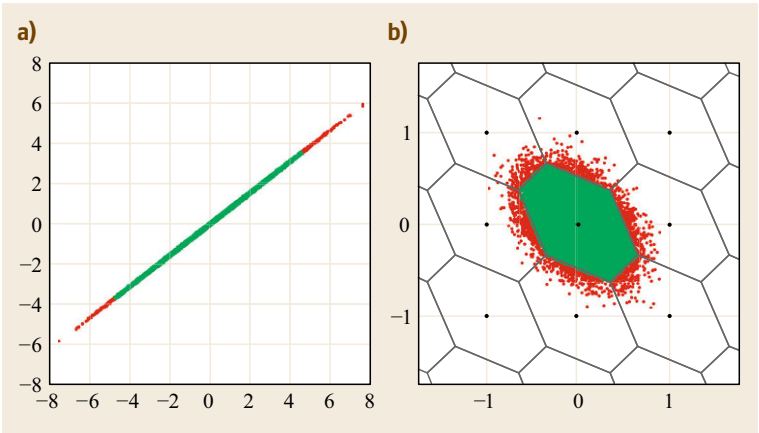

**Fig. 23.7a,b** 2-D ILS (original and transformed) pull-in regions and 50 000 float solutions. **(a)** Original ambiguities $\hat{\boldsymbol{a}}$ [cycles]; **(b)** $Z$-transformed ambiguities $\hat{\boldsymbol{z}} = \mathbf{Z}\hat{\boldsymbol{a}}$ [cycles]. Red dots will be pulled to wrong integer solutions, while green dots will be pulled to the correct integer solution

*Theorem 23.4 ILS Optimality [23.35]*
Let $\hat{\boldsymbol{a}} \sim N(\boldsymbol{a}, \mathbf{Q}_{\hat{a}\hat{a}})$. Then the integer least-squares estimator

$$\check{\boldsymbol{a}}_{\mathrm{LS}} = \arg\min_{z\in\mathbb{Z}^n} ||\hat{\boldsymbol{a}} - z||^2_{\mathbf{Q}_{\hat{a}\hat{a}}}$$

has the largest success rate of all integer estimators. Furthermore

$$P(\check{\boldsymbol{a}}_{\mathrm{R}} = \boldsymbol{a}) \le P(\check{\boldsymbol{a}}_{\mathrm{B}} = \boldsymbol{a}) \le P(\check{\boldsymbol{a}}_{\mathrm{LS}} = \boldsymbol{a}) \,. \qquad (23.54)$$

This result shows that there exists a clear ordering among the three most popular integer estimators. Integer rounding (IR) is the simplest, but it also has the poorest success rate. Integer least-squares (ILS) is the most complex, but also has the highest success rate of all. Integer bootstrapping (IB) sits in between. It does not need an integer search as is the case with ILS, and it does not completely neglect the information content of the ambiguity variance matrix as IR does.

The ordering (23.54) is illustrated by the empirical success rates in Table 23.4 for the cases shown in Figs. 23.5–23.7.

## 23.4.2 The ILS Computation

In this section the computation of the ILS solution (23.52) is presented. The two main parts of its computation are (a) the integer ambiguity search, and (b) the ambiguity decorrelation. Although the ILS solution can in principle be computed on the basis of only (a), the decorrelation step is essential in the case of GNSS for improving the numerical efficiency of (a). This is particularly true in case of short observation time spans. Then the DD ambiguities turn out to be highly correlated due to the small change over time in the relative receiver–satellite geometry.

**Table 23.4** The percentages of correctly IR-, IB- and ILS-estimated ambiguities in original and transformed domain for the cases shown in Figs 23.5–23.7

| Success rate | IR (%) | IB (%) | ILS (%) |
|---|---|---|---|
| Original $\hat{\boldsymbol{a}}$ | 23 | 29 | 97 |
| Transformed $\hat{\boldsymbol{z}}$ | 95 | 96 | 97 |

### Integer Ambiguity Search

In contrast to rounding and bootstrapping, an integer search is needed to compute the ILS ambiguity solution

$$\check{\boldsymbol{a}} = \arg\min_{z\in\mathbb{Z}^n} ||\hat{\boldsymbol{a}} - z||^2_{\mathbf{Q}_{\hat{a}\hat{a}}} \,. \qquad (23.55)$$

The search space is defined as

$$\Psi_{\boldsymbol{a}} = \{\boldsymbol{a} \in \mathbb{Z}^n \mid ||\hat{\boldsymbol{a}} - \boldsymbol{a}||^2_{\mathbf{Q}_{\hat{a}\hat{a}}} \le \chi^2\} \,, \qquad (23.56)$$

where $\chi^2$ is a to-be-chosen positive constant. This ellipsoidal search space is centered at $\hat{\boldsymbol{a}}$, its elongation is governed by $\mathbf{Q}_{\hat{a}\hat{a}}$ and its size is determined by $\chi^2$. In the case of GNSS, the search space is usually extremely elongated due to the high correlations between the carrier-phase ambiguities. Since this extreme elongation hinders the computational efficiency of the search, the search space is first transformed to a more spherical shape by means of a decorrelating $Z$-transformation,

$$\Psi_z = \left\{z \in \mathbb{Z}^n \mid ||\hat{z} - z||^2_{\mathbf{Q}_{\hat{z}\hat{z}}} \le \chi^2\right\} \,, \qquad (23.57)$$

where $\hat{\boldsymbol{z}} = \mathbf{Z}\hat{\boldsymbol{a}}$ and $\mathbf{Q}_{\hat{z}\hat{z}} = \mathbf{Z}\mathbf{Q}_{\hat{a}\hat{a}}\mathbf{Z}^\top$.

In order for the search to be efficient, one would like the search space to be small such that it contains not too many integer vectors. This requires the choice of a small value for $\chi^2$, but one that still guarantees that the search space contains at least one integer vector. After all, $\Psi_z$

has to be nonempty to guarantee that it contains the ILS solution $\check{z}_{\mathrm{LS}}$. Since the easy-to-compute (decorrelated) bootstrapped estimator gives a good approximation to the ILS estimator, $\check{z}_{\mathrm{B}}$ is a good candidate for setting the size of the search space,

$$\chi^2 = ||\hat{z} - \check{z}_{\mathrm{B}}||^2_{\mathbf{Q}_{\hat{z}\hat{z}}} \,. \tag{23.58}$$

In this way one can work with a very small search space and still guarantee that the sought-for ILS solution is contained in it. If the rounding success rate is sufficiently high, one may also use $\check{z}_{\mathrm{R}}$ instead of $\check{z}_{\mathrm{B}}$.

For the actual search, the quadratic form $||\hat{z} - z||^2_{\mathbf{Q}_{\hat{z}\hat{z}}}$ is first written as a sum-of-squares. This is achieved by using the triangular decomposition $\mathbf{Q}_{\hat{z}\hat{z}} = \mathbf{L}\mathbf{D}\mathbf{L}^{\top}$,

$$||\hat{z} - z||^2_{\mathbf{Q}_{\hat{z}\hat{z}}} = \sum_{i=1}^{n} \frac{(\hat{z}_{i|I} - z_i)^2}{\sigma^2_{i|I}} \;\leq\; \chi^2 \,. \tag{23.59}$$

This sum-of-squares structure can now be used to set up the $n$ intervals that are used for the search. These sequential intervals are given as

$$\begin{aligned}
(\hat{z}_1 - z_1)^2 &\leq \sigma^2_1 \chi^2 \,, \\
(\hat{z}_{2|1} - z_2)^2 &\leq \sigma^2_{2|1} \left( \chi^2 - \frac{(\hat{z}_1 - z_1)^2}{\sigma^2_1} \right) , \\
&\vdots \\
(\hat{z}_{n|(n-1),\ldots,1} - z_n)^2 &\leq \sigma^2_{n|(n-1),\ldots,1} \\
&\quad \times \left( \chi^2 - \sum_{i=1}^{n-1} \frac{(\hat{z}_{i|I} - z_i)^2}{\sigma^2_{i|I}} \right) .
\end{aligned} \tag{23.60}$$

To search for all integer vectors that are contained in $\Psi_z$, one can now proceed as follows. First collect all integers $z_1$ that are contained in the first interval. Then for each of these integers, one computes the corresponding length and center point of the second interval, followed by collecting all integers $z_2$ that lie inside this second interval. By proceeding in this way to the last interval, one finally ends up with the set of integer vectors that lie inside $\Psi_z$. From this set one then picks the ILS solution as the integer vector that returns the smallest value for $||\hat{z} - z||^2_{\mathbf{Q}_{\hat{z}\hat{z}}}$.

Various refinements on this search, with further efficiency improvements such as search space shrinking, are possible, see for example [23.27–29, 36, 37].

### Ambiguity Decorrelation

To understand why the decorrelating $Z$-transformation is necessary to improve the efficiency of the search, consider the structure of the sequential intervals (23.60) and assume that they are formulated for the original, nontransformed DD ambiguities of a single-baseline GNSS model. The DD ambiguity sequential conditional standard deviations $\sigma_{\hat{a}_{i|I}}$, $i = 1, \ldots, n$, will then show a large discontinuity when going from the third to the fourth ambiguity.

As an example consider a single short baseline, with seven GPS satellites tracked, using dual-frequency phase-only data for two epochs separated by two seconds. Figure 23.8 shows its spectrum of sequential conditional standard deviations expressed in cycles, original as well as transformed. Note the logarithmic scale along the vertical axis. Since seven satellites were observed on both frequencies, we have twelve double-differenced ambiguities and therefore also twelve conditional standard deviations. The figure clearly shows the large drop in value when passing from the third to the fourth DD standard deviation, i. e., from $\sigma_{\hat{a}_{3|2,1}}$ to $\sigma_{\hat{a}_{4|3,2,1}}$. With the short time span, the DD ambiguities are namely poorly estimable, i. e., have large standard deviations, unless already three of them are assumed known, since with three DD ambiguities known, the baseline and remaining ambiguities can be estimated with a very high precision. Thus with $\sigma_{\hat{a}_1}$, $\sigma_{\hat{a}_{2|1}}$ and $\sigma_{\hat{a}_{3|2,1}}$ large, the first three bounds of (23.60), when formulated for the DD ambiguities, will be rather loose, while those of the remaining 9 inequalities will be very tight. As a consequence one will experience *search halting*. Of many of the collected integer candidates that satisfy the first three inequalities of (23.60), one will not

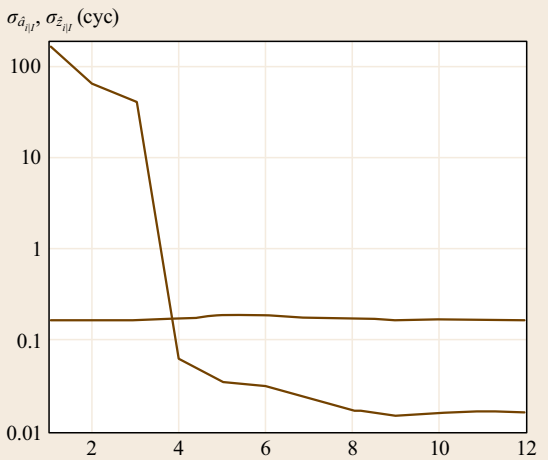

**Fig. 23.8** Original and transformed (flattened) spectra of sequential conditional ambiguity standard deviations, $\sigma_{\hat{a}_{i|I}}$ and $\sigma_{\hat{z}_{i|I}}$, $i = 1, \ldots, 12$, for a seven-satellite, dual-frequency, short GPS baseline (after [23.27])

be able to find corresponding integers that satisfy the remaining inequalities.

This inefficiency in the search is eliminated when using the $Z$-transformed ambiguities instead of the DD ambiguities. The decorrelating $Z$-transformation eliminates the discontinuity in the spectrum of sequential conditional standard deviations and, by virtue of the fact that the product of the sequential variances remains invariant (i. e., volume is preserved), also reduces the large values of the first three conditional variances.

In essence, the $n$-dimensional $Z$-transformation is constructed from two-dimensional decorrelating transformations as presented in Sect. 23.3.3. In two dimensions, the decorrelation achieves $\rho_{\hat{z}}^2 \leq 1/4$ (23.46) and therefore

$$\sigma_{\hat{z}_{2|1}}^2 = \sigma_{\hat{z}_2}^2(1-\rho_{\hat{z}}^2) \geq \frac{3}{4}\sigma_{\hat{z}_2}^2 \geq \frac{3}{4}\sigma_{\hat{z}_1}^2 \,, \quad \text{if } \sigma_{\hat{z}_1}^2 \leq \sigma_{\hat{z}_2}^2 .$$

Now let $\hat{a}_{i|I}$ and $\hat{a}_{i+1|I}$ play the role of $\hat{a}_1$ and $\hat{a}_2$ in the two-dimensional case. Then the decorrelation would achieve

$$\sigma_{\hat{z}_{i+1|I+1}}^2 = \sigma_{\hat{z}_{i+1|I}}^2(1-\rho_{\hat{z}}^2) \geq \frac{3}{4}\sigma_{\hat{z}_{i+1|I}}^2$$

and thus

$$\sigma_{\hat{z}_{i+1|I+1}}^2 \geq \frac{3}{4}\sigma_{\hat{z}_{i|I}}^2 \tag{23.61}$$

for $\sigma_{\hat{z}_{i|I}}^2 \leq \sigma_{\hat{z}_{i+1|I}}^2$. This shows that the originally large gap between $\sigma_{\hat{a}_{i|I}}$ and $\sigma_{\hat{a}_{i+1|I+1}}$, for $i = 3$, gets eliminated to a large extent, since now $\sigma_{\hat{z}_{i+1|I+1}}$ cannot be much smaller than $\sigma_{\hat{z}_{i|I}}$. Through a repeated application of such two-dimensional transformations, the whole spectrum of sequential conditional standard deviations can be flattened. In the case of Fig. 23.8 the transformed spectrum is flattened to a level slightly less than 0.2 cycles, while the original level for the DD standard deviations was more than 100 cycles.

The above described ILS procedure is mechanized in the GNSS LAMBDA (Least-squares AMBiguity Decorrelation Adjustment) method. For more information on the LAMBDA method, we refer to [23.14, 27–29, 37].

The following are examples for which one can see the LAMBDA method at work in a variety of different applications. Examples of such applications are baseline and network positioning [23.38–43], satellite formation flying [23.44–46], InSAR and VLBI [23.15, 16], GNSS attitude determination [23.47–50] and next-generation GNSS [23.51–53].

### 23.4.3 Least-Squares Success Rate

We have seen that the 2-D pull-in regions of rounding and bootstrapping are squares and parallelograms respectively. It follows that those of ILS are hexagons. The ILS pull-in region of $\boldsymbol{z} \in \mathbb{Z}^n$ consists by definition of all those points that are closer to $\boldsymbol{z}$ than to any other integer vector in $\mathbb{R}^n$,

$$\mathcal{L}_z = \{\boldsymbol{x} \in \mathbb{R}^n \mid \, ||\boldsymbol{x}-\boldsymbol{z}||_{\mathbf{Q}_{\hat{a}\hat{a}}}^2 \leq \, ||\boldsymbol{x}-\boldsymbol{u}||_{\mathbf{Q}_{\hat{a}\hat{a}}}^2, \forall \boldsymbol{u} \in \mathbb{Z}^n\}, \quad \boldsymbol{z} \in \mathbb{Z}^n .$$

By rewriting the inequality, we obtain a representation that more closely resembles the ones of rounding $\mathcal{R}_z$ and bootstrapping $\mathcal{B}_z$ (23.21), (23.26),

$$\mathcal{L}_z = \left\{\boldsymbol{x} \in \mathbb{R}^n \mid \, \mid w \mid \leq \frac{1}{2}||\boldsymbol{u}||_{\mathbf{Q}_{\hat{a}\hat{a}}} \,, \quad \forall \boldsymbol{u} \in \mathbb{Z}^n\right\}, \tag{23.62}$$

with $\boldsymbol{z} \in Z^n$ and

$$w = \frac{\boldsymbol{u}^\top \mathbf{Q}_{\hat{a}\hat{a}}^{-1}(\boldsymbol{x}-\boldsymbol{z})}{||\boldsymbol{u}||_{\mathbf{Q}_{\hat{a}\hat{a}}}} \tag{23.63}$$

the orthogonal projection of $(\boldsymbol{x}-\boldsymbol{z})$ onto the direction vector $\boldsymbol{u}$. This shows that the ILS pull-in regions are constructed from intersecting banded subsets centered at $\boldsymbol{z}$ and having width $||\boldsymbol{u}||_{\mathbf{Q}_{\hat{a}\hat{a}}}$. One can show that at most $2^n - 1$ of such subsets are needed for constructing the pull-in region. Note that $\mathcal{L}_z = \mathcal{R}_z$ when $\mathbf{Q}_{\hat{a}\hat{a}}$ is diagonal.

The ILS PMF is given as

$$P(\check{\boldsymbol{a}}_{\mathrm{LS}} = \boldsymbol{z}) = \int_{\mathcal{L}_z} f_{\hat{\boldsymbol{a}}}(\boldsymbol{x}|\boldsymbol{a})\mathrm{d}\boldsymbol{x} \,. \tag{23.64}$$

To obtain the ILS success rate, set $\boldsymbol{z} = \boldsymbol{a}$.

#### Simulation

Due to the complicated geometry of the ILS pull-in regions, methods of Monte Carlo simulation are needed to evaluate the multivariate integral (23.64). Note that $\boldsymbol{a}$ is not needed for the computation of the success rate. Thus one may simulate as if $\hat{\boldsymbol{a}}$ has the zero-mean distribution $N(\mathbf{0}, \mathbf{Q}_{\hat{a}\hat{a}})$. Also recall that the ILS success rate is $Z$-invariant, $P(\check{z}_{\mathrm{ILS}} = \mathbf{Z}\boldsymbol{a}) = P(\check{\boldsymbol{a}}_{\mathrm{ILS}} = \boldsymbol{a})$. This property can be used to one's advantage when simulating. Since the simulation requires the repeated computation of an ILS solution, one is much better off doing this for a decorrelated $\hat{\boldsymbol{z}} = \mathbf{Z}\hat{\boldsymbol{a}}$, than for the original $\hat{\boldsymbol{a}}$.

The first step of the simulation is to use a random generator to generate $n$-independent samples from

the univariate standard normal distribution $N(0,1)$, and then collect these in an $n$-vector $\boldsymbol{s}$. This vector is transformed as $\mathbf{G}\boldsymbol{s}$, with $\mathbf{G}$ equal to the Cholesky factor of $\mathbf{Q}_{\hat{z}\hat{z}} = \mathbf{G}\mathbf{G}^\top$. The result is a sample $\mathbf{G}\boldsymbol{s}$ from $N(\mathbf{0}, \mathbf{Q}_{\hat{z}\hat{z}})$, and this sample is used as input for the ILS estimator. If the output of this estimator equals the null vector, then it is correct, otherwise it is incorrect. This simulation process can be repeated $N$ number of times, and one can count how many times the null vector is obtained as a solution, say $N_\mathrm{s}$ times, and how often the outcome equals a nonzero integer vector, say $N_\mathrm{f}$ times. The approximations of the success rate and fail rate follow then as

$$P_\mathrm{s} \approx \frac{N_\mathrm{s}}{N} \quad \text{and} \quad P_\mathrm{f} \approx \frac{N_\mathrm{f}}{N} \,. \tag{23.65}$$

Further details on the success-rate simulation can be found in [23.18, 54, 55].

### Lower and Upper Bounds

Instead of using simulation, one may also consider using bounds on the success rate. The following theorem gives sharp lower and upper bounds on the ILS success rate.

*Theorem 23.5 ILS success-rate bounds*

Let $\hat{\boldsymbol{a}} \sim N(\boldsymbol{a}, \mathbf{Q}_{\hat{a}\hat{a}})$, $\boldsymbol{a} \in \mathbb{Z}^n$, $\hat{\boldsymbol{z}} = \mathbf{Z}\hat{\boldsymbol{a}}$ and $c_n = (\frac{n}{2}\Gamma(\frac{n}{2}))^{2/n}/\pi$, with $\Gamma(\boldsymbol{x})$ the gamma function. Then

$$P(\check{\boldsymbol{z}}_\mathrm{B} = \boldsymbol{z}) \le P(\check{\boldsymbol{a}}_\mathrm{ILS} = \boldsymbol{a}) \le P\left(\chi^2_{n,0} \le \frac{c_n}{\mathrm{ADOP}^2}\right) \tag{23.66}$$

for any admissible $Z$-transformation and where $\chi^2_{n,0}$ denotes a random variable having a central chi-square distribution with $n$ degrees of freedom.

The upper bound was first given in [23.56], albeit without proof. A proof is given in [23.24]. The lower bound was first given in [23.22, 35]. This lower bound (after decorrelation) is currently the sharpest lower bound available for the ILS success rate. A study on the performances of the various bounds can be found in [23.18, 54, 57, 58].

## 23.5 Partial Ambiguity Resolution

When the precision of the float ambiguity solution is poor, reliable integer estimation is not possible, i. e., the success rate will be too low. Instead of relying on the float solution and collecting more data, it might still be possible to reliably fix a subset of ambiguities, referred to as partial ambiguity resolution (PAR) [23.59].

The key issue is then the selection of the subset such that on the one hand the corresponding success rate will exceed a user-defined threshold, while at the same time it will result in a significant precision improvement of the position estimates. The first condition is important in order to prevent large positioning errors due to wrong fixing occurring. The second condition is optional, although it is obvious that PAR will only be beneficial if indeed the baseline precision is improved. Many options would be possible to select a subset of ambiguities to be fixed in the case of fixing the full set (FAR, fullset ambiguity resolution) is not possible or needed. Several approaches have been proposed in the literature in which it is first tried to fix only the (extra) widelane ambiguities in the case where two or more frequencies are being used [23.60–63]. Other ideas are to include only ambiguities with variances below a certain level, or ambiguities from satellites at a minimum elevation, with a minimum required signal-to-noise ratio, or which are visible for a certain time [23.59, 64].

Yet another strategy is to fix only (linear combinations of) ambiguities for which the best and second-best solutions are consistent [23.65]. A disadvantage of most of the PAR strategies is that the choice of the subset is not based on the success rate and/or precision improvement of the baseline solution. Moreover, some of the strategies involve an iterative procedure in which many different subsets are evaluated. This may require long search times.

The approach already proposed in [23.59] is easy to implement and does allow for choosing a minimum required success rate $P_\mathrm{min}$. The idea is to fix only the largest possible subset of decorrelated ambiguities, such that this success rate requirement can be met

$$\prod_{i=1}^{k}\left[2\Phi\left(\frac{1}{2\sigma_{\hat{z}_{i|I}}}\right) - 1\right] \ge P_\mathrm{min} \,. \tag{23.67}$$

Hence, only the first $k$ entries of $\boldsymbol{z}$ will be fixed, and the corresponding subset will be denoted as $\boldsymbol{z}_\mathrm{S}$. Adding more ambiguities implies multiplication with another probability, which by definition is smaller than or equal to 1. Hence, $k$ will be chosen such that the inequality in (23.67) holds, while a larger $k$ (i. e., larger subset)

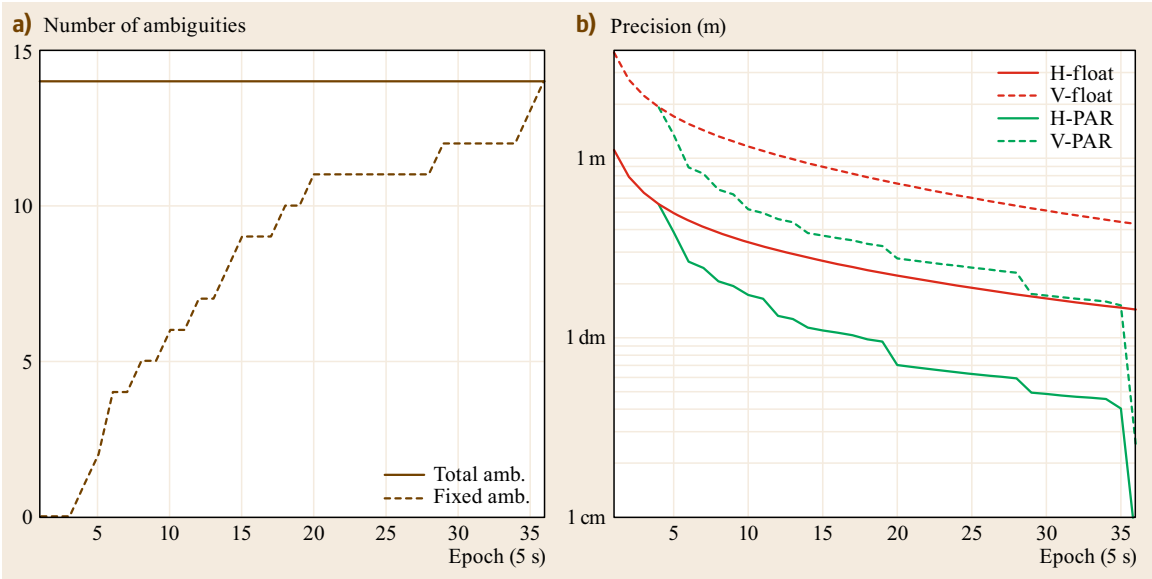

**Fig. 23.9a,b** Example of benefit of PAR for a 50 km baseline with a minimum required success rate of 99.9%. **(a)** Number of fixed ambiguities. **(b)** Baseline precision of float and partially fixed solutions

would result in a too low success rate. The corresponding precision improvement can be evaluated as well with

$$\mathbf{Q}_{\check{b}\check{b}} = \mathbf{Q}_{\hat{b}\hat{b}} - \mathbf{Q}_{\hat{b}\hat{z}_S}\mathbf{Q}_{\hat{z}_S\hat{z}_S}\mathbf{Q}_{\hat{z}_S\hat{b}} \,. \tag{23.68}$$

The uncertainty in the fixed subset solution can be ignored due to the high success rate requirement. An example of the benefit of PAR is shown in Fig. 23.9. It is an example of a dual-frequency 50 km baseline with eight GPS satellites tracked. The total number of ambiguities is thus equal to 14, and remains constant for the whole timespan. Figure 23.9a shows the number of fixed ambiguities as function of the number of epochs based on recursive estimation. In this case full ambiguity resolution (FAR) is only possible after 36 epochs, but with PAR the number of fixed ambiguities gradually increases. For both PAR and FAR the minimum required success rate is set to 99.9%. The effect on the baseline precision is shown in the bottom panel. Both the precision of the vertical and horizontal baseline components start to improve with respect to the corresponding float precision as soon as a subset of the ambiguities is fixed.

## 23.6 When to Accept the Integer Solution?

So far no explicit description of the decision rule for accepting or rejecting the integer solution was given. In this section a flexible class of such rules is presented.

### 23.6.1 Model- and Data-Driven Rules

When do we accept the integer ambiguity solution $\check{\boldsymbol{a}}$? It was shown in Sect. 23.1.3 that working with the integer solution $\check{\boldsymbol{a}}$ only makes sense if the ambiguity success rate $P(\check{\boldsymbol{a}} = \boldsymbol{a})$ is sufficiently large or, equivalently, the fail rate $P(\check{\boldsymbol{a}} \neq \boldsymbol{a})$ is sufficiently small. Otherwise there would exist unacceptable chances of ending up with large errors in the fixed solution $\check{\boldsymbol{b}}$ (Fig. 23.3).

The above suggests the following decision rule for computing an outcome of the ambiguity resolution process,

$$\text{outcome} = \begin{cases} \check{\boldsymbol{a}} \in \mathbb{Z}^n & \text{if } P(\hat{\boldsymbol{a}} \notin \mathcal{P}_a) \leq P_0 \,, \\ \hat{\boldsymbol{a}} \in \mathbb{R}^n & \text{otherwise} \,. \end{cases} \tag{23.69}$$

Thus with this rule the integer solution $\check{\boldsymbol{a}}$ is only accepted if the fail rate is smaller than a user-defined threshold $P_0$. Otherwise it is rejected in favor of the float solution $\hat{\boldsymbol{a}}$. This is a *model-driven* rule, as the outcome is solely dependent on the strength of the underlying model. The actual data, i. e., the actual float solution $\hat{\boldsymbol{a}}$

itself, does not play a role in the decision. Only its PDF, through the probability $P(\hat{\boldsymbol{a}} \notin \mathcal{P}_a)$, affects the decision.

Instead of the model-driven rule (23.69), also a *data-driven* decision rule can be used. Such rules are of the form

$$\text{outcome} = \begin{cases} \check{\boldsymbol{a}} \in \mathbb{Z}^n \text{ if } \mathcal{T}(\hat{\boldsymbol{a}}) \le \tau_0 \,, \\ \hat{\boldsymbol{a}} \in \mathbb{R}^n \quad \text{otherwise} \,, \end{cases} \tag{23.70}$$

with testing function $\mathcal{T} : \mathbb{R}^n \mapsto \mathbb{R}$ and user-selected threshold value $\tau_0 \ge 0$. Thus in this case the integer solution $\check{\boldsymbol{a}}$ is accepted when $\mathcal{T}(\hat{\boldsymbol{a}})$ is sufficiently small; otherwise, it is rejected in favor of the float solution $\hat{\boldsymbol{a}}$. This rule is data driven, as the actual value of the float solution is used in the evaluation of $\mathcal{T}(\hat{\boldsymbol{a}})$.

In practice one usually uses a data-driven rule. Different choices for the testing function $\mathcal{T}$ are then still possible. Examples include those of the ratio test, the difference test and the projector test. Each of these tests can be shown to be a member of the class of integer aperture (IA) estimators as introduced in [23.66–68]. A review and evaluation of these tests can be found in [23.54, 69–71].

The advantage of the data-driven rules over the model-driven rule (23.69) is the greater flexibility that they provide to the user, in particular with respect to the fail rate. With the data-driven rule, users can be given complete control over the fail rate, irrespective the strength of the underlying GNSS model. This is impossible with the model-driven rule.

### 23.6.2 Four Ambiguity Resolution Steps

By including the test (23.70) into the ambiguity resolution process, its four steps become:

1. *Float solution*: Compute the float solution $\hat{\boldsymbol{a}} \in \mathbb{R}^n$ and $\hat{\boldsymbol{b}} \in \mathbb{R}^p$.
2. *Integer solution*: Choose an integer map $\mathcal{I} : \mathbb{R}^n \mapsto \mathbb{Z}^n$ and compute the integer solution $\check{\boldsymbol{a}} = \mathcal{I}(\hat{\boldsymbol{a}})$. Since the user has no real control over the success rate $P_s = P(\check{\boldsymbol{a}} = \boldsymbol{a})$, confidence cannot be assured if one relies solely on the outcome $\check{\boldsymbol{a}}$ of this second step. This is why the next step is needed. The role of the ambiguity acceptance test is namely to provide confidence in the integer outcomes of ambiguity resolution.
3. *Accept/reject integer solution*: Choose a testing function $\mathcal{T} : \mathbb{R}^n \mapsto \mathbb{R}$, with threshold $\tau_0$, and execute the test. Accept $\check{\boldsymbol{a}}$ if $\mathcal{T}(\hat{\boldsymbol{a}}) \le \tau_0$, otherwise reject in favor of the float solution $\hat{\boldsymbol{a}}$.
4. *Fixed solution*: Compute the fixed solution $\check{\boldsymbol{b}}$ if the integer solution $\check{\boldsymbol{a}}$ is accepted, otherwise stick with the float solution $\hat{\boldsymbol{b}}$.

Due to the inclusion of the above ambiguity acceptance test, the quality of the outcome of the above four-step procedure will be different from that of the three-step procedure discussed in Sect. 23.1.2. We now determine the quality of the above four-step procedure.

### 23.6.3 Quality of Accepted Integer Solution

The integer $\check{\boldsymbol{a}} = \boldsymbol{z}$ is the outcome of the above step 3 (23.70) if both the conditions

$$\hat{\boldsymbol{a}} \in \mathcal{P}_z \text{ and } \mathcal{T}(\hat{\boldsymbol{a}}) \le \tau_0 \tag{23.71}$$

are satisfied. Thus

$$\check{\boldsymbol{a}} = \boldsymbol{z} \text{ iff } \hat{\boldsymbol{a}} \in \Omega_z = \mathcal{P}_z \cap \Omega \,, \tag{23.72}$$

with acceptance region

$$\Omega = \{\boldsymbol{x} \in \mathbb{R}^n | \, \mathcal{T}(\boldsymbol{x}) \le \tau_0\} \,. \tag{23.73}$$

The intersecting region $\Omega_z = \mathcal{P}_z \cap \Omega$ is called the *aperture pull-in region* of $\boldsymbol{z}$. The aperture pull-in regions are, just like the pull-in regions $\mathcal{P}_z$, translational invariant: $\Omega_z = \Omega_{\boldsymbol{0}} + \boldsymbol{z}$. The (green and red) ellipse-like regions of Fig. 23.10 are examples of such aperture pull-in regions. This figure also visualizes and summarizes which of the test outcomes are correct and which are not.

The outcome of the ambiguity acceptance test is correct if it is either the correct integer or a float solution that otherwise would be pulled to a wrong integer. The first happens when $\hat{\boldsymbol{a}} \in \Omega_a$, the second when $\hat{\boldsymbol{a}} \in \Omega^c \setminus (\mathcal{P}_a \setminus \Omega_a)$. The outcome is wrong if it is either the wrong integer or a float solution that otherwise would be pulled to the correct integer. The first happens when $\hat{\boldsymbol{a}} \in \Omega \setminus \Omega_a$, the second when $\hat{\boldsymbol{a}} \in \mathcal{P}_a \setminus \Omega_a$.

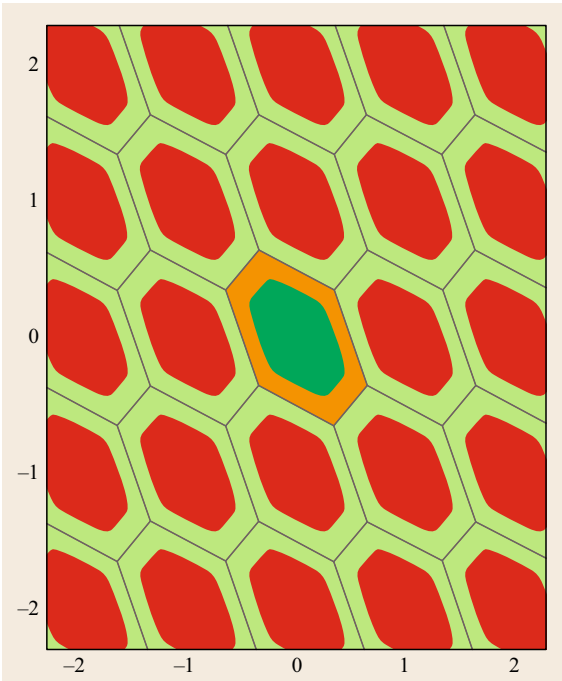
Once accepted by the test, the distribution of the integer $\check{\boldsymbol{a}}$ becomes a *conditional* PMF. Hence, instead of (23.12), we now have

$$P(\check{\boldsymbol{a}} = \boldsymbol{z} | \hat{\boldsymbol{a}} \in \Omega) = \frac{P(\hat{\boldsymbol{a}} \in \Omega_z)}{P(\hat{\boldsymbol{a}} \in \Omega)} \,. \tag{23.74}$$

Similarly, since the fixed solution is now only computed if $\check{\boldsymbol{a}}$ is accepted, its multimodal PDF is, instead of (23.14), given as

$$f_{\check{\boldsymbol{b}}}(\boldsymbol{x}) = \sum_{\boldsymbol{z} \in \mathbb{Z}^n} f_{\hat{\boldsymbol{b}}(\boldsymbol{z})}(\boldsymbol{x}) P(\check{\boldsymbol{a}} = \boldsymbol{z} | \hat{\boldsymbol{a}} \in \Omega) \,. \tag{23.75}$$

As a wrong integer outcome, i. e., $\check{\boldsymbol{a}} \neq \boldsymbol{a}$, can result in large position errors (Fig. 23.3), it is of importance that sufficient confidence can be provided in the correctness of the integers as determined by the ambiguity



| | Correct outcome | Wrong outcome |
|---|---|---|
| Fixed $\hat{a} \in \Omega$ | Success $\hat{a} \in \Omega_a$ | Failure $\hat{a} \in \Omega \setminus \Omega_a$ |
| Float $\hat{a} \in \Omega$ | Detection $\hat{a} \in \Omega^c \setminus (\mathcal{P}_a \setminus \Omega_a)$ | False alarm $\hat{a} \in \mathcal{P}_a \setminus \Omega_a$ |

**Fig. 23.10** Aperture pull-in regions $\Omega_z \subset \mathcal{P}_z$ and the four types of outcome: success (*green*), detection (*light green*), false alarm (*orange*) and failure (*red*) (after [23.71])

acceptance test. This confidence is described by the *probability of successful fixing*

$$P_{\mathrm{SF}} = P(\check{a} = a \,|\, \hat{a} \in \Omega) = \frac{P(\hat{a} \in \Omega_a)}{P(\hat{a} \in \Omega)} \,. \tag{23.76}$$

This is the conditional version of the unconditional success rate (23.13). It can be further expressed in the probability of *success*, $P_{\mathrm{S}} = P(\hat{a} \in \Omega_a)$, and the probability of *failure*, $P_{\mathrm{F}} = P(\hat{a} \in \Omega \setminus \Omega_a)$, as

$$P_{\mathrm{SF}} = \frac{P_{\mathrm{S}}}{P_{\mathrm{S}} + P_{\mathrm{F}}} \,. \tag{23.77}$$

From this important relation it follows that the user can now be given control over the probability of successful fixing. If, through an appropriate choice of the tolerance value $\tau_0$ in (23.70), the aperture of $\Omega_{\mathbf{0}}$ is chosen to be sufficiently small, then $P_{\mathrm{F}} \approx 0$ and therefore $P_{\mathrm{SF}} \approx 1$, which, with (23.76) and (23.75), results in the peaked distribution $f_{\check{b}}(x) \approx f_{\hat{b}(a)}(x)$.

Thus with the inclusion of the ambiguity acceptance test, the user is given control over the quality of the integer outcome and thereby over the quality of the fixed solution $\check{b}$. This control is absent when only the three ambiguity resolution steps of Sect. 23.1.2 are used.

### 23.6.4 Fixed Failure-Rate Ratio Test

In practice, different testing functions $\mathcal{T}$ are in use. Examples are those of the ratio test, the difference test or the projector test [23.12, 38, 72–76]. Here we describe the popular ratio test.

With the ratio test the ILS solution $\check{a}$ is accepted iff

$$\mathcal{T}_{\mathrm{R}}(\hat{a}) = \frac{||\hat{a} - \check{a}||^2_{Q_{\hat{a}\hat{a}}}}{||\hat{a} - \check{a}'||^2_{Q_{\hat{a}\hat{a}}}} \leq \tau_0 \,, \tag{23.78}$$

with $0 < \tau_0 \leq 1$ and

$$\begin{aligned} \check{a} &= \arg \min_{z \in \mathbb{Z}^n} ||\hat{a} - z||^2_{Q_{\hat{a}\hat{a}}} \,, \\ \check{a}' &= \arg \min_{z \in \mathbb{Z}^n, z \neq \check{a}} ||\hat{a} - z||^2_{Q_{\hat{a}\hat{a}}} \,. \end{aligned} \tag{23.79}$$

The ratio test tests the closeness of the float solution to its nearest integer vector. If it is close enough, the test leads to acceptance of $\check{a}$. If it is not close enough, then the test leads to rejection in favor of the float solution $\hat{a}$.

The origin-centered aperture pull-in region of the ratio test is given as [23.70]

$$\begin{aligned} \Omega_{\mathrm{R},\mathbf{0}} &= \left\{ x \in \mathbb{R}^n \,|\, ||x||^2_{Q_{\hat{a}\hat{a}}} \leq \tau_0 ||x - z||^2_{Q_{\hat{a}\hat{a}}} \right\} \\ &= \left\{ x \in \mathbb{R}^n \,|\, ||x + \frac{\tau_0}{1 - \tau_0} z||^2_{Q_{\hat{a}\hat{a}}} \right. \\ &\qquad \left. \leq \frac{\tau_0}{(1 - \tau_0)^2} ||z||^2_{Q_{\hat{a}\hat{a}}} \right\} \end{aligned} \tag{23.80}$$

for all $z \in \mathbb{Z}^n \setminus \{\mathbf{0}\}$. This shows that the aperture pull-in region is equal to the intersection of all ellipsoids with centers $-[\tau_0/(1-\tau_0)]z$ and radius $[\sqrt{\tau_0}/(1-\tau_0)]||z||_{Q_{\hat{a}\hat{a}}}$. Figure 23.11 shows two two-dimensional examples of the geometry of such aperture pull-in regions.

It is clear that the size or aperture of the pull-in region $\Omega_{\mathrm{R},\mathbf{0}}$ determines the largest ratio $\mathcal{T}_{\mathrm{R}}$ one is willing to accept. The threshold value $\tau_0$ can be used to tune this aperture. Smaller values corresponds to smaller apertures and thus smaller failure rates $P_{\mathrm{F}}$. In the case where the threshold is taken equal to its maximal value $\tau_0 = 1$, the aperture pull-in regions become equal to the ILS pull-in regions, in which case the integer solution is always accepted. In such a case, the ratio test would be obsolete and can be discarded.

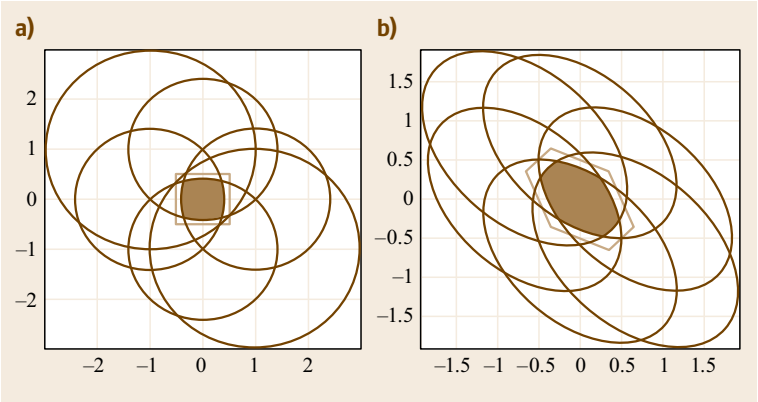


**Fig. 23.11a,b** Geometry of two-dimensional aperture pull-in region (*brown*) of the ratio test as constructed from intersecting circles **(a)** and ellipses **(b)** (after [23.70])

#### On the Choice of the Critical Value

The question is now how to choose the critical value $\tau_0$. Different values have been proposed in the literature, all based on empirical results. Typical values reported for $\tau_0$ are $\frac{1}{3}$, $\frac{1}{2}$, and $\frac{2}{3}$ [23.3, 72, 75, 77]. The different values are already an indication that there is not one specific value that will always give the best performance. Care should therefore be exercised to consider these values generally applicable.

In [23.71, 78] it has been shown that the traditional usage of the ratio test, that is, with a fixed critical $\tau_0$-value, often results in either unacceptably high failure rates or is overly conservative. In the case of the next generation multifrequency, multi-GNSS models, for instance, the increase in strength of the models, due to, for example, more frequencies and more satellites, implies that the $\tau_0$-values can be chosen larger than the currently used fixed values. Thus for strong models, the fixed $\tau_0$-values currently in use are often too conservative, so that the false alarm rates are unnecessarily high, while the failure rates are very close to zero. For weak models, on the other hand, the currently used fixed $\tau_0$-values are often too large, so that the fixed solution is often wrongly accepted, thus resulting in high failure rates. These problems can be overcome if the ratio test is made adaptive to the strength of the underlying GNSS model.

It was therefore proposed in [23.67, 70, 71] to replace the fixed critical-value approach by the more flexible *fixed failure-rate* approach. With this approach, the user is given control over the failure rate for their particular application. Hence, depending on the requirements of the application (e.g., high, medium or low integrity), the user chooses a fixed value for the failure rate, say $P_F = 0.1\%$, and then computes the corresponding critical value $\tau_0$. The value of $\tau_0$ will then adapt itself, in dependence on the underlying model strength, to ensure that the specified failure rate is indeed achieved (Fig. 23.12). In this way each project or experiment can be executed with an a priori specified and guaranteed failure rate. The numerical procedure for computing $\tau_0$ from $P_F$ is described in [23.71] and is implemented in the LAMBDA-package (version 3).

### 23.6.5 Optimal Integer Ambiguity Test

As mentioned, the ratio test is not the only test with which the integer ambiguities can be validated. Hence, the fixed failure-rate approach can be applied to these other tests as well. Such work would then also be able to compare the performance of these tests and answer the question of which of the traditional tests, such as ratio test, difference test or projector test, performs best.

Instead of restricting attention to current tests, one can also take a more fundamental approach and try to determine an optimal test from first principles. This is the approach taken in [23.67, 68]. It resulted in the constrained maximum success-rate (CMS) test and the minimum mean penalty (MMP) test.

#### Constrained Maximum Success-Rate (CMS) Test

So far we considered fixed failure-rate ambiguity validation with an a priori given testing function $\mathcal{T}$ or an a priori given aperture pull-in region $\Omega_{\mathbf{0}}$. Instead of working with a predefined $\mathcal{T}$ or $\Omega_{\mathbf{0}}$, we now relax the situation and ask for which $\mathcal{T}$ or $\Omega_{\mathbf{0}}$ the success rate $P_S$ is maximized, given a user-defined failure rate $P_F$. The answer is given by the following theorem.

*Theorem 23.6 Optimal integer ambiguity test [23.68]*

Let $f_{\check{\boldsymbol{\epsilon}}}(\boldsymbol{x})$ and $f_{\hat{\boldsymbol{\epsilon}}}(\boldsymbol{x})$ be the PDFs of the ambiguity residual vectors $\check{\boldsymbol{\epsilon}} = \hat{\boldsymbol{a}} - \check{\boldsymbol{a}}$ and $\hat{\boldsymbol{\epsilon}} = \hat{\boldsymbol{a}} - \boldsymbol{a}$ respectively. Then the solution to

$$\max_{\Omega_{\mathbf{0}}} P_S \quad \text{subject to given } P_F \tag{23.81}$$

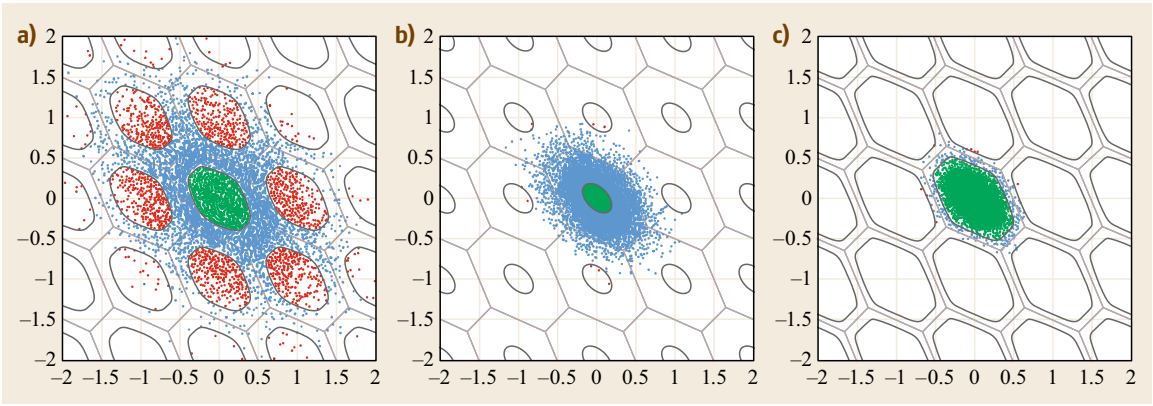

**Fig. 23.12a–c** A two-dimensional illustration of three different cases of integer ambiguity ratio-test validation. The *green* and *red dots* result in correct and incorrect integer outcomes respectively, while the *blue dots* result in the float solution as outcome. The first case **(a)** has poor performance, while the other two **(b,c)** have good performance. In the first case, due to an inappropriately chosen critical value $\tau_0$, the aperture pull-in region is too large thus producing too many wrong integer solutions. In the other two cases, the fixed failure-rate approach ($P_F = 0.1\%$) was used, thus resulting in critical values that adapt to the strength of the underlying model. As the second case **(b)** corresponds to a weaker model than the third case **(c)**, its aperture pull-in region is smaller thus producing more float solutions than in the third case. Both however have the same guaranteed small failure rate (after [23.79])

is given by the aperture pull-in region

$$\hat{\Omega}_{\mathbf{0}} = \left\{ \boldsymbol{x} \in \mathcal{P}_{\mathbf{0}} \mid \frac{f_{\hat{\epsilon}}(\boldsymbol{x})}{f_{\check{\epsilon}}(\boldsymbol{x})} \geq \lambda \right\} , \tag{23.82}$$

with $\mathcal{P}_{\mathbf{0}}$ the ILS pull-in region of the origin and $\lambda$ ($0 < \lambda < 1$) the aperture parameter chosen so as to satisfy the a priori fixed failure rate $P_F$.

The PDFs of the ambiguity residuals are given as [23.80, 81],

$$f_{\check{\epsilon}}(\boldsymbol{x}) = \sum_{z \in \mathbb{Z}^n} f_{\hat{\epsilon}}(\boldsymbol{x}+z) p_{\mathbf{0}}(\boldsymbol{x}) ,$$
$$f_{\hat{\epsilon}}(\boldsymbol{x}) \propto \exp\left( -\frac{1}{2} ||\boldsymbol{x}||^2_{\mathbf{Q}_{\hat{a}\hat{a}}} \right) , \tag{23.83}$$

with $p_{\mathbf{0}}(\boldsymbol{x})$ the indicator function of $\mathcal{P}_{\mathbf{0}}$, i. e., $p_{\mathbf{0}}(\boldsymbol{x}) = 1$ if $\boldsymbol{x} \in \mathcal{P}_{\mathbf{0}}$ and $p_{\mathbf{0}}(\boldsymbol{x}) = 0$ otherwise.

Note, since the PDFs $f_{\hat{\epsilon}}(\boldsymbol{x})$ and $f_{\check{\epsilon}}(\boldsymbol{x})$ differ less, when $P(\check{\boldsymbol{a}} = \boldsymbol{a}) \uparrow 1$, then the difference between the optimal aperture pull-in region $\hat{\Omega}_{\mathbf{0}}$ and the ILS pull-in region $\mathcal{P}_{\mathbf{0}}$ will also differ less when the ILS success rate increases. In the limit, all integer solutions will be accepted, since then $\hat{\Omega}_{\mathbf{0}} = \mathcal{P}_{\mathbf{0}}$.

### Minimum Mean Penalty (MMP) Test

This is also an optimal integer ambiguity acceptance test. The MMP test is based on the idea of penalizing certain outcomes of the test. The penalties, for example costs, are chosen by the user and can be made dependent on the application at hand. Different penalties are assigned to different outcomes: a success penalty $p_S$ if $\hat{\boldsymbol{a}} \in \Omega_{\boldsymbol{a}}$ (green area in Fig. 23.10), a failure penalty $p_F$ if $\hat{\boldsymbol{a}} \in \Omega \setminus \Omega_{\boldsymbol{a}}$ (red area in Fig. 23.10), and a detection penalty $p_D$ if $\hat{\boldsymbol{a}} \in \Omega^c \setminus (\mathcal{P}_{\boldsymbol{a}} \setminus \Omega_{\boldsymbol{a}})$ (light green area in Fig. 23.10).

With this assignment, a discrete random variable, the penalty $p$, is constructed. It has three possible outcomes, $p = \{p_S, p_F, p_D\}$. We may now consider the average of the discrete random variable $p$, the average penalty $\mathrm{E}(p)$, which is a weighted sum of the individual penalties, with the weights being equal to the three probabilities $P_S$, $P_F$, and $P_D$

$$\mathrm{E}(p) = p_S P_S + p_F P_F + p_D P_D . \tag{23.84}$$

The MMP test is defined as the one having the smallest mean penalty. It follows from solving the minimization problem $\min_{\Omega_{\mathbf{0}}} \mathrm{E}(p)$ [23.67]. The solution is again given by (23.82), but now with the aperture parameter given as

$$\lambda = \frac{p_F - p_D}{p_F - p_S} . \tag{23.85}$$

Note that increasing the failure penalty $p_F$ increases $\lambda$ and contracts the aperture pull-in region $\hat{\Omega}_{\mathbf{0}}$. This is as it should be, since a contracting $\hat{\Omega}_{\mathbf{0}}$ reduces the occurrences of wrong integer solutions.

### The Computational Steps

It is gratifying to see that the above two optimization principles provide the same structure for the optimal

ambiguity test. It implies, somewhat in analogy with the pairing of least-squares estimation and best linear unbiased estimation, that the same procedure can be given two different interpretations of optimality.

The steps for computing the CMS and MMP test are:

1. Compute the ILS ambiguity solution

$$\check{\boldsymbol{a}} = \arg\min_{z\in\mathbb{Z}^n} ||\hat{\boldsymbol{a}} - z||^2_{\mathbf{Q}_{\hat{a}\hat{a}}} \,. \tag{23.86}$$

2. Construct the ambiguity residual $\check{\boldsymbol{\epsilon}} = \hat{\boldsymbol{a}} - \check{\boldsymbol{a}}$ and compute the PDF ratio

$$R(\check{\boldsymbol{\epsilon}}) = \frac{f_{\hat{\epsilon}}(\check{\boldsymbol{\epsilon}})}{f_{\hat{\epsilon}}(\check{\boldsymbol{\epsilon}})} \,. \tag{23.87}$$

This outcome provides a measure of confidence in the solution. The larger the ratio, the more confidence one has. Note that the ratio can be seen as an approximation to the success fix-rate $P_{\mathrm{SF}}$.

3. Determine the aperture parameter $\lambda$, either from the user-defined fail rate in the case of CMS, or from (23.85) in the case of MMP. Output the integer solution $\check{\boldsymbol{a}}$ if $R(\check{\boldsymbol{\epsilon}}) \geq \lambda$, otherwise the outcome is the float solution $\hat{\boldsymbol{a}}$. Both $\check{\boldsymbol{a}}$ and $R(\check{\boldsymbol{\epsilon}})$ can be computed efficiently with the LAMBDA method.

# 24. Batch and Recursive Model Validation

Peter J.G. Teunissen

Modeling errors, when passed unnoticed, may seriously deteriorate the final results of any estimation process. It is therefore of importance to have quality control procedures in place so as to be able to judge and validate the outcome of estimation. This chapter presents such methods for global navigation satellite system (GNSS) model validation and qualification. Since batch and recursive estimation are common methods of GNSS data processing, the validation and integrity monitoring of both will be discussed in this chapter.

## 24.1 Modeling and Validation

When linking a mathematical model to data, care has to be exercised in formulating its functional and stochastic model. The functional model describes the relations that are believed to exist between the observables and the unknown parameters, while the stochastic model is used to capture the expected uncertainty or variability of the data.

We write

$$\boldsymbol{y} \sim \mathcal{N}\left(E(\boldsymbol{y}), D(\boldsymbol{y})\right) , \tag{24.1}$$

to denote that the data vector $\boldsymbol{y}$ is assumed to be distributed as ($\sim$) a normal distribution ($\mathcal{N}$) with expectation $E(\boldsymbol{y})$ and dispersion $D(\boldsymbol{y})$.

In the case of GNSSs, the functional model, $E(\boldsymbol{y}) = \mathbf{A}(\boldsymbol{x})$, links the pseudorange (code) and/or carrier-phase observables collected in vector $\boldsymbol{y} \in \mathbb{R}^m$ to the unknown entries of the parameter vector $\boldsymbol{x} \in \mathbb{R}^n$, for example coordinates and clocks (receiver, satellite), atmospheric delays (troposphere, ionosphere), hardware/environmental delays (instrumental biases, multipath), and carrier-phase ambiguities (Chap. 21). Whether or not all these parameters need to be included depends very much on the circumstances of measurement and the particular application at hand. For instance, differential ionospheric delays could be negligible in the case of sufficiently short baselines, or multipath may be avoided when sufficient precautions in the measurement setup are taken.

In the stochastic model, $D(\boldsymbol{y}) = \mathbf{Q}_{yy}$, one tries to capture the intrinsic uncertainties of the measurements. For this one needs a proper understanding of the instrumentation and the measurement procedures used. Formulating the stochastic model does not only involve

the precision of the individual measurements, but may also involve cross correlation and/or time correlation. Depending on how the measurement process is implemented in the GNSS receivers, the observables may or may not be cross correlated (Chaps. 13 and 14). Also the potential presence of time correlation should be considered, in particular when use is made of high sampling rates.

Depending on the application at hand, one can choose from a whole suite of GNSS functional models $\mathbf{A} : \mathbb{R}^n \mapsto \mathbb{R}^m$ (Chap. 21). A GNSS model for relative positioning may be based on the simultaneous use of two receivers (single-baseline) or more than two receivers (multibaseline or network). It may have the relative receiver-satellite geometry included (geometry-based) or excluded (geometry-free). When it is excluded, it is not the baseline components that are involved as unknowns in the model, but instead the receiver-satellite ranges themselves. GNSS models may also be discriminated as to whether the receiver(s) are in motion (nonstationary) or not (stationary). When in motion, one solves for one or more trajectories, since with the receiver-satellite geometry included, one will have a new position for each new epoch.

It will be clear that various modeling errors can be made when formulating a mathematical model like

$$\boldsymbol{y} \sim \mathcal{N}(\mathbf{A}(\boldsymbol{x}), \mathbf{Q}_{yy}) \,. \tag{24.2}$$

The functional model could be misspecified, $E(\boldsymbol{y}) \neq \mathbf{A}(\boldsymbol{x})$. The variance matrix could be misspecified $D(\boldsymbol{y}) \neq \mathbf{Q}_{yy}$, or even the assumed normal distribution of $\boldsymbol{y}$ could be a poor approximation.

In this chapter we restrict attention to misspecifications in the mean only, as these are by far the most common modeling errors to occur in practice. Examples are cycle slips in phase data, outliers in code data, antenna-height errors, erroneous negligence of atmospheric delays, or any other underparametrization of the GNSS model, see for example [24.1–9]. As such modeling errors, when passed unnoticed, may seriously deteriorate the final results of the GNSS estimation process, it is of importance that proper quality control procedures of data and model are in place so as to be able to judge and validate the outcome of estimation.

This chapter presents such tools for GNSS model validation and qualification. The material presented is generally valid and therefore not dependent on any specific GNSS application. As it applies to the whole suite of different GNSS models, the quality control can be exercised at various different processing stages, such as at the channel/receiver/baseline/network levels. At a single-channel level for instance, it is already possible to validate the time series of undifferenced data. By combining some of the parameters (e.g., range, clock errors, tropospheric delay, orbital uncertainty) and by introducing a dynamic model on the time behavior of the ionospheric delays, the necessary redundancy enters that is needed for validation. Such single-channel data validation is useful for detecting the larger anomalies at an early stage; see for example [24.10–13].

Due to the additional redundancy, more powerful testing becomes possible at the receiver and baseline level [24.14–19]. In this case the observation equations are parametrized in terms of the position- or baseline coordinates of a single (e.g., in case of precise point positioning (PPP)) or dual (e.g., in case of real time kinematic (RTK)) receiver. Here the redundancy primarily stems from the presence of the receiver-satellite geometry in the design matrix and from the assumed time constancy of the ambiguities. Additional redundancy enters when the receiver position is considered stationary instead of moving, and/or when an array or network of receivers is considered; see for example [24.20–22].

Since batch and recursive estimation are both common methods of GNSS data processing, the quality control of both will be discussed in this chapter. We start with the batch approach as this for a large part already paves the way for the recursive treatment. In Sect. 24.2 we formulate the hypothesis framework for testing and introduce the concepts of testable and influential biases. The general form of the most powerful test statistic is introduced in Sect. 24.3, together with a discussion of its properties and its usage for GNSS. This includes the important concepts of minimal detectable biases (MDBs) and hazardous missed detection (HMD). A testing procedure for the handling of multiple hypotheses is discussed in Sect. 24.4. It includes separate steps for the detection, identification and adaptation of modeling errors. This is extended in Sect. 24.5 to a Kalman-filter-based recursive algorithm for the detection, identification and adaptation of GNSS modeling errors. Depending on the required power of testing, a difference is hereby made between local and global testing. Various GNSS examples are given throughout the chapter to illustrate the concepts discussed.

## 24.2 Batch Model Validation

### 24.2.1 Null versus Alternative Hypothesis

Before any start can be made with statistical model validation, one needs to have a clear idea of the null and alternative hypotheses: $\mathcal{H}_0$ and $\mathcal{H}_a$ respectively. The null hypothesis, also referred to as working hypothesis, consists of the model that one believes to be valid under normal working conditions. We assume the null hypothesis to be of the form

$$\mathcal{H}_0: \quad E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x}\,,\; D(\boldsymbol{y}) = \mathbf{Q}_{\boldsymbol{yy}}\,, \tag{24.3}$$

with vector of observables $\boldsymbol{y} \in \mathbb{R}^m$, vector of unknown parameters $\boldsymbol{x} \in \mathbb{R}^n$, known $m \times n$ design matrix $\mathbf{A}$ of full rank$(\mathbf{A}) = n$, and known positive-definite $m \times m$ variance-matrix $\mathbf{Q}_{\boldsymbol{yy}}$. In case of GNSS, the model (24.3) is formed by the linear(ized) code and/or carrier-phase observation equations; Chaps. 19, 21, and [24.5, 7, 23, 24].

In order to test the null hypothesis against an alternative hypothesis, we need to know what kind of misspecifications one can expect. Although every part of the null hypothesis can be wrong of course, we assume here that the misspecifications are confined to mismodeling of the mean of $\boldsymbol{y}$, $E(\boldsymbol{y})$. Experience has shown that these are by and large the most common errors that occur when formulating the model. Hence, the alternative hypothesis takes the form

$$\mathcal{H}_a: \quad E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x} + \mathbf{C}\boldsymbol{b}\,,\; D(\boldsymbol{y}) = \mathbf{Q}_{\boldsymbol{yy}}\,, \tag{24.4}$$

with $[\mathbf{A}, \mathbf{C}]$ a known full-rank matrix of order $m \times (n+q)$ and $\boldsymbol{b} \in \mathbb{R}^q/\{0\}$ the additional unknown parameter vector. The number of entries in $\boldsymbol{b}$, i. e., $q$, can range from 1 to $m-n$. Thus the maximum number of additional parameters that can be accommodated equals the redundancy under $\mathcal{H}_0$. In that case $q = m-n$ and $[\mathbf{A}, \mathbf{C}]$ becomes a square and invertible matrix, implying that no restrictions are put anymore on the mean of $\boldsymbol{y}$, $E(\boldsymbol{y}) \in \mathbb{R}^m$.

The vector

$$\boldsymbol{b}_{\boldsymbol{y}} = \mathbf{C}\boldsymbol{b} \tag{24.5}$$

in (24.4) models the bias that is potentially present in the mean of $\boldsymbol{y}$. For instance, through $\boldsymbol{b}_{\boldsymbol{y}} = \mathbf{C}\boldsymbol{b}$ one may model the presence of one or more blunders (outliers) in the data, or the presence of neglected atmospheric effects, or any other systematic effect that one failed to take into account under $\mathcal{H}_0$.

Here we give some such GNSS examples of the $m \times q$ matrix $\mathbf{C}$ (note: in the case $q = 1$, the $m \times q$ matrix $\mathbf{C}$ becomes a vector, which we denote with the lower case $\boldsymbol{c}$):

*Outlier* in $i$th code observable: if the vector of observables $\boldsymbol{y}$ consists of code data only, then $q = 1$ and $\boldsymbol{c} = (0, \ldots, 0, 1, 0, \ldots, 0)^{\mathrm{T}}$, with the 1 as the $i$th entry of $\boldsymbol{c}$.

*Cycle-slip* in carrier-phase that started at epoch $l \le k$: if $\boldsymbol{y}$ consists of single-channel carrier-phase data covering $k$ epochs, then $q = 1$ and $\boldsymbol{c} = (0, \ldots, 0, 1, 1, \ldots, 1)^{\mathrm{T}}$, with the 1s occupying the last $k-l+1$ entries of $\boldsymbol{c}$.

*Baseline error* in $i$th baseline of a GNSS baseline network: if $\boldsymbol{y}$ consists of the baseline vectors, then $q = 3$ and $\mathbf{C} = (0, \ldots, 0, \mathbf{I}_3, 0, \ldots, 0)^{\mathrm{T}}$, with the unit matrix $\mathbf{I}_3$ as the $i$th matrix entry.

*Antenna height error* at GNSS receiver location: if $\boldsymbol{y}$ consists of Cartesian baseline vectors, then $q = 1$ and $\boldsymbol{c} = (0, \ldots, 0, \partial N/\partial h, \partial E/\partial h, \partial U/\partial h, 0, \ldots, 0)^{\mathrm{T}}$, with the nonzero entries being the elements of the linearized transformation matrix from N-E-U Cartesian to ellipsoidal coordinates.

*Satellite failure* Let $\boldsymbol{y} = (\ldots, \boldsymbol{y}^{s\top}, \ldots)^{\mathrm{T}}$ be the vector of observables, with $\boldsymbol{y}^s$ containing all $m_s$ observations to the failed satellite $s$. Then $q = m_s$ and $\mathbf{C} = (0, \ldots, 0, \mathbf{I}_{m_s}, 0, \ldots, 0)^{\mathrm{T}}$, under the assumption that a failed satellite affects all $m_s$ observations to that satellite $s$.

*Ionospheric gradient* in single-frequency array signals to pivot-satellite $s$. Let $\boldsymbol{y}$ consist of the $2(m-1)(n-1)$ single-epoch double-differenced (DD) code and phase data of a small three-dimensional array of $n$ receivers, tracking $m$ satellites of which the pivot-satellite data are assumed affected by the ionospheric gradient. Then $q = 3$, $\boldsymbol{b}$ is the three-dimensional ionospheric gradient, and

$$\mathbf{C} = \left[(\boldsymbol{e} \otimes \mathbf{B}^{\mathrm{T}})^{\mathrm{T}}, -(\boldsymbol{e} \otimes \mathbf{B}^{\mathrm{T}})^{\mathrm{T}}\right]^{\mathrm{T}},$$

with $\boldsymbol{e}$ the $(m-1)$-vector of 1s, $\otimes$ the Kronecker product, and $\mathbf{B} = [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{n-1}]$, the $3 \times (n-1)$ matrix of array baseline vectors.

These are just a few examples of how modeling errors can be cast in the formulation of (24.4) and (24.5). For *any* such case the theory and methods of this chapter apply. More examples can be found in [24.20, 25–28].

### 24.2.2 Unbiased versus Biased Solution

Before discussing the testing of $\mathcal{H}_0$ against $\mathcal{H}_a$, we first consider the impact that a bias can have on our solutions. Under the working hypothesis $\mathcal{H}_0$ (24.3), we would compute the least-squares (LS) estimators of $\boldsymbol{x}$

and $\mathbf{A}\boldsymbol{x}$, together with the residual vector, as

$$\begin{aligned}\hat{\boldsymbol{x}} &= \mathbf{A}^{+}\boldsymbol{y}\,,\\ \hat{\boldsymbol{y}} &= \mathbf{P}_{\mathbf{A}}\boldsymbol{y}\,,\\ \hat{\boldsymbol{e}} &= \mathbf{P}_{\mathbf{A}}^{\perp}\boldsymbol{y}\,,\end{aligned} \tag{24.6}$$

with LS inverse

$$\mathbf{A}^{+} = (\mathbf{A}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\mathbf{A})^{-1}\mathbf{A}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}$$

and orthogonal projectors

$$\mathbf{P}_{\mathbf{A}} = \mathbf{A}\mathbf{A}^{+} \quad \text{and} \quad \mathbf{P}_{\mathbf{A}}^{\perp} = \mathbf{I}_m - \mathbf{P}_{\mathbf{A}}\,.$$

The geometry of this LS estimation, with its orthogonal decomposition $\boldsymbol{y} = \hat{\boldsymbol{y}} + \hat{\boldsymbol{e}}$, is depicted in Fig. 24.1. Orthogonality is here defined in the metric defined by the variance matrix $\mathbf{Q}_{yy}$. One important consequence of the orthogonality $\hat{\boldsymbol{y}} \perp \hat{\boldsymbol{e}}$ is that the normally distributed vectors $\hat{\boldsymbol{y}}$ and $\hat{\boldsymbol{e}}$ are independent. Thus also $\hat{\boldsymbol{x}}$ is independent of $\hat{\boldsymbol{e}}$.

Under $\mathcal{H}_0$ and $\mathcal{H}_\mathrm{a}$, the estimators $\hat{\boldsymbol{x}}$, $\hat{\boldsymbol{y}}$ and $\hat{\boldsymbol{e}}$ are distributed as

$$\begin{aligned}\hat{\boldsymbol{x}} &\overset{\mathcal{H}_0}{\sim} \mathcal{N}(\boldsymbol{x}, \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}})\,, & \hat{\boldsymbol{x}} &\overset{\mathcal{H}_\mathrm{a}}{\sim} \mathcal{N}(\boldsymbol{x}+\boldsymbol{b}_{\hat{\boldsymbol{x}}}, \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}})\,,\\ \hat{\boldsymbol{y}} &\overset{\mathcal{H}_0}{\sim} \mathcal{N}(\mathbf{A}\boldsymbol{x}, \mathbf{Q}_{\hat{\boldsymbol{y}}\hat{\boldsymbol{y}}})\,, & \hat{\boldsymbol{y}} &\overset{\mathcal{H}_\mathrm{a}}{\sim} \mathcal{N}(\mathbf{A}\boldsymbol{x}+\boldsymbol{b}_{\hat{\boldsymbol{y}}}, \mathbf{Q}_{\hat{\boldsymbol{y}}\hat{\boldsymbol{y}}})\,,\\ \hat{\boldsymbol{e}} &\overset{\mathcal{H}_0}{\sim} \mathcal{N}(\boldsymbol{0}, \mathbf{Q}_{\hat{\boldsymbol{e}}\hat{\boldsymbol{e}}})\,, & \hat{\boldsymbol{e}} &\overset{\mathcal{H}_\mathrm{a}}{\sim} \mathcal{N}(\boldsymbol{b}_{\hat{\boldsymbol{e}}}, \mathbf{Q}_{\hat{\boldsymbol{e}}\hat{\boldsymbol{e}}})\,,\end{aligned} \tag{24.7}$$

with the variance matrices $\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}} = (\mathbf{A}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\mathbf{A})^{-1}$, $\mathbf{Q}_{\hat{\boldsymbol{y}}\hat{\boldsymbol{y}}} = \mathbf{A}\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}\mathbf{A}^{\mathrm{T}}$, and $\mathbf{Q}_{\hat{\boldsymbol{e}}\hat{\boldsymbol{e}}} = \mathbf{Q}_{yy} - \mathbf{Q}_{\hat{\boldsymbol{y}}\hat{\boldsymbol{y}}}$ respectively, and the bias vectors given as

$$\begin{aligned}\boldsymbol{b}_{\hat{\boldsymbol{x}}} &= \mathbf{A}^{+}\boldsymbol{b}_y\,,\\ \boldsymbol{b}_{\hat{\boldsymbol{y}}} &= \mathbf{P}_{\mathbf{A}}\boldsymbol{b}_y\,,\\ \boldsymbol{b}_{\hat{\boldsymbol{e}}} &= \mathbf{P}_{\mathbf{A}}^{\perp}\boldsymbol{b}_y\,.\end{aligned} \tag{24.8}$$

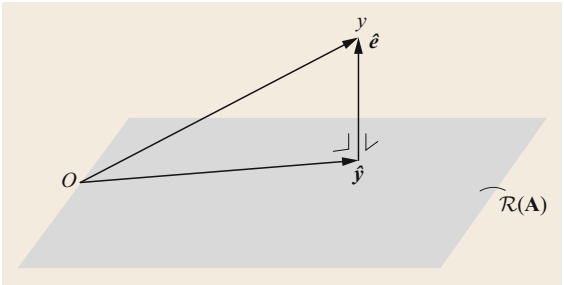

**Fig. 24.1** Orthogonal decomposition of the vector of observables $\boldsymbol{y} = \hat{\boldsymbol{y}} + \hat{\boldsymbol{e}}$, with $\hat{\boldsymbol{y}} = \mathbf{P}_{\mathbf{A}}\boldsymbol{y} \in \mathcal{R}(\mathbf{A})$ and $\hat{\boldsymbol{e}} = \mathbf{P}_{\mathbf{A}}^{\perp}\boldsymbol{y} \in \mathcal{R}(\mathbf{A})^{\perp}$

Hence, the LS estimators (24.6) are unbiased under the null hypothesis, but not so under the alternative hypothesis. Their biases (24.8) follow from propagating the bias $\boldsymbol{b}_y$ (24.5) through (24.6).

A geometric interpretation similar to (24.6) can be given to (24.8) (Fig. 24.2). In analogy to $\boldsymbol{y} = \hat{\boldsymbol{y}} + \hat{\boldsymbol{e}}$, we have the orthogonal decomposition

$$\boldsymbol{b}_y = \boldsymbol{b}_{\hat{\boldsymbol{y}}} + \boldsymbol{b}_{\hat{\boldsymbol{e}}} \tag{24.9}$$

in which we call

$$\begin{aligned}\boldsymbol{b}_y &= \text{actual bias}\,,\\ \boldsymbol{b}_{\hat{\boldsymbol{y}}} &= \text{influential bias}\,,\\ \boldsymbol{b}_{\hat{\boldsymbol{e}}} &= \text{testable bias}\,.\end{aligned} \tag{24.10}$$

As the vector $\boldsymbol{b}_{\hat{\boldsymbol{e}}}$ is expected to be zero under $\mathcal{H}_0$ (24.7), it is this component of the bias vector $\boldsymbol{b}_y$ that can be tested. The component $\boldsymbol{b}_{\hat{\boldsymbol{y}}}$ however cannot be tested. It lies in the range space of matrix $\mathbf{A}$, $\boldsymbol{b}_{\hat{\boldsymbol{y}}} \in \mathcal{R}(\mathbf{A})$, and will therefore be directly absorbed by the parameter vector. Hence, this is the component of the bias vector $\boldsymbol{b}_y$ that directly influences the parameter solution.

It will be clear that $\boldsymbol{b}_y \in \mathcal{R}(\mathbf{A})^{\perp}$ would be the most favorable situation. In that case the complete bias vector is testable, while any influence on the parameter solution would be absent. The worst situation occurs if $\boldsymbol{b}_y \in \mathcal{R}(\mathbf{A})$. Testability of the bias is then impossible and the complete bias vector will propagate into the parameter solution.

### 24.2.3 Effect of the Influential Bias

In order to evaluate the bias influence in a probabilistic sense, we consider the effect it has on the *confidence region* of the parameter estimator $\hat{\boldsymbol{x}}$. Since

$$||\hat{\boldsymbol{x}} - \boldsymbol{x}||^2_{\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}} \overset{\mathcal{H}_0}{\sim} \chi^2(n, 0)\,,$$

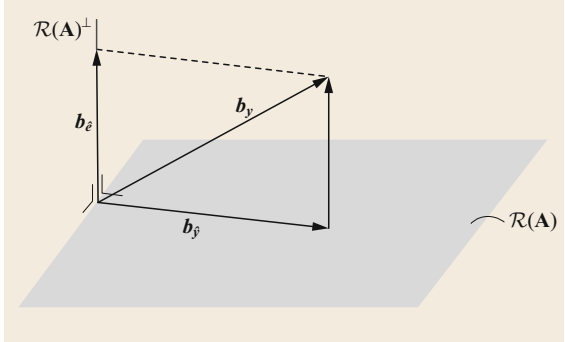

**Fig. 24.2** Bias decomposition: orthogonal decomposition of actual bias $\boldsymbol{b}_y = \boldsymbol{b}_{\hat{\boldsymbol{y}}} + \boldsymbol{b}_{\hat{\boldsymbol{e}}}$ into influential bias $\boldsymbol{b}_{\hat{\boldsymbol{y}}} \in \mathcal{R}(A)$ and testable bias $\boldsymbol{b}_{\hat{\boldsymbol{e}}} \in \mathcal{R}(A)^{\perp}$ (after [24.29])

with

$$||\hat{\boldsymbol{x}}-\boldsymbol{x}||^2_{\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}} = (\hat{\boldsymbol{x}}-\boldsymbol{x})^{\mathrm{T}}\mathbf{Q}^{-1}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}(\hat{\boldsymbol{x}}-\boldsymbol{x}) \,,$$

the $100(1-\eta)\%$ confidence region is given as

$$||\hat{\boldsymbol{x}}-\boldsymbol{x}||^2_{\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}} \leq \chi^2_\eta(n,0) \tag{24.11}$$

in which $\chi^2_\eta(n,0)$ is the ordinate value of the $\chi^2(n,0)$-distribution above which we find an area of size $\eta$. Hence, under $\mathcal{H}_0$, the probability that $\hat{\boldsymbol{x}}$ lies *outside* the $\boldsymbol{x}$-centered ellipsoidal region (24.11) is equal to $100\eta\%$.

In practice it is the criteria for system design that will provide information on what is considered an acceptable size and shape of the $100(1-\eta)\%$ confidence region. Once $\eta$ is given, one would know how precise the estimator $\hat{\boldsymbol{x}}$ needs to be in order to meet the prescribed geometry of the confidence region. Hence, one would then know what variance matrix $\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}} = (\mathbf{A}^{\mathrm{T}}\mathbf{Q}^{-1}_{\boldsymbol{y}\boldsymbol{y}}\mathbf{A})^{-1}$ to aim for in the design of the system or design of the measurement scenario (i. e., through choice of $\mathbf{A}$ and $\mathbf{Q}_{\boldsymbol{y}\boldsymbol{y}}$).

Since one would like the occurrence of $\hat{\boldsymbol{x}}$ falling outside the confidence region to be rare, the size $\eta$ will usually be small. In safety-critical situations one would even consider such occurrences as *hazardous*. Such hazardous occurrences may not be rare however, if biases are present in the solution $\hat{\boldsymbol{x}}$. In the presence of biases, i. e., under $\mathcal{H}_\mathrm{a}$, the probability of a hazardous occurrence will be larger than $100\eta\%$. To evaluate such a probability we make use of the noncentral $\chi^2$-distribution. We have

$$||\hat{\boldsymbol{x}}-\boldsymbol{x}||^2_{\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}} \overset{\mathcal{H}_\mathrm{a}}{\sim} \chi^2(n,\lambda^2_{\hat{y}}) \,, \tag{24.12}$$

with the noncentrality parameter given as

$$\lambda^2_{\hat{y}} = \boldsymbol{b}^{\mathrm{T}}_{\hat{\boldsymbol{x}}}\mathbf{Q}^{-1}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}\boldsymbol{b}_{\hat{\boldsymbol{x}}} = \boldsymbol{b}^{\mathrm{T}}_{\hat{y}}\mathbf{Q}^{-1}_{\boldsymbol{y}\boldsymbol{y}}\boldsymbol{b}_{\hat{y}} = ||\boldsymbol{b}_{\hat{y}}||^2_{\mathbf{Q}_{\boldsymbol{y}\boldsymbol{y}}} \,. \tag{24.13}$$

Thus under $\mathcal{H}_\mathrm{a}$, the $\chi^2$-distribution is driven by the influential *bias-to-noise* (BNR) ratio $\lambda_{\hat{y}}$. Under $\mathcal{H}_\mathrm{a}$, the probability of a hazardous occurrence, i. e., the probability that $\hat{\boldsymbol{x}}$ lies outside its $100(1-\eta)\%$ confidence region, is then given as

$$P_\mathrm{H} = P\left(||\hat{\boldsymbol{x}}-\boldsymbol{x}||^2_{\mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}} \geq \chi^2_\eta(n,0) \mid \mathcal{H}_\mathrm{a}\right) \tag{24.14}$$

and this probability will get larger the larger the influential bias-to-noise ratio $\lambda_{\hat{y}}$ gets.

The hazardous probability $P_\mathrm{H}$ depends, next to $\mathbf{A}$ and $\mathbf{Q}_{\boldsymbol{y}\boldsymbol{y}}$, on $\mathbf{C}$ and $\boldsymbol{b}$, i. e., on the type and size of the bias. Hence, (24.14) can now be used to determine the probability of a hazardous occurrence as function of the bias. In this way one can find out which biases really matter. For instance, if a criterion was set on the maximal allowable $P_\mathrm{H}$, then *inversion* of (24.14) would give the corresponding maximal allowable bias.

Above we have chosen the confidence region as the region against which to judge the quality of the solution. However, instead of the confidence region itself, one can of course take any other $\boldsymbol{x}$-centered region $R_x$. In some cases such a region may be more suitable for the application at hand. Instead of using (24.14), one would then be using $P_\mathrm{H} = P\,(\hat{\boldsymbol{x}} \notin R_x |\, \mathcal{H}_\mathrm{a})$ to compute the hazardous probability.

We now present a few examples of the influential bias-to-noise ratio.

### *Example 24.1 Influential outlier*

Consider a time series of uncorrelated scalar observations $y_i$, $i = 1,\ldots,k$, all of which are assumed to have the same mean $E(y_i) = x$ and same variance $D(y_i) = \sigma^2$. Then we have the simple linear model with $\mathbf{A} = (1,\ldots,1)^{\mathrm{T}}$ and $\mathbf{Q}_{\boldsymbol{y}\boldsymbol{y}} = \sigma^2\mathbf{I}_k$. If we consider that an outlier of size $b$ occurred at epoch $l$, then $\boldsymbol{b}_{\boldsymbol{y}} = \boldsymbol{c}_l b$, with $\boldsymbol{c}_l$ being the canonical unit vector having the 1 as its $l$th entry. From this we can compute the variance of the LS estimator as $\sigma^2_{\hat{x}} = \sigma^2/k$ and the influential bias as $b_{\hat{x}} = b/k$. Hence, the influential bias-to-noise ratio (24.13) follows then as

$$\lambda_{\hat{y}}(\text{outlier}) = \frac{1}{\sqrt{k}}\frac{|b|}{\sigma} \,. \tag{24.15}$$

This shows that the impact of the outlier on the LS solution becomes less significant as $k$ gets larger.

### *Example 24.2 Influential slip*

In the previous example, the symmetry of the problem was such that the time $l$ of outlier occurrence did not affect its influence on the estimated parameter. Now we assume that a slip of size $b$ occurred at epoch $l$. Then $\boldsymbol{b}_{\boldsymbol{y}} = \boldsymbol{s}_l b$, with $\boldsymbol{s}_l = (0,\ldots,0,1,\ldots,1)^{\mathrm{T}}$ having $(k-l+1)$ entries equal to 1. From this we can compute the influential bias as $b_{\hat{x}} = (k-l+1)b/k$. This shows that the influential bias is largest when $l = 1$ and smallest when $l = k$. In the first case, since $\mathbf{A}$ and $\boldsymbol{s}_l$ are the same, the bias is nontestable and gets completely passed on to the parameter solution. In the second case, the slip occurs at the last epoch and therefore acts as if it is an outlier. With $\sigma^2_{\hat{x}} = \sigma^2/k$, the influential bias-to-noise ratio (24.13) follows as

$$\lambda_{\hat{y}}(\text{slip}) = \frac{(k-l+1)}{\sqrt{k}}\frac{|b|}{\sigma} \,. \tag{24.16}$$

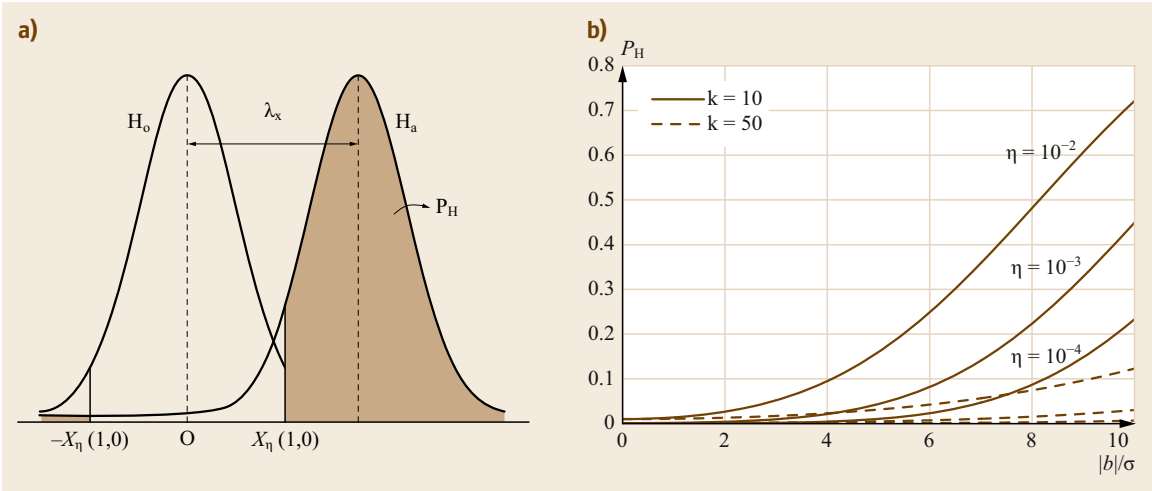

**Fig. 24.3** **(a)** The probability density function (PDF) of $(\hat{x}-x)/\sigma_{\hat{x}}$ under $\mathcal{H}_0$ and $\mathcal{H}_a$ of Example 24.1. **(b)** Hazardous probability $P_H = P((\hat{x}-x)^2/\sigma_{\hat{x}}^2 \geq \chi_\eta^2(1,0) \mid \mathcal{H}_a)$ as function of $|b|/\sigma$

This shows, in contrast to (24.15), that the impact of a slip gets more significant as $k$ gets larger.

*Example 24.3 Outlier influential BNR*

If the variance matrix of the observables is diagonal, i. e., $\mathbf{Q}_{yy} = \mathrm{diag}(\sigma_{y_1}^2, \ldots, \sigma_{y_m}^2)$, and matrix $\mathbf{C}$ is the canonical unit vector $\boldsymbol{c}_i = (0, \ldots, 1, \ldots, 0)^T$, then the influential BNR (24.13) simplifies to

$$\lambda_{\hat{y}} = \frac{\sigma_{\hat{y}_i}}{\sigma_{y_i}} \frac{|b|}{\sigma_{y_i}} \,. \tag{24.17}$$

Hence, outliers in observations that do not improve much in precision will be most influential.

*Example 24.4 $P_H$ and bias*

The probability of hazardous occurrence, $P_H$ (24.14), is given in Fig. 24.3 for the case of Example 24.1 as function of $|b|/\sigma$ for different values of $\eta$ and $k$. In this case we have

$$\frac{(\hat{x}-x)}{\sigma_{\hat{x}}} \overset{\mathcal{H}_a}{\sim} N(\lambda_{\hat{y}}(\text{outlier}), 1) \,,$$

(24.15) and therefore

$$P\left(\frac{(\hat{x}-x)^2}{\sigma_{\hat{x}}^2} \geq \chi_\eta^2(1,0) \mid \mathcal{H}_a\right) = \Phi(-\chi_\eta(1,0) + \lambda_{\hat{y}}) + \Phi(-\chi_\eta(1,0) - \lambda_{\hat{y}}) \,,$$

with

$$\Phi(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} \exp -\frac{1}{2} v^2 \mathrm{d}v \,.$$

As the figure shows, the probability of hazardous occurrence gets larger for larger biases. It gets smaller if $\eta$, the hazardous occurrence under $\mathcal{H}_0$ is smaller and/or if more epochs of data are used (stronger model).

## 24.3 Testing for a Bias

### 24.3.1 The Most Powerful Test Statistic

The aim of testing the working hypothesis $\mathcal{H}_0$ against the alternative is to obtain protection against hazardous occurrences. Note that with

$$E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x} + \mathbf{C}\boldsymbol{b} \,,$$
$$D(\boldsymbol{y}) = \mathbf{Q}_{yy} \,,$$

the pair (24.3)–(24.4) can alternatively be written as

$$\mathcal{H}_0 : \boldsymbol{b} = \mathbf{0} \text{ versus } \mathcal{H}_a : \boldsymbol{b} \neq \mathbf{0} \,. \tag{24.18}$$

To decide now whether or not the bias $\boldsymbol{b}$ can be neglected, it seems reasonable to estimate $\boldsymbol{b}$ under $\mathcal{H}_a$ and evaluate its significance. The LS solution of $\boldsymbol{b}$ is given

as

$$\hat{\boldsymbol{b}} = (\bar{\mathbf{C}}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\bar{\mathbf{C}})^{-1}\bar{\mathbf{C}}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\boldsymbol{y}\,,$$
$$\bar{\mathbf{C}} = \mathbf{P}_{\mathbf{A}}^{\perp}\mathbf{C}\,. \tag{24.19}$$

To evaluate its significance, we include the precision of $\hat{\boldsymbol{b}}$ as well and therefore compare $\hat{\boldsymbol{b}}$ with its variance matrix $\mathbf{Q}_{\hat{b}\hat{b}} = (\bar{\mathbf{C}}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\bar{\mathbf{C}})^{-1}$. A scalar measure that makes such comparison possible is the (dimensionless) quadratic form

$$T_q = \hat{\boldsymbol{b}}^{\mathrm{T}}\mathbf{Q}_{\hat{b}\hat{b}}^{-1}\hat{\boldsymbol{b}}\,. \tag{24.20}$$

The estimate $\hat{\boldsymbol{b}}$ is considered insignificant if the outcome for $T_q$ is small enough. With the estimate $\hat{\boldsymbol{b}}$ being insignificant, the decision is then made that there is no reason to believe that a bias is present. Thus, $\mathcal{H}_0$ is accepted (not rejected) if $T_q$ is small enough

$$\text{Accept } \mathcal{H}_0 \text{ if } T_q \leq \chi^2_\alpha(q,0) \tag{24.21}$$

and rejected otherwise, with $\chi^2_\alpha(q,0)$ the tolerance (or critical) value that still needs to be chosen. To judge what is large and what is small, we need the distribution of the test statistic $T_q$. It is given by the noncentral $\chi^2$-distribution [24.29–31]

$$T_q \sim \chi^2(q, \lambda^2_{\hat{e}})\,, \tag{24.22}$$

with noncentrality parameter

$$\lambda^2_{\hat{e}} = \boldsymbol{b}^{\mathrm{T}}\mathbf{Q}_{\hat{b}\hat{b}}^{-1}\boldsymbol{b} = \boldsymbol{b}_{\hat{\boldsymbol{e}}}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\boldsymbol{b}_{\hat{\boldsymbol{e}}}$$
$$= ||\boldsymbol{b}_{\hat{\boldsymbol{e}}}||^2_{\mathbf{Q}_{yy}}\,. \tag{24.23}$$

Note that $\lambda_{\hat{e}} = 0$ under $\mathcal{H}_0$, in which case the test statistic $T_q$ has a central $\chi^2$-distribution. With the distribution of $T_q$ given, we can compute the probabilities

$$P_{\mathrm{FA}} = P[T_q > \chi^2_\alpha(q,0)|\mathcal{H}_0] = \alpha\,,$$
$$P_{\mathrm{MD}} = P[T_q \leq \chi^2_\alpha(q,0)|\mathcal{H}_{\mathrm{a}}] = \beta\,. \tag{24.24}$$

The probability of *false alarm*, $P_{\mathrm{FA}}$, is the probability of rejecting the null hypothesis $\mathcal{H}_0$ while it is true. It is also referred to as the level of significance or size of the test. By choosing a false-alarm rate, say $P_{\mathrm{FA}} = \alpha$, one can compute the corresponding critical value $\chi^2_\alpha(q,0)$ and execute the test (24.21). The value chosen for $\alpha$ depends on the application. A choice $\alpha = 0.1\%$ for instance, implies that one is willing to accept that the test will have one out of thousand wrongful rejections. The larger $\alpha$ is chosen, the smaller the tolerance value $\chi^2_\alpha(q,0)$ will be.

When the false alarms are costly, one will tend to choose smaller values for $\alpha$ than otherwise. In classical terrestrial surveying, for instance, false alarms could be costly due to the need of having to do a remeasurement in case observations were rejected. The situation with GNSS is quite different. Observations are relatively cheap to come by and with today's high sampling rates, there is also an abundance of observations. Hence, with many of today's GNSS applications the level of significance can be chosen as larger than what the classical surveyor was used to.

Only *rejecting* or *not rejecting* the null hypothesis is not always informative. One may also want to know the strength of evidence on which the decision is made. Hence, one could ask for every $\alpha$ whether the test rejects at that level. The smallest $\alpha$ at which the test rejects is called the *p-value*. It is defined as the probability under $\mathcal{H}_0$ of obtaining an outcome of the test statistic equal to or more extreme than what was actually observed,

$$p(T_q) = \int_{T_q}^{\infty} f_{\chi^2(q,0)}(x)\mathrm{d}x \tag{24.25}$$

in which $f_{\chi^2(q,0)}(x)$ is the probability density function (PDF) of the $\chi^2$-distribution. The smaller the $p$-value, the larger one considers the evidence against $\mathcal{H}_0$.

The probability of *missed detection*, $P_{\mathrm{MD}}$, is the probability of wrongfully accepting the null hypothesis. The complement to the probability of missed detection, $P_{\mathrm{power}} = 1 - P_{\mathrm{MD}} = \gamma$, is known as the *power* of the test.

The missed detection probability $P_{\mathrm{MD}}$ depends, through $\chi^2_\alpha(q,0)$, on the chosen false-alarm rate $\alpha$, and, through the distribution of $T_q$ under $\mathcal{H}_{\mathrm{a}}$, it also depends on the testable bias-to-noise ratio $\lambda_{\hat{e}}$ (24.23). It thus depends on the bias $\boldsymbol{b}$ and on the precision with which it can be estimated, $\mathbf{Q}_{\hat{b}\hat{b}}$. $P_{\mathrm{MD}}$ is monotone decreasing with $\lambda_{\hat{e}}$. Thus the larger the bias and/or the more precise it can be estimated, the smaller the missed detection probability $P_{\mathrm{MD}}$ becomes.

Preferably one would like both error probabilities, $P_{\mathrm{FA}}$ and $P_{\mathrm{MD}}$, to be small. Unfortunately, however, it is not possible to minimize both simultaneously. If $\alpha$ is chosen smaller, then $\beta$ will get larger, and vice versa (Fig. 24.4). This fundamental trade-off in hypothesis testing motivated *Neyman* and *Pearson* [24.32] to develop tests that maximize power $\gamma = 1 - \beta$ for given false alarm $\alpha$. The above test (24.21), which is a *uniformly most powerful invariant* (UMPI) test, can be shown to be optimal in this sense [24.29, 30]. It thus has, for a fixed false alarm, the smallest missed detection probability of all invariant tests.

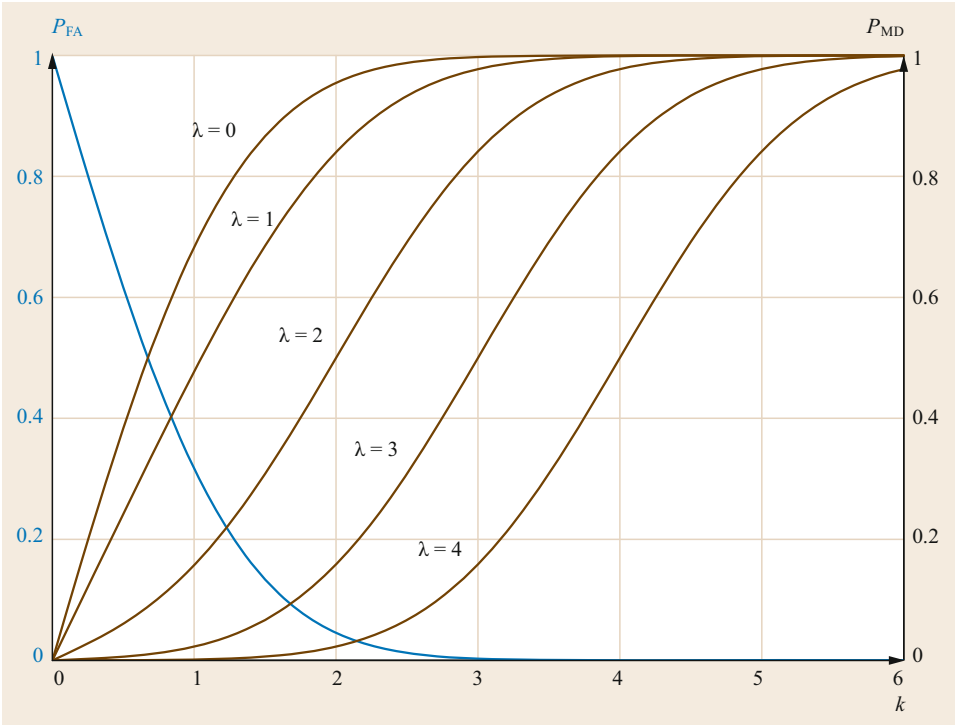

**Fig. 24.4** False alarm and missed detection probabilities, $P_{FA} = 2[1-\Phi(k)]$ and $P_{MD} = [\Phi(k-\lambda)+\Phi(k+\lambda)-1]$, as function of $k$ and $\lambda$, for testing $\mathcal{H}_0 : \lambda = 0$ versus $\mathcal{H}_a : \lambda \neq 0$ with test statistic $T_{q=1} \sim \chi^2(1,\lambda^2)$ and rejection interval $T_{q=1} > k^2$. For a smaller probability of false alarm, $P_{FA} = \alpha$, the probability of missed detection, $P_{MD} = \beta$, gets larger. For a fixed $P_{FA}$ (or $k$), the missed detection probability gets smaller for larger $\lambda$

We now present a few examples on the testable bias-to-noise ratio.

### *Example 24.5 Testable outlier*

For the case of Example 24.1, one can compute the testable bias-to-noise ratio (24.23) for an outlier as

$$\lambda_{\hat{e}}(\text{outlier}) = \left(1-\frac{1}{k}\right)^{\frac{1}{2}} \frac{|b|}{\sigma} \,. \tag{24.26}$$

Hence, the outlier is nontestable in the case $k = 1$, which of course corresponds to the case when redundancy is lacking. ■

### *Example 24.6 Outlier $P_{MD}$*

For the case of Example 24.1, with an assumed outlier in the $j$th observation, the outlier test statistic reads

$$T_{q=1} = \left(\frac{\hat{b}}{\sigma_{\hat{b}}}\right)^2 \,, \tag{24.27}$$

with

$$\hat{b} = \frac{k}{k-1}(y_j - \bar{y})$$

and variance

$$\sigma_{\hat{b}}^2 = \frac{k}{k-1}\sigma^2$$

where $\bar{y}$ is the average of the $k$ observations. The probability of missed detection $P_{MD}$ for the outlier test $T_{q=1} > \chi^2_\alpha(1,0)$ is shown in Fig. 24.5 for different values of $k$ and $\alpha$. ■

### *Example 24.7 Testable slip*

For the case of Example 24.2, one can compute the testable bias-to-noise ratio for the slip as

$$\lambda_{\hat{e}}(\text{slip}) = \left[(l-1)\left(1-\frac{l-1}{k}\right)\right]^{\frac{1}{2}} \frac{|b|}{\sigma} \,. \tag{24.28}$$

Hence, the slip is nontestable for $l = 1$ and $k = 1$. It is nontestable in the first case, since the slip gets then completely absorbed by the parameters solution, while in the second case it is nontestable due to lack of redundancy. The slip is best testable if it occurs halfway into the time series at the epoch being the nearest integer of

$$\frac{1}{2}k+1 = \arg\max_l \lambda_{\hat{e}} \,.$$

■

### *Example 24.8 Outlier testable BNR*

If the variance matrix of the observables is diagonal, i. e., $\mathbf{Q}_{yy} = \text{diag}(\sigma^2_{y_1}, \ldots, \sigma^2_{y_m})$, and matrix $\mathbf{C}$ is the

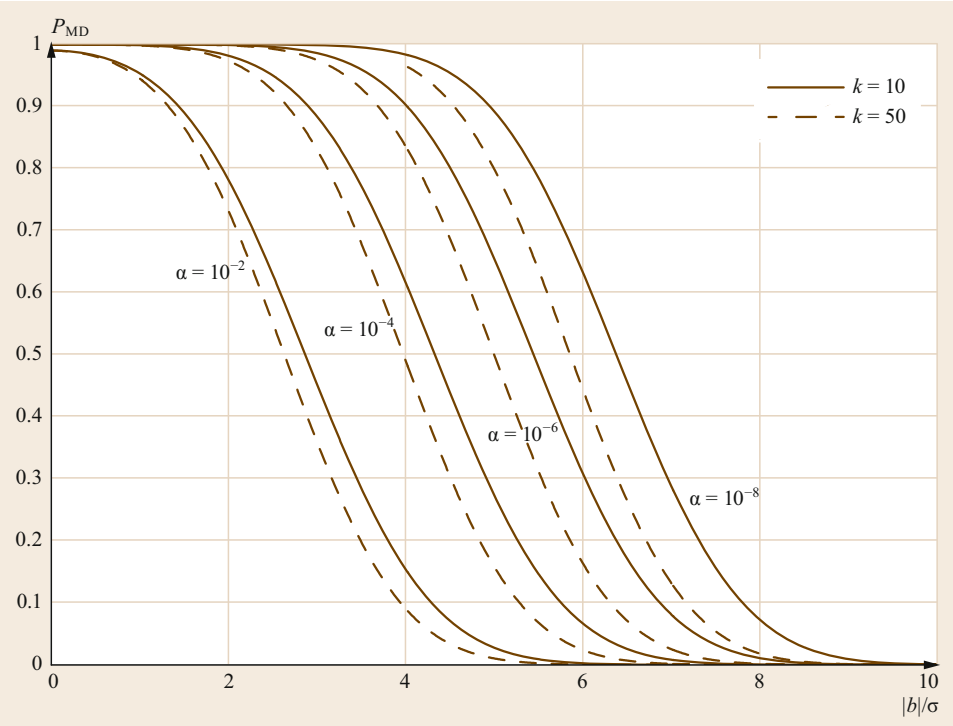

**Fig. 24.5** Probability of missed detection $P_{MD}$, for the outlier test of Examples 24.1, 24.5 and 24.6, as function of $|b|/\sigma$, shown for different number of epochs $k$ $(10, 50)$ and different levels of significance $\alpha$

canonical unit vector $\boldsymbol{c}_i = (0, \ldots, 1, \ldots, 0)^{\mathrm{T}}$, then the testable BNR (24.23) simplifies to

$$\lambda_{\hat{e}} = \left[1 - \left[\frac{\sigma_{\hat{y}_i}}{\sigma_{y_i}}\right]^2\right]^{\frac{1}{2}} \frac{|b|}{\sigma_{y_i}} \,. \tag{24.29}$$

Hence, outliers in observations that do not improve much in precision will be poorly testable. ■

### 24.3.2 Alternative Expressions for Test Statistic $T_q$

Alternative expressions exist for the UMPI test statistic (24.21). They provide extra insight and give alternative ways of computing the test statistic. Here we present three such geometric expressions taken from [24.29]. First note that $T_q$ can be interpreted as the squared weighted norm of the estimated bias vector,

$$T_q = \hat{\boldsymbol{b}}^{\mathrm{T}} \mathbf{Q}_{\hat{b}\hat{b}}^{-1} \hat{\boldsymbol{b}} = ||\hat{\boldsymbol{b}}||^2_{\mathbf{Q}_{\hat{b}\hat{b}}} \,. \tag{24.30}$$

This shows that $T_q$ measures the square of the *length* of $\hat{\boldsymbol{b}}$. Three alternative ways of expressing the test statistic in geometric terms are (Fig. 24.6)

$$\begin{aligned} ||\hat{\boldsymbol{b}}||^2_{\mathbf{Q}_{\hat{b}\hat{b}}} &= ||\mathbf{P}_{\bar{\mathbf{C}}} \boldsymbol{y}||^2_{\mathbf{Q}_{yy}} \\ &= ||\hat{\boldsymbol{y}} - \hat{\boldsymbol{y}}_{\mathrm{a}}||^2_{\mathbf{Q}_{yy}} \\ &= ||\hat{\boldsymbol{e}}||^2_{\mathbf{Q}_{yy}} - ||\hat{\boldsymbol{e}}_{\mathrm{a}}||^2_{\mathbf{Q}_{yy}} \,. \end{aligned} \tag{24.31}$$

The first expression follows from substitution of

$$\hat{\boldsymbol{b}} = (\bar{\mathbf{C}}^{\mathrm{T}} \mathbf{Q}_{yy}^{-1} \bar{\mathbf{C}})^{-1} \bar{\mathbf{C}}^{\mathrm{T}} \mathbf{Q}_{yy}^{-1} \boldsymbol{y} \,,$$

with $\bar{\mathbf{C}} = \mathbf{P}_{\mathbf{A}}^{\perp} \mathbf{C}$, (24.19), into (24.30). The second expression follows from the first by using the projector decomposition $\mathbf{P}_{[\mathbf{A},\mathbf{C}]} = \mathbf{P}_{\mathbf{A}} + \mathbf{P}_{\bar{\mathbf{C}}}$, thereby recognizing that $\hat{\boldsymbol{y}} = \mathbf{P}_{\mathbf{A}} \boldsymbol{y}$ and $\hat{\boldsymbol{y}}_{\mathrm{a}} = \mathbf{P}_{[\mathbf{A},\mathbf{C}]} \boldsymbol{y}$ are the LS estimators of the mean of $\boldsymbol{y}$ under $\mathcal{H}_0$ and $\mathcal{H}_{\mathrm{a}}$ respectively. This second expression of (24.31) shows that the test statistic is the squared norm of the *solution separation* between the two hypotheses. Finally, the third expression of (24.31) follows from the second by using

$$\mathbf{P}_{\mathbf{A}}^{\perp} = \mathbf{P}_{[\mathbf{A},\mathbf{C}]}^{\perp} + \mathbf{P}_{\bar{\mathbf{C}}} \,,$$

thereby recognizing that

$$\begin{aligned} \hat{\boldsymbol{e}} &= \mathbf{P}_{\mathbf{A}}^{\perp} \boldsymbol{y} \,, \\ \hat{\boldsymbol{e}}_{\mathrm{a}} &= \mathbf{P}_{[\mathbf{A},\mathbf{C}]}^{\perp} \boldsymbol{y} \,, \end{aligned}$$

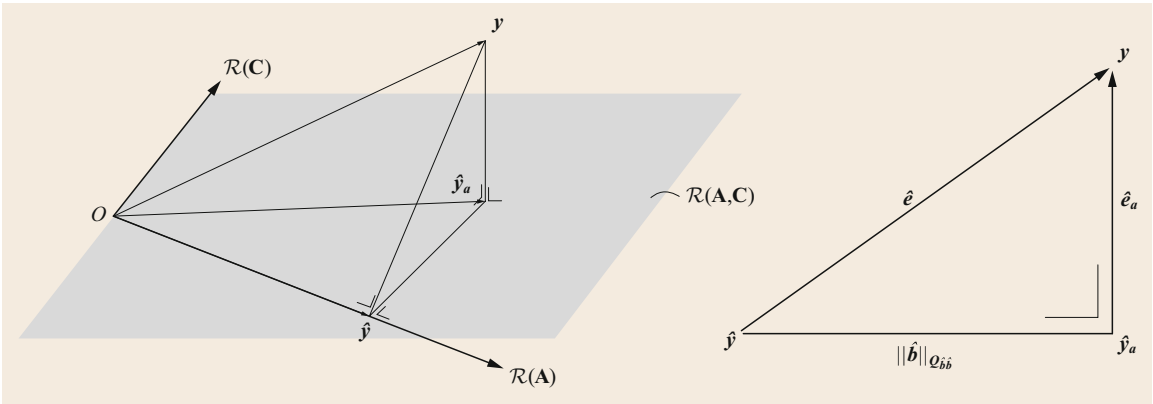

**Fig. 24.6** The geometry of the UMPI test statistic $T_q = ||\hat{b}||^2_{Q_{\hat{b}\hat{b}}}$ (after [24.29])

and

$$\mathcal{R}(\mathbf{A},\mathbf{C})^{\perp} \perp \mathcal{R}(\bar{\mathbf{C}}) \,.$$

This third expression shows that the test statistic can also be written as the difference of the squared norm LS residuals under $\mathcal{H}_0$ and $\mathcal{H}_a$ respectively. Hence,

$$T_q = ||\hat{\boldsymbol{b}}||^2_{\mathbf{Q}_{\hat{b}\hat{b}}}$$

is the value by which the weighted sum-of-squared residuals gets reduced when going from $\mathcal{H}_0$ to $\mathcal{H}_a$.

### 24.3.3 Test Statistic $T_q$ Expressed in LS Residuals

When (24.30), or one of the last two expressions of (24.31), is used for the computation of $T_q$, an explicit estimation under $\mathcal{H}_a$ is needed to obtain $\hat{\boldsymbol{b}}$, $\hat{\boldsymbol{y}}_a$ or $\hat{\boldsymbol{e}}_a$ respectively. This can be avoided if one makes use of the first expression of (24.31), thereby recognizing that $\mathbf{P}_{\bar{\mathbf{C}}}\boldsymbol{y} = \mathbf{P}_{\bar{\mathbf{C}}}\hat{\boldsymbol{e}}$. We have

$$\begin{aligned} T_q &= ||\mathbf{P}_{\bar{\mathbf{C}}}\hat{\boldsymbol{e}}||^2_{\mathbf{Q}_{yy}} \\ &= \hat{\boldsymbol{e}}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\mathbf{C}(\mathbf{C}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\mathbf{Q}_{\hat{e}\hat{e}}\mathbf{Q}_{yy}^{-1}\mathbf{C})^{-1}\mathbf{C}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\hat{\boldsymbol{e}} \,. \end{aligned} \tag{24.32}$$

This is the expression most often used for computing the test statistic, since $\hat{\boldsymbol{e}} = \boldsymbol{y} - \hat{\boldsymbol{y}}$ and $\mathbf{Q}_{\hat{e}\hat{e}} = \mathbf{Q}_{yy} - \mathbf{Q}_{\hat{y}\hat{y}}$ are usually readily available when computing under $\mathcal{H}_0$. Thus only the $m \times q$ matrix $\mathbf{C}$ in (24.32) changes when one changes to a different $\mathcal{H}_a$. We now consider the two special cases $q = m - n$ and $q = 1$.

#### The $q = m - n$ Case

In this case the matrix $[\mathbf{A}, \mathbf{C}]$ of $\mathcal{H}_a$ (24.4) is square and invertible, implying that its range space coincides with the complete observation space, $\mathcal{R}[\mathbf{A}, \mathbf{C}] = \mathbb{R}^m$. Hence, no restrictions are then put on the mean $E(\boldsymbol{y})$ of $\boldsymbol{y}$ under $\mathcal{H}_a$. As a consequence, the least-squares residual vector under $\mathcal{H}_a$ will be zero, $\hat{\boldsymbol{e}}_a = \mathbf{0}$, from which it follows, using the last expression in (24.31), that the UMPI test statistic simplifies to

$$T_{q=m-n} = ||\hat{\boldsymbol{e}}||^2_{\mathbf{Q}_{yy}} \,. \tag{24.33}$$

This statistic is used when one wants to test the null hypothesis against the most relaxed hypothesis $E(\boldsymbol{y}) \in \mathbb{R}^m$. Its expression can be further simplified in the case of a diagonal variance matrix of the observables. We then have $T_{q=m-n} = \sum_{i=1}^{m}(\hat{e}_i/\sigma_{y_i})^2$, which is often referred to as the (weighted) residual sum of squares (RSSs).

#### The $q = 1$ Case

In the one-dimensional case, matrix $\mathbf{C}$ becomes a vector $\boldsymbol{c}$ and the test statistic can be written as the square of a normally distributed variable $w$,

$$T_{q=1} = (w)^2 \,, \tag{24.34}$$

with

$$w = \frac{\boldsymbol{c}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\hat{\boldsymbol{e}}}{\sqrt{\boldsymbol{c}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\mathbf{Q}_{\hat{e}\hat{e}}\mathbf{Q}_{yy}^{-1}\boldsymbol{c}}} \tag{24.35}$$

distributed as

$$w \overset{\mathcal{H}_0}{\sim} \mathcal{N}(0,1); \; w \overset{\mathcal{H}_a}{\sim} \mathcal{N}(\lambda_{\hat{e},q=1}, 1) \,.$$

Hence, for $q = 1$, test (24.21) can be equivalently written as

$$\text{Accept } \mathcal{H}_0 \text{ if } |w| \le \mathcal{N}_{\alpha/2}(1,0) \,. \tag{24.36}$$

This statistic (24.35) is known as Baarda's $w$-test statistic [24.33, 34]. It is used when one has a specific one-dimensional bias in mind. The specification is then made through the choice of the $\boldsymbol{c}$-vector. The acceptance region of (24.36) is an interval. The acceptance interval becomes a region in the case where more than one $w$-test is used, each with its own $\boldsymbol{c}$-vector (Fig. 24.7).

The expression for the $w$-statistic simplifies considerably in the case where the observables are uncorrelated (i. e., $\mathbf{Q}_{yy} = \mathrm{diag}(\sigma_{y_1}^2, \ldots, \sigma_{y_m}^2)$) and the $\boldsymbol{c}$-vector is of canonical unit-vector form as used for outlier identification (i. e., $\boldsymbol{c} = (0, \ldots, 0, 1, 0, \ldots, 0)^{\mathrm{T}}$, with the 1 at its $i$th entry). Then, since

$$\boldsymbol{c}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\hat{\boldsymbol{e}} = \frac{\hat{e}_i}{\sigma_{y_i}}$$

and

$$(\boldsymbol{c}^{\mathrm{T}}\mathbf{Q}_{yy}^{-1}\mathbf{Q}_{\hat{e}\hat{e}}\mathbf{Q}_{yy}^{-1}\boldsymbol{c})^{\frac{1}{2}} = \frac{\sigma_{\hat{e}_i}}{\sigma_{y_i}} ,$$

the general expression (24.35) reduces to the normalized LS residual

$$w = \frac{\hat{e}_i}{\sigma_{\hat{e}_i}} . \tag{24.37}$$

In this case it is simply the LS residual divided by its standard deviation.

### 24.3.4 Optimality of the *w*-Test Statistic

We already mentioned that the $T_q$ statistic and therefore for $q = 1$ the $w$ statistic, is optimal in the sense of having the smallest missed detection probability for a given level of significance. This optimality can also be looked at from a geometric point of view. Let

$$v = \frac{\boldsymbol{f}^{\mathrm{T}}\hat{\boldsymbol{e}}}{\sqrt{\boldsymbol{f}^{\mathrm{T}}\mathbf{Q}_{\hat{e}\hat{e}}\boldsymbol{f}}} \tag{24.38}$$

be any normalized linear function of the least-squares residual vector $\hat{\boldsymbol{e}}$. Then

$$v \overset{\mathcal{H}_0}{\sim} \mathcal{N}(0,1) \quad \text{and} \quad v \overset{\mathcal{H}_a}{\sim} \mathcal{N}\left(\frac{\boldsymbol{f}^{\mathrm{T}}\boldsymbol{b}_{\hat{e}}}{\sqrt{\boldsymbol{f}^{\mathrm{T}}\mathbf{Q}_{\hat{e}\hat{e}}\boldsymbol{f}}}, 1\right) . \tag{24.39}$$

The bias, i. e., nonzero mean, of $v$ under $\mathcal{H}_a$ becomes better detectable the larger it is. Hence, the optimal test statistic $v$ is the one for which $\boldsymbol{f}$ is chosen to maximize this bias. The solution is

$$\hat{\boldsymbol{f}} = \mathbf{Q}_{yy}^{-1}\mathbf{P}_{\mathbf{A}}^{\perp}\boldsymbol{b}_{\hat{e}} = \arg\max_{\boldsymbol{f}} \frac{|\boldsymbol{f}^{\mathrm{T}}\boldsymbol{b}_{\hat{e}}|}{\sqrt{\boldsymbol{f}^{\mathrm{T}}\mathbf{Q}_{\hat{e}\hat{e}}\boldsymbol{f}}} , \tag{24.40}$$

which indeed shows that $w = \hat{\boldsymbol{f}}^{\mathrm{T}}\hat{\boldsymbol{e}}/(\hat{\boldsymbol{f}}^{\mathrm{T}}\mathbf{Q}_{\hat{e}\hat{e}}\hat{\boldsymbol{f}})^{\frac{1}{2}}$.

### 24.3.5 The Minimal Detectable Bias

The performance of the UMPI test (24.21) is described by its probabilities of false alarm $P_{\mathrm{FA}}$ and missed detection $P_{\mathrm{MD}}$ respectively. The probability of missed

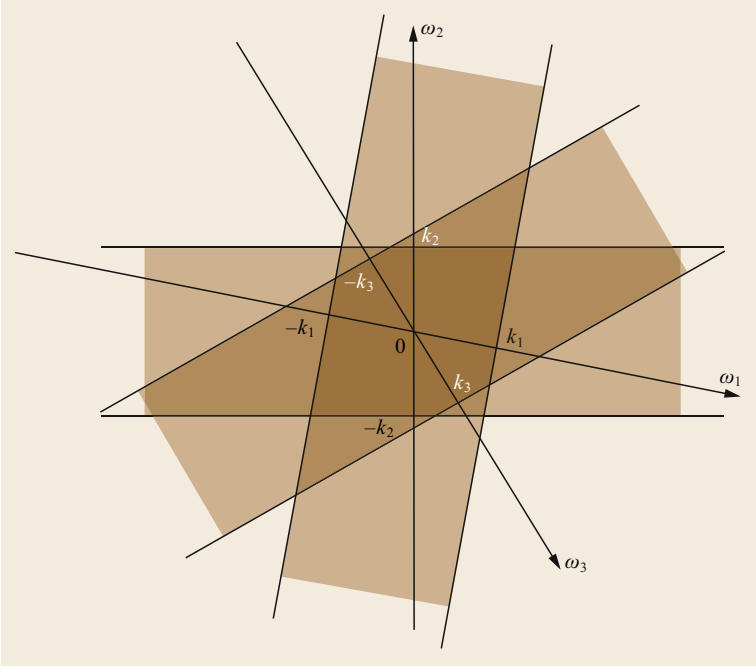

**Fig. 24.7** Intersection of multiple $w$-test acceptance regions (after [24.33])

detection $P_{\mathrm{MD}}$ (24.24) can be computed for any type and size of bias. One can however also follow the reverse route and determine the bias that can at least be found for a certain probability of missed detection, say $P_{\mathrm{MD}} = \beta$. The steps are then as follows. From setting $\alpha$, $\beta$, and $q$, one computes through *inversion* the corresponding testable bias-to-noise ratio, denoted as $\lambda_{\hat{e}}(\alpha, \beta, q)$, the value of which provides then a yardstick for the testable bias,

$$\lambda^2_{\hat{e}}(\alpha, \beta, q) = ||\boldsymbol{b}_{\hat{\boldsymbol{e}}}||^2_{\mathbf{Q}_{yy}} = ||\mathbf{P}^{\perp}_{\mathbf{A}}\mathbf{C}\boldsymbol{b}||^2_{\mathbf{Q}_{yy}} \,. \tag{24.41}$$

This quadratic equation describes a $q$-dimensional ellipsoid for the bias $\boldsymbol{b}$. Biases outside this region will have a larger than $\gamma = 1-\beta$ probability of being detected under $\mathcal{H}_{\mathrm{a}}$, while biases inside it will have a smaller probability. A further inversion is possible to find the corresponding biases themselves. Let $\boldsymbol{u}$ be a unit vector ($||\boldsymbol{u}|| = 1$) and parametrize the bias vector as $\boldsymbol{b} = ||\boldsymbol{b}||\boldsymbol{u}$. Substitution into (24.41), followed by inversion gives then

$$\boldsymbol{b} = \sqrt{\frac{\lambda^2_{\hat{e}}(\alpha, \beta, q)}{||\mathbf{P}^{\perp}_{\mathbf{A}}\mathbf{C}\boldsymbol{u}||^2_{\mathbf{Q}_{yy}}}}\,\boldsymbol{u} \quad \text{with} \quad ||\boldsymbol{u}|| = 1 \,. \tag{24.42}$$

This is the vectorial form of Baarda's *minimal detectable bias* (MDB) [24.33, 34]. Baarda referred to his MDBs as *boundary values* (in Dutch: grenswaarden); the nowadays more customary term MDB was introduced in [24.35].

The length $||\boldsymbol{b}||$ of the MDB vector is the smallest size of bias vector that can be found with probability $\gamma = 1-\beta$ in the direction $\boldsymbol{u}$ using the UMPI test (24.21). By letting $\boldsymbol{u}$ vary over the unit sphere in $\mathbb{R}^q$ one obtains the whole range of MDBs that can be detected with probability $\gamma$. Baarda in his work on the strength analysis of general purpose networks, applied his general MDB-form to data snooping [24.36]. Applications of the vectorial form can be found, for example, in [24.37, 38] for deformation analysis and in [24.39, 40] for trend testing. MDB analyses for the Global Positioning System (GPS) can be found in [24.41–43], for comparing and combining GNSSs in [24.44–52], and for recursive testing with applications to navigation in [24.35, 53].

### Outlier MDB

For outliers ($q = 1$), the MDB expression simplifies when the variance matrix is diagonal,

$$\mathbf{Q}_{yy} = \mathrm{diag}\left(\sigma^2_{y_1}, \ldots, \sigma^2_{y_m}\right) \,.$$

The MDB of the $i$th observable reads then

$$||\boldsymbol{b}_i|| = \sigma_{y_i}\sqrt{\frac{\lambda^2_{\hat{e}}(\alpha, \beta, q=1)}{1 - \frac{\sigma^2_{\hat{y}_i}}{\sigma^2_{y_i}}}} \,, \quad i = 1, \ldots, m \,. \tag{24.43}$$

This shows that the outlier MDB is small if $\sigma^2_{\hat{y}_i}$ is small compared to $\sigma^2_{y_i}$. On the other hand, it will be large if the precision of the adjusted observation has not improved by much, i. e., if $\sigma^2_{\hat{y}_i}$ is close to $\sigma^2_{y_i}$. The dimensionless number

$$r_i = 1 - \frac{\sigma^2_{\hat{y}_i}}{\sigma^2_{y_i}}$$

is called the *local redundancy number*. Since $\sigma^2_{\hat{y}_i} \le \sigma^2_{y_i}$, we have $0 \le r_i \le 1$. The reason why $r_i$ is called the local redundancy number is due to the property that they add up to the redundancy itself

$$\sum_{i=1}^{m} r_i = m - n \,.$$

This can be shown by using the projector property of $\mathbf{P}_{\mathbf{A}}$ [24.29]. If we replace $r_i$ by its average

$$\bar{r} = \frac{m-n}{m} \,,$$

we get the rough MDB approximation

$$||\boldsymbol{b}_i|| \approx \sigma_{y_i}\sqrt{\frac{\lambda^2_{\hat{e}}(\alpha, \beta, q=1)}{\frac{(m-n)}{m}}} \,, \quad i = 1, \ldots, m \,. \tag{24.44}$$

*Example 24.9 Outlier MDB*

Consider the null hypothesis $\mathcal{H}_0$: $E(\boldsymbol{y}) = \mathbf{A}\boldsymbol{x}$, $\mathbf{Q}_{yy} = \sigma^2\mathbf{I}_m$, with $m \times 2$ design matrix

$$\mathbf{A} = \begin{bmatrix} 1 & a_1 \\ \vdots & \vdots \\ 1 & a_m \end{bmatrix} \,. \tag{24.45}$$

To determine the outlier MDB, we first need

$$\sigma^2_{\hat{y}_i} = \boldsymbol{c}_i^{\mathrm{T}}\mathbf{A}\mathbf{Q}_{\hat{x}\hat{x}}\mathbf{A}^{\mathrm{T}}\boldsymbol{c}_i$$

(cf. (24.43)). With the variance matrix of the LS solution $\hat{\boldsymbol{x}}$ given as

$$\mathbf{Q}_{\hat{x}\hat{x}} = \frac{\sigma^2}{\sum_{i=1}^{m}\bar{a}_i^2}\begin{bmatrix} \frac{1}{m}\sum_{i=1}^{m} a_i^2 & -a_c \\ -a_c & 1 \end{bmatrix} \,, \tag{24.46}$$

where

$$\bar{a}_i = a_i - a_c, \quad a_c = \frac{1}{m}\sum_{i=1}^{m} a_i \,,$$

the outlier MDB follows then as

$$||\boldsymbol{b}_i|| = \sigma \sqrt{\frac{\lambda_{\hat{e}}^2(\alpha,\beta,q=1)}{1-\left(\frac{1}{m}+\frac{\bar{a}_i^2}{\sum_{j=1}^{m}\bar{a}_j^2}\right)}} \,, \; i = 1,\ldots,m \,. \tag{24.47}$$

This shows that the MDB gets smaller the smaller $\bar{a}_i$ is. Hence, an outlier in the $i$th observable is better detectable if its coefficient $a_i$ is closer to the coefficient's mean value $a_c$ [24.29]. ■

### MDB and GNSS Geometry

The previous example applies to GNSS in the case where two of the three position coordinates would be constrained. The first column of (24.45) would then correspond to the receiver clock, while the second would refer to the remaining unknown position coordinate. In case all three coordinates are unknown, the $m \times 4$ GNSS design matrix reads

$$\mathbf{A} = \begin{bmatrix} 1 & \boldsymbol{u}_1^{\mathrm{T}} \\ \vdots & \vdots \\ 1 & \boldsymbol{u}_m^{\mathrm{T}} \end{bmatrix} \,, \tag{24.48}$$

with $\boldsymbol{u}_i$ being the unit direction vector from receiver to satellite $i$. The GNSS code-outlier MDB follows then as [24.54]

$$||\boldsymbol{b}_i|| = \sigma \sqrt{\frac{\lambda_{\hat{e}}^2(\alpha,\beta,q=1)}{1-\left[\frac{1}{m}+\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i\right]}} \,, \; i = 1,\ldots,m \,, \tag{24.49}$$

with projector

$$\mathbf{P}_{\bar{\mathbf{G}}} = \bar{\mathbf{G}}(\bar{\mathbf{G}}^{\mathrm{T}}\bar{\mathbf{G}})^{-1}\bar{\mathbf{G}}^{\mathrm{T}},$$

centered geometry matrix

$$\bar{\mathbf{G}} = \mathbf{G} - \boldsymbol{e}\boldsymbol{g}_c^{\mathrm{T}} \,,$$
$$\mathbf{G} = (\boldsymbol{u}_1,\ldots,\boldsymbol{u}_m)^{\mathrm{T}} \,,$$
$$\boldsymbol{g}_c^{\mathrm{T}} = \frac{1}{m}\boldsymbol{e}^{\mathrm{T}}\mathbf{G},$$

and $\boldsymbol{e} = (1,\ldots,1)^{\mathrm{T}}$ the vector of ones. Compare (24.49) with (24.47).

We can now infer, using (24.49), what the impact of the receiver-satellite geometry is on the detectability of code outliers. A good geometry is one where

$$\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i = 0 \,.$$

As

$$\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i = ||\boldsymbol{u}_i - \boldsymbol{g}_c||^2_{\bar{\mathbf{G}}^{\mathrm{T}}\bar{\mathbf{G}}} \,,$$

it follows the closer $\boldsymbol{u}_i$ is to the average $\boldsymbol{g}_c$ in the metric of $(\bar{\mathbf{G}}^{\mathrm{T}}\bar{\mathbf{G}})^{-1}$, the smaller the MDB.

A poor geometry for detecting an outlier in the $i$th code observable is one where the unit direction vectors $\boldsymbol{u}_j$ of all other code observables, $j \neq i$, lie on a cone. In that case we have for all

$$j \neq i : \; \boldsymbol{u}_j^{\mathrm{T}}\boldsymbol{a} = 1$$

for some vector $\boldsymbol{a}$ (the symmetry axis of the cone). Therefore, $\boldsymbol{c}_i$ would lie in the range space of $\mathbf{A}$, $\boldsymbol{c}_i \in \mathcal{R}(\mathbf{A})$, and thus

$$\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\mathbf{A}}\boldsymbol{c}_i = 1 \,,$$

where $\mathbf{A} = [\boldsymbol{e}, \mathbf{G}]$. The MDB $||\boldsymbol{b}_i||$ would then be infinite.

The following is an actual example that demonstrates the above.

#### *Example 24.10 GNSS code-outlier MDBs*

This example shows how the receiver-satellite geometry affects the MDBs. Figure 24.8 shows the distribution of six GPS satellites and Table 24.1 shows the MDBs of a single-epoch, code-only solution using these satellites. In this case the average horizontal precision in terms of the horizontal dilution of precision was good, HDOP $\approx 1.23$. The results of Table 24.1 show however that a sufficient precision in the position solution need not necessarily correspond with a sufficiently small MDB. When the skyplot of Fig. 24.8 is compared with Table 24.1, the following remarks can be made. First note that satellites pseudorandom noise (PRN) code 6 and PRN 16 are close together. The two pseudoranges to these two satellites therefore check each other well. This explains the relatively small and almost equal

**Table 24.1** Code-outlier MDBs of six GPS satellites having the receiver-satellite geometry of Fig. 24.8

| PRN | $\lvert b\rvert/\sigma_p$ |
|---|---|
| 16 | 5.41 |
| 18 | 8.81 |
| 2 | 5.25 |
| 9 | 69.55 |
| 6 | 5.62 |
| 17 | 22.63 |

MDBs for the first and fifth pseudorange. Also note that in the absence of satellite PRN 2, one would expect, because of symmetry, the MDBs of the pseudoranges to PRNs 18 and 17 to be of the same order. With satellite PRN 2 however, additional redundancy for checking pseudorange to PRN 18 enters, which explains why its MDB is smaller than that of the pseudorange to PRN 17. Finally note the large value for the MDB of PRN 9. This is due to the fact that all unit direction vectors, except that of PRN 9, approximately lie on a common cone, the symmetry axis of which is indicated with a *star* in the skyplot of Fig. 24.8. ■

*Example 24.11 MDB of nonoptimal test*

The derivation and computation of the MDB is not restricted to optimal tests. It can be done for any test and thus for the nonoptimal $v$ test statistic of (24.38) as well. Using a similar derivation as before, its MDB follows as

$$|b|_v = \sqrt{\frac{\lambda_{\hat{e}}^2(\alpha,\beta,1)}{||\mathbf{P}_{\mathbf{A}}^{\perp}\boldsymbol{c}||_{\mathbf{Q}_{yy}}^2 \cos^2\theta}}\,, \tag{24.50}$$

with the angle defined as $\theta = \angle(\mathbf{Q}_{yy}\boldsymbol{f}, \mathbf{P}_{\mathbf{A}}^{\perp}\boldsymbol{c})$. This indeed shows that the MDB is smallest if $\boldsymbol{f}$ is chosen as $\hat{\boldsymbol{f}}$ of (24.40), in which case it becomes identical to the MDB of the $w$-test. ■

### 24.3.6 Hazardous Missed Detection

False alarm (FA) and missed detection (MD) are the two possible incorrect outcomes of the test (24.21). To be able to evaluate their significance, we take the occurrences of hazardous solutions into account as well. Consider therefore Fig. 24.9. It has along the horizontal axis the parameter statistic

$$P_n = ||\hat{\boldsymbol{x}} - \boldsymbol{x}||_{\mathbf{Q}_{\hat{x}\hat{x}}}^2$$

and along the vertical axis the test statistic

$$T_q = ||\hat{\boldsymbol{b}}||_{\mathbf{Q}_{\hat{b}\hat{b}}}^2 .$$

These two random variables are independent, since $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{e}}$ are independent. With the use of $\chi_\eta^2(n,0)$ and $\chi_\alpha^2(q,0)$, the sample space of the two statistics is divided into four rectangular regions. Figure 24.9a shows the situation under $\mathcal{H}_0$ and Fig. 24.9b shows the situation under $\mathcal{H}_a$.

Under $\mathcal{H}_0$, there is a false alarm region (FA) and a hazardous region (H) (Fig. 24.9a). The hazardous part

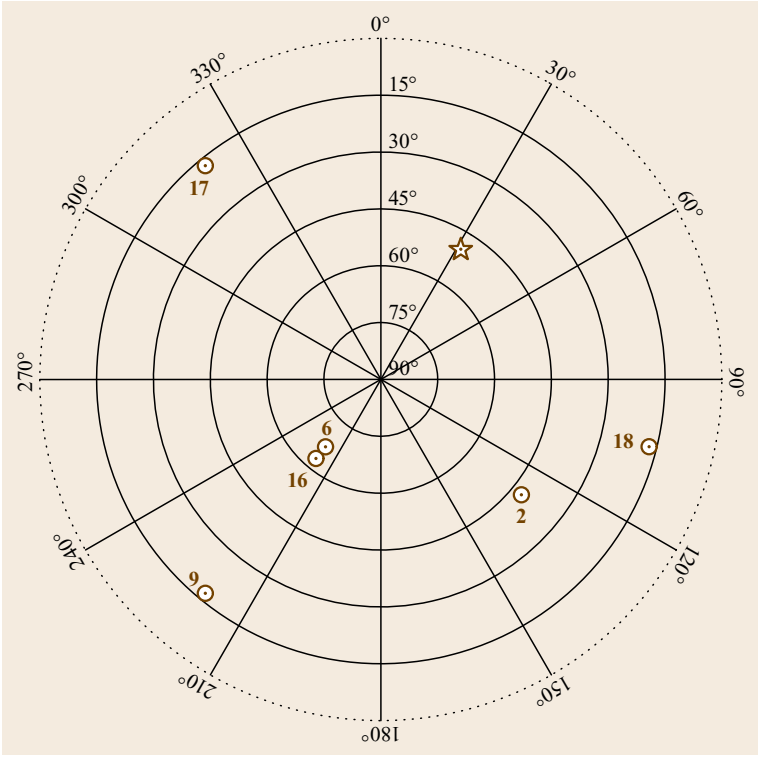

**Fig. 24.8** GPS skyplot of Example 10's PRNs 2, 6, 9, 16, 17, 18. The *star* indicates the symmetry axis of the cone determined by all PRNs excluding PRN 9

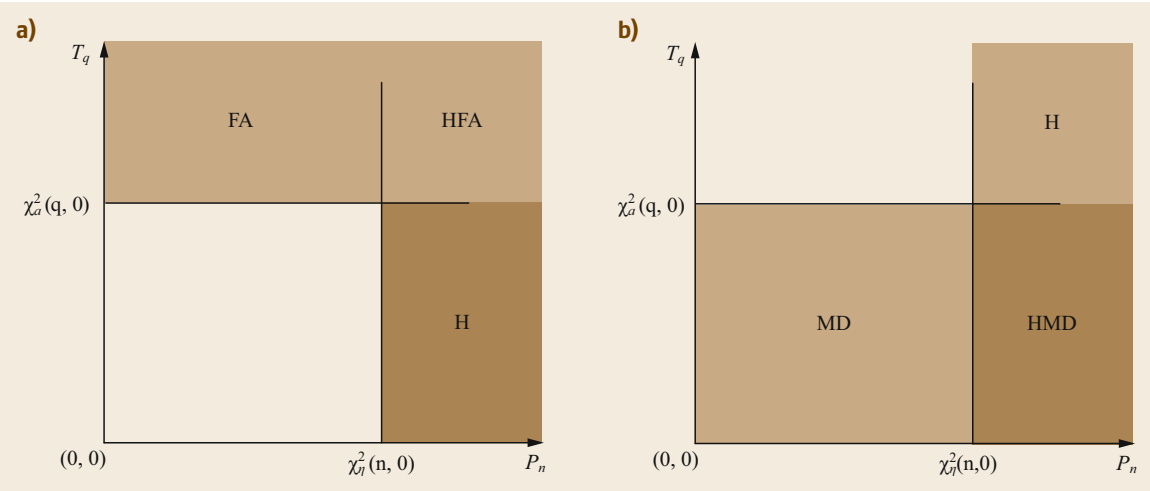

**Fig. 24.9a,b** The joint $(P_n, T_q)$-sample space of the parameter statistic $P_n = ||\hat{\boldsymbol{x}}-\boldsymbol{x}||^2_{\mathbf{Q}_{\hat{x}\hat{x}}}$ and the test statistic $T_q = ||\hat{\boldsymbol{b}}||^2_{\mathbf{Q}_{\hat{b}\hat{b}}}$. The sample space has been divided into four regions both under $\mathcal{H}_0$ **(a)** and $\mathcal{H}_a$ **(b)** (H = hazardous, FA = false alarm, MD = missed detection)

of FA should not be too much of a concern, since even though the null hypothesis is falsely rejected, outcomes in the hazardous region is what one would like to avoid anyway. The probability of occurrence of the remaining hazardous part is $P_H \times (1 - P_{FA}) = [\eta \times (1-\alpha)]\%$. This probability is controlled by choosing $\eta$ small enough. The remaining region one should be concerned about under $\mathcal{H}_0$ is the nonhazardous FA region. This is the region for which one rejects the working hypothesis, while having solutions that are nonhazardous and therefore acceptable. The probability of this happening is given by the product $(1-P_H)\times P_{FA} = [(1-\eta)\times\alpha]100\%$. This probability is usually controlled by choosing $\alpha$ sufficiently small.

Under $\mathcal{H}_a$, also the missed detection (MD) region can be further divided into a hazardous and nonhazardous part (Fig. 24.9b). Outcomes in the nonhazardous part are not a problem, because it would mean that despite the presence of undetected biases, their impact is such that the parameter solutions are still acceptable. What is unacceptable however, are missed detections that result in hazardous solutions. The probability that this happens is given by the product

$$P_{HMD} = P_H \times P_{MD} \,. \tag{24.51}$$

Recall that the hazardous probability $P_H$ is driven by the influential BNR $\lambda_{\hat{y}}$ (24.13), while the missed detection probability $P_{MD}$ is driven by the testable BNR $\lambda_{\hat{e}}$ (24.23), both of which in their turn are driven by the actual BNR $\lambda_y = ||\boldsymbol{b}_y||_{\mathbf{Q}_{yy}}$. The BNR relation is given by the Pythagorean decomposition (Fig. 24.10)

$$\lambda_y^2 = \lambda_{\hat{y}}^2 + \lambda_{\hat{e}}^2 \,, \tag{24.52}$$

with actual, influential and testable BNRs,

$$\begin{aligned} \lambda_y &= ||\boldsymbol{b}_y||_{\mathbf{Q}_{yy}} \,, \\ \lambda_{\hat{y}} &= ||\boldsymbol{b}_{\hat{y}}||_{\mathbf{Q}_{yy}} = ||\boldsymbol{b}_y||_{\mathbf{Q}_{yy}} \cos(\phi) \,, \\ \lambda_{\hat{e}} &= ||\boldsymbol{b}_{\hat{e}}||_{\mathbf{Q}_{yy}} = ||\boldsymbol{b}_y||_{\mathbf{Q}_{yy}} \sin(\phi) \,. \end{aligned} \tag{24.53}$$

The BNRs $\lambda_{\hat{e}}$ and $\lambda_{\hat{y}}$ were introduced by Baarda as his measures of *internal* and *external* reliability, respectively [24.33, 34, 36], see also [24.55–59].

As the angle $\phi$ in (24.53) determines how much of the actual bias is testable and influential respectively, it determines the ratio of the testable BNR to the influential BNR: $\lambda_{\hat{e}} = \lambda_{\hat{y}} \tan(\phi)$. The smaller the angle $\phi$, the more $\boldsymbol{b}_y$ and $\mathcal{R}(\mathbf{A})$ are aligned and the more influential the bias will be. The angle itself is determined by the type of bias (i. e., matrix $\mathbf{C}$) and the strength of the underlying model (i. e., matrices $\mathbf{A}$ and $\mathbf{Q}_{yy}$). If we parametrize the bias as before, $\boldsymbol{b} = ||\boldsymbol{b}||\boldsymbol{u}$, with $||\boldsymbol{u}|| = 1$ (cf. (24.42)), then

$$\lambda_{\hat{y}} = \frac{||\mathbf{P}_A \mathbf{C}\boldsymbol{u}||_{\mathbf{Q}_{yy}}}{||\mathbf{P}_A^{\perp}\mathbf{C}\boldsymbol{u}||_{\mathbf{Q}_{yy}}}\lambda_{\hat{e}} \,. \tag{24.54}$$

To compute and evaluate the probability of hazardous missed detection $P_{HMD}$ one can follow different routes. The first approach goes as follows. From choosing $\alpha$, $\beta$ and knowing $q$, one can first compute the yardstick $\lambda_{\hat{e}}(\alpha, \beta, q)$. This, together with knowledge of matrix $\mathbf{C}$ (i. e., type of bias), enables the computation of the MDB (24.42), the corresponding BNR $\lambda_y$, and via Pythagoras, the corresponding influential BNR

$$\lambda_{\hat{y}} = (\lambda_y^2 - \lambda_{\hat{e}}^2)^{\frac{1}{2}} \,.$$

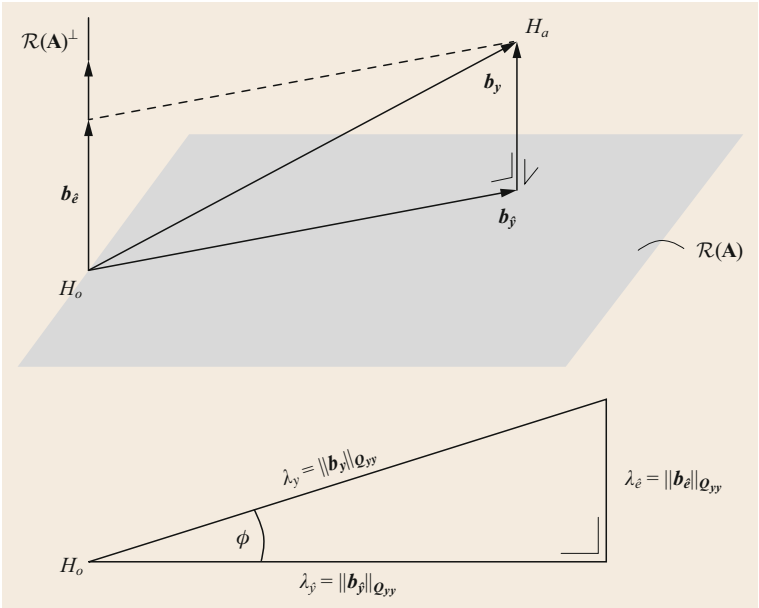

**Fig. 24.10** The Pythagorian BNR decomposition $\lambda_y^2 = \lambda_{\hat{y}}^2 + \lambda_{\hat{e}}^2$. The distance between the two hypotheses, $\mathcal{H}_0$ and $\mathcal{H}_a$, is given by the actual BNR $\lambda_y = ||E(\mathbf{y}|\mathcal{H}_a) - E(\mathbf{y}|\mathcal{H}_0)||_{\mathbf{Q}_{yy}} = ||\boldsymbol{b}_y||_{\mathbf{Q}_{yy}}$. Its orthogonal projection onto $\mathcal{R}(\mathbf{A})$ and $\mathcal{R}(\mathbf{A})^{\perp}$ gives the influential and testable BNRs $\lambda_{\hat{y}}$ and $\lambda_{\hat{e}}$ respectively

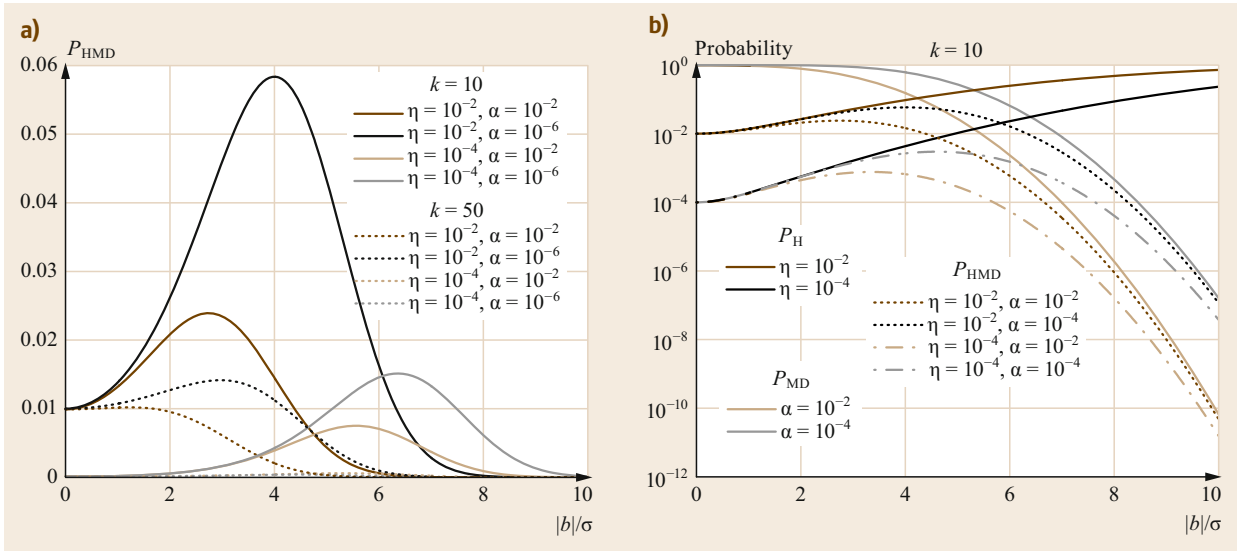

**Fig. 24.11a,b** Hazardous missed detection probability $P_{HMD}$ as a function of $|b|/\sigma$ for the outlier example (1 and 5) with different settings of $k$, $\eta$, and $\alpha$ **(a)**. Separate graphs of the three probabilities $P_H$, $P_{MD}$ and $P_{HMD}$ **(b)**

From it one can then compute the hazardous probability $P_H$ and finally $P_{HMD}$. This is in essence the procedure as devised by *Baarda* in [24.34] for designing *general purpose* geodetic networks and for describing their (internal and external) reliability. Thus

$$P_{HMD} = P_H \times \beta$$

in which (24.54) is used for computing $P_H$, with $\lambda_{\hat{e}} = \lambda_{\hat{e}}(\alpha, \beta, q)$ as a yardstick. Instead of starting with $P_{MD}$ (or $\lambda_{\hat{e}}$) one can alternatively start with the probability of a hazardous occurrence $P_H$ (or $\lambda_{\hat{y}}$) would such criterion be available, say $P_H = \eta_a$. Then $P_{HMD} = \eta_a \times P_{MD}$ in which the inverse of (24.54) is used for computing $P_{MD}$ from $\lambda_{\hat{y}}$, $\alpha$ and $q$.

An alternative approach to the above two would be to directly evaluate the probability of hazardous missed detection as function of the bias, $P_{HMD}(\boldsymbol{b})$, in which case explicit choices of $P_{MD} = \beta$ or $P_H = \eta_a$ are not involved. As $P_{MD}$ gets smaller, but $P_H$ larger, for larger

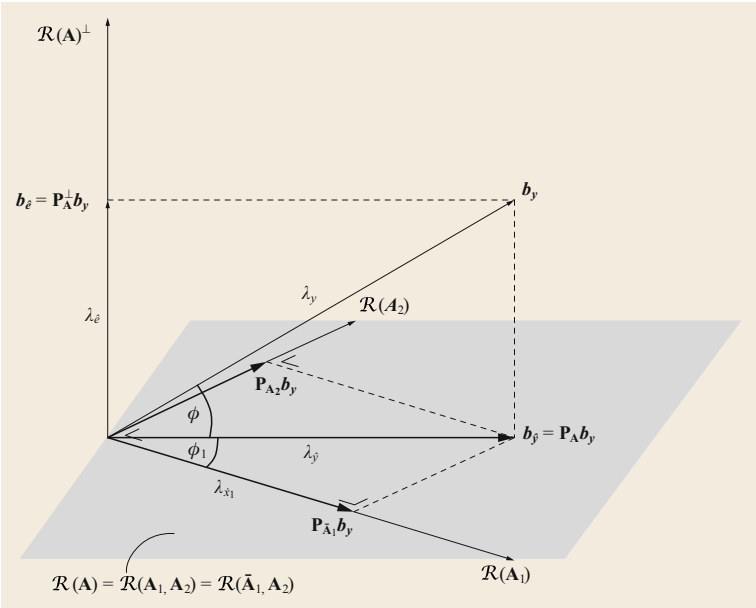

**Fig. 24.12** Pythagorian BNR decomposition $\lambda_{\hat{y}}^2 = \lambda_{\hat{x}_1}^2 + \lambda_{\hat{x}_2|x_1}^2$ for the parameters $\boldsymbol{x} = (\boldsymbol{x}_1^{\mathrm{T}}, \boldsymbol{x}_2^{\mathrm{T}})^{\mathrm{T}}$, where $\mathbf{A} = (\mathbf{A}_1, \mathbf{A}_2)$, $\bar{\mathbf{A}}_1 = \mathbf{P}_{\mathbf{A}_2}^{\perp}\mathbf{A}_1$

biases, the probability $P_{\mathrm{HMD}}(\boldsymbol{b})$ will have a maximum for a certain bias (Fig. 24.11). With this approach one can thus evaluate whether the *worst-case* scenario

$$\max_{\boldsymbol{b}} P_{\mathrm{HMD}}(\boldsymbol{b})$$

still satisfies ones criterion.

As the computations of the above approaches can be done without the need for having the actual measurements available, they are very useful for design verification purposes. Starting from a certain assumed design or measurement setup as described by $\mathbf{A}$ and $\mathbf{Q}_{\boldsymbol{yy}}$, one can then infer how well the design can be expected to be protected by the statistical testing against biases $\boldsymbol{b}_{\boldsymbol{y}} = \mathbf{C}\boldsymbol{b}$.

Note that in the above considerations, we have taken the complete parameter vector $\boldsymbol{x}$ into account. This need not be necessary, however, if only certain functions of $\boldsymbol{x}$, say $\boldsymbol{\theta} = \mathbf{F}^{\mathrm{T}}\boldsymbol{x}$, are of interest for the application (e.g., only coordinates in the case of positioning, or only clocks in the case of time transfer). In that case one can follow the same approach as above, but now restricted to $\boldsymbol{\theta}$ [24.29, p. 110]. As a special case, consider the partitioning

$$\boldsymbol{x} = [\boldsymbol{x}_1^{\mathrm{T}}, \boldsymbol{x}_2^{\mathrm{T}}]^{\mathrm{T}}$$

and assume that one is only interested in $\boldsymbol{x}_1$ (i. e., $\boldsymbol{\theta} = \boldsymbol{x}_1$ and $\mathbf{F}^{\mathrm{T}} = [\mathbf{I}_{n_1}, \mathbf{0}]$). Then in analogy with (24.12),

$$||\hat{\boldsymbol{x}}_1 - \boldsymbol{x}_1||^2_{\mathbf{Q}_{\hat{\boldsymbol{x}}_1\hat{\boldsymbol{x}}_1}} \overset{\mathcal{H}_a}{\sim} \chi^2(n_1, \lambda_{\hat{x}_1}^2) \,,$$

with its noncentrality parameter

$$\lambda_{\hat{x}_1}^2 = \boldsymbol{b}_{\hat{\boldsymbol{x}}_1}^{\mathrm{T}} \mathbf{Q}_{\hat{\boldsymbol{x}}_1\hat{\boldsymbol{x}}_1}^{-1} \boldsymbol{b}_{\hat{\boldsymbol{x}}_1}$$

linked to $\lambda_{\hat{y}}^2$ through the Pythagorian decomposition

$$\lambda_{\hat{y}}^2 = \lambda_{\hat{x}_1}^2 + \lambda_{\hat{x}_2|x_1}^2 \,, \tag{24.55}$$

where

$$\lambda_{\hat{x}_2|x_1}^2 = ||\mathbf{P}_{\mathbf{A}_2}\boldsymbol{b}_{\boldsymbol{y}}||^2_{\mathbf{Q}_{\boldsymbol{yy}}} \,.$$

In geometric terms, $\lambda_{\hat{x}_1}$ is related to $\lambda_{\hat{y}}$ and $\lambda_y$ as (Fig. 24.12)

$$\begin{aligned} \lambda_{\hat{x}_1} &= \lambda_{\hat{y}} \cos(\phi_1) \\ &= \lambda_y \cos(\phi) \cos(\phi_1) \,. \end{aligned} \tag{24.56}$$

Thus now also the angle $\phi_1$ plays a role in determining how much of the actual bias $\boldsymbol{b}_{\boldsymbol{y}}$ is passed on to the LS solution of $\boldsymbol{x}_1$. The larger the angle $\phi_1$, the smaller the impact.

*Example 24.12 Example 3 continued*

Under the assumptions of Example 24.3, the influential BNR (24.13) for $\boldsymbol{x}_1$ of $\boldsymbol{x} = [\boldsymbol{x}_1^{\mathrm{T}}, \boldsymbol{x}_2^{\mathrm{T}}]^{\mathrm{T}}$ is

$$\lambda_{\hat{x}_1} = \left( \frac{\sigma_{\hat{y}_i}^2 - \sigma_{\hat{y}_i|x_1}^2}{\sigma_{y_i}^2} \right)^{\frac{1}{2}} \frac{|b|}{\sigma_{y_i}} \,. \tag{24.57}$$

Hence, a large reduction in the BNR takes place if the constraining of $\boldsymbol{x}_1$ would not do much for the precision improvement of the adjusted observations. ■

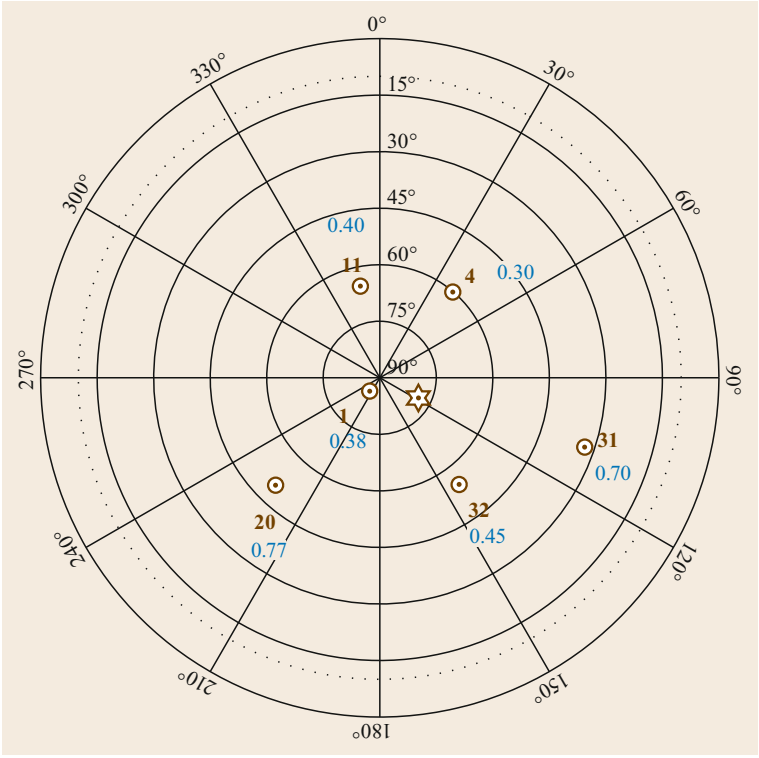

**Fig. 24.13** Skyplot of PRNs 1, 4, 11, 20, 31 and 32, showing their values $\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i$ in *blue*. The direction of the average $\boldsymbol{g}_c = \frac{1}{m}\mathbf{G}^{\mathrm{T}}\boldsymbol{e}$ is shown as a *star*

*Example 24.13 Example 24.7 continued*

Application of (24.55) to the model of Example 24.7 allows one to study the impact on the intercept and slope separately. The influential BNR of the *intercept*, $\lambda_{\hat{x}_1} = |b_{\hat{x}_1}|/\sigma_{\hat{x}_1}$, reads

$$\lambda_{\hat{x}_1} = \left( \frac{1 - \frac{a_i^2}{\sum_{j=1}^m a_j^2}}{1 - \frac{\bar{a}_i^2}{\sum_{j=1}^m \bar{a}_j^2} - \frac{1}{m}} - 1 \right)^{\frac{1}{2}} \lambda_{\hat{e}} \,. \tag{24.58}$$

Thus $\lambda_{\hat{x}_1}$ is small if $a_i$ is large and/or $\bar{a}_i$ is small.

Similarly the influential BNR of the *slope*, $\lambda_{\hat{x}_2} = |b_{\hat{x}_1}|/\sigma_{\hat{x}_2}$, reads

$$\lambda_{\hat{x}_2} = \left( \frac{1}{1 - \frac{\bar{a}_i^2}{\sum_{j=1}^m \bar{a}_j^2}} - 1 \right)^{\frac{1}{2}} \lambda_{\hat{e}} \,. \tag{24.59}$$

Thus $\lambda_{\hat{x}_2} = 0$ if $\bar{a}_i = 0$. Hence the effect of a possible nondetected outlier the size of the MDB on the *slope* estimator $\hat{x}_2$ is insignificant if $a_i$ is close to $a_c$. ■

*Example 24.14 Pruning of satellites*

Consider a code-based single receiver model having (24.48) as design matrix and

$$\mathbf{Q}_{yy} = \sigma^2 \mathbf{I}_m$$

as variance matrix. With the partitioned parameter vector $\boldsymbol{x} = (x_1, \boldsymbol{x}_2^{\mathrm{T}})^{\mathrm{T}}$, in which the first entry is the clock and the second contains the three E-N-U coordinate increments, $\boldsymbol{x}_2 = (E, N, U)^T$, the influential position BNR for an outlier in the $i$th code observable reads

$$\lambda_{\hat{x}_{2(i)}} = \left( \frac{\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i}{1 - \left(\frac{1}{m} + \boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i\right)} \right)^{\frac{1}{2}} \lambda_{\hat{e}} \,. \tag{24.60}$$

This BNR can now be used to measure the positional significance of MDB-sized code outliers. The larger the ratio $\lambda_{\hat{x}_{2(i)}}/\lambda_{\hat{e}}$, i. e., the larger the scalar $\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i$, the more significant a code outlier of MDB-size is for positioning. The values $\boldsymbol{c}_i^{\mathrm{T}}\mathbf{P}_{\bar{\mathbf{G}}}\boldsymbol{c}_i$ are given in Fig. 24.13 for each of the satellites shown. The direction of the average $\boldsymbol{g}_c$ is also shown. ■

## 24.4 Testing Procedure

### 24.4.1 Detection, Identification and Adaptation

So far we considered the testing of the null hypothesis $\mathcal{H}_0$ against one particular alternative hypothesis $\mathcal{H}_a$. In most practical applications however, it is usually not only one single mismodeling error one is concerned about, but quite often many more than one. This implies that one needs a *testing procedure* for handling the various alternative hypotheses $\mathcal{H}_{a_i}$. In this subsection we discuss a way of structuring such a testing procedure. The detection, identification and adaptation (DIA) procedure consists of the following three steps:

1. *Detection*: An overall model test is performed to diagnose whether an unspecified model error occurred.
2. *Identification*: After detection of a model error, identification of the potential source of model error is needed.
3. *Adaptation*: After identification of a model error, adaptation of the null hypothesis is needed to reduce the presence of biases in the solution.

#### Detection

This first step consists of a check on the overall validity of the null hypothesis $\mathcal{H}_0$. It provides information on whether one can have any confidence in the assumed null hypothesis, without the explicit need to specify any particular alternative hypothesis. This implies that one opposes the null hypothesis to the most relaxed alternative hypothesis possible, namely $\mathcal{H}_a : E(\boldsymbol{y}) \in \mathbb{R}^m$. Under this hypothesis no restrictions are imposed on the observables. The test makes use of the statistic $T_{m-n}$ (24.33) and reads

$$\text{Reject } \mathcal{H}_0 \text{ if } T_{m-n} = ||\hat{\boldsymbol{e}}||^2_{\mathbf{Q}_{yy}} > \chi^2_\alpha(m-n,0) \quad (24.61)$$

and accept (not reject) otherwise.

The detection step constitutes a safeguard against all possible types of modeling errors. If the test is passed, the system can be considered available and no further action is required. If the test is rejected one may either consider the system unavailable or move on to the identification step. The latter is done if one has a fair idea of the type of modeling errors that may occur.

#### Identification

Assuming that the detection step led to a rightful rejection of the null hypothesis, one can try to search for the likely model misspecifications. That is, one can then try to identify the model error that caused the rejection of the null hypothesis. This implies that one will have to specify, through the matrix $\mathbf{C}$, the type of likely model error $\boldsymbol{b}_y = \mathbf{C}\boldsymbol{b}$. This specification of possible alternative hypotheses is application-dependent and is one of the more difficult tasks in hypothesis testing. It depends on experience, which type of model errors are considered likely.

One can have alternative hypotheses of varying degrees of freedom $q$, as well as more than one with the same degrees of freedom. Let us first assume that the degrees of freedom of all alternatives are the same and equal to $q$. The hypotheses considered are then

$$\mathcal{H}_{q,i} : \boldsymbol{b}_y = \mathbf{C}_i \boldsymbol{b}_i,\ \boldsymbol{b}_i \in \mathbb{R}^q,\ \ i = 1, \ldots, r_q\,. \quad (24.62)$$

The identified hypothesis $\mathcal{H}_{q,j_q}$ is then the one for which

$$j_q = \arg\max_i T_{q,i}\,. \quad (24.63)$$

Thus it is the maximum value of the $r_q$ test statistics $T_{q,i}$ that is singled out as the most likely alternative hypothesis of $q$ degrees of freedom. This can also be understood by considering the relation (24.31)

$$||\hat{\boldsymbol{e}}_{q,i}||^2_{\mathbf{Q}_{yy}} = ||\hat{\boldsymbol{e}}||^2_{\mathbf{Q}_{yy}} - T_{q,i}\,.$$

It shows that selecting the largest $T_{q,i}$ amounts to selecting the *best-fitting* model among the $\mathcal{H}_{q,i}$s with $q$ degrees of freedom, i. e., the one with smallest $||\hat{\boldsymbol{e}}_{q,i}||^2_{\mathbf{Q}_{yy}}$ for $i = 1, \ldots, r_q$.

This simple approach of choosing the hypothesis with largest value of its test statistic does not work anymore in the case where (24.63) is applied to hypotheses with varying degrees of freedom. Since $E(T_{q,i}|\mathcal{H}_0) = q$, the mean of the test statistic gets larger for larger $q$. Hence, if identification would be based on the size of $T_{q,i}$, one would tend to select under $\mathcal{H}_0$ hypotheses with largest degrees of freedom. Although one could compensate by considering the maximum of $T_{q,i} - q$ or $T_{q,i}/q$ instead, it is better to base the identification on test statistics that have the same distribution under the null hypothesis.

A straightforward way to transform different random variables such that their transformations have the same distribution is by using their cumulative distribution function (CDF) as the transformation. If $a$ and $b$ are two random variables with CDFs $F_a(x)$ and $F_b(x)$, then $F_a(a)$ and $F_b(b)$ have the same distribution, and so have $1 - F_a(a)$ and $1 - F_b(b)$. Their common distribution is then the uniform distribution on the interval $[0, 1]$ [24.60]. Thus if we are using normally distributed

$w$-test statistics and chi-squared distributed test statistics $T_q$ with varying degrees of freedom $q$, we can transform the latter so that they also become standard normally distributed under $\mathcal{H}_0$. This transformation is given as $w(x) = \Phi^{-1}(\chi_q(x))$, with $\chi_q(x)$ and $\Phi(x)$ the CDFs of $\chi^2(q, 0)$ and $\mathcal{N}(0, 1)$ respectively. As a result we have

$$w(T_q) \overset{\mathcal{H}_0}{\sim} \mathcal{N}(0, 1) \, .$$

In the above $F$-transformations we recognize the transformation to the $p$-values of $a$ and $b$ respectively. Hence, instead of transforming back to the normal distribution, one can in the general case of varying degrees of freedom also use the concept of the uniformly distributed $p$-values and select the hypothesis with smallest $p(T_{q,i})$ (24.25) as the most likely hypothesis,

$$\min_{q,i} p(T_{q,i}) \, . \tag{24.64}$$

These $p$-values do not need to be compared to a criterion if it is assumed that the set (24.62) indeed covers all hypotheses that can possibly occur. The identification can then be restricted to choosing the most likely alternative. However, if one leaves the option open of alternative hypotheses that are not in the set, then a comparison with a chosen level of significance is needed so as to decide whether the most likely alternative is indeed likely enough. An alert is then given if none are considered likely enough. In that case we have rejection at the detection stage, but no identification among the set of specified alternative hypotheses. Different approaches exist to link the levels of significance of identification to that of detection; see for example, [24.34, 61–63].

### Adaptation

Once one or more likely model errors have been identified, a corrective action needs to be undertaken in order to get the null hypothesis accepted. Here, one of the two following approaches can be used in principle. Either one replaces the data or part of the data with new data such that the null hypothesis does get accepted, or, one replaces the original null hypothesis with a new hypothesis that does take the identified model errors into account. The first approach amounts to a remeasurement of (part of) the data. In the second approach no remeasurement is undertaken. Instead the identified hypothesis becomes the new null hypothesis. Thus the model of the null hypothesis is enlarged by adding the additional parameters as identified in the identification step. With $\mathcal{H}_a$ being the identified hypothesis and $\hat{\boldsymbol{b}}$ its estimated bias vector, the adaptation amounts to correcting the biased solution $\hat{\boldsymbol{x}}$ through

$$\hat{\boldsymbol{x}}_a = \hat{\boldsymbol{x}} - \mathbf{A}^+\mathbf{C}\hat{\boldsymbol{b}} \overset{\mathcal{H}_a}{\sim} \mathcal{N}(\boldsymbol{x}, \mathbf{Q}_{\hat{\boldsymbol{x}}_a\hat{\boldsymbol{x}}_a}) \, , \tag{24.65}$$

with $\mathbf{Q}_{\hat{\boldsymbol{x}}_a\hat{\boldsymbol{x}}_a} = \mathbf{Q}_{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}} + \mathbf{A}^+\mathbf{C}\mathbf{Q}_{\hat{\boldsymbol{b}}\hat{\boldsymbol{b}}}\mathbf{C}^{\mathrm{T}}\mathbf{A}^{+\top}$. Note that although $\hat{\boldsymbol{x}}_a$ is unbiased, it has a poorer precision than the biased solution $\hat{\boldsymbol{x}}$. This is the price one pays for reducing the bias from the solution.

Once the adaptation step is completed, one of course still has to make sure whether the newly created situation is acceptable or not. This at least implies a repetition of the detection step. When adaptation is applied, one also has to be aware of the fact that since the model may have changed, also the *strength of the model* may have changed. In fact, when the model is adapted through the addition of more explanatory parameters, the model has become weaker in the sense that the test statistics will now have less detection and identification power. It depends on the particular application at hand whether this is considered acceptable or not.

## 24.4.2 Data Snooping

An important example of multiple hypothesis testing is the problem of screening the observations for possible outliers [24.34, 56, 64–73].

The set of alternative hypotheses will then include those that describe outliers in individual observations. Here we restrict ourselves to the case of one outlier at a time. In that case there are as many alternative hypotheses as there are observations, with each alternative describing the outlier in an observation. Thus

$$\mathcal{H}_i : \boldsymbol{b}_{\boldsymbol{y}} = \boldsymbol{c}_i b_i, \; b_i \in \mathbb{R} \;\; , \;\; i = 1, \ldots, m \, , \tag{24.66}$$

with $\boldsymbol{c}_i$ the canonical unit vector having 1 as its $i$th entry. Thus $b_i$ is the scalar outlier and $i$ indicates the observation that is assumed to be affected by it. By letting $i$ run from 1 up to and including $m$, one can screen the whole dataset for the presence of potential blunders in the individual observations. The test statistic $w_i$ ((24.35), with $\boldsymbol{c} := \boldsymbol{c}_i$), which returns the in absolute value largest value, then pinpoints the observation that is most likely corrupted with an outlier or blunder. Its significance is measured by comparing the value of the test statistic with the critical value $k$. Thus, in analogy with (24.63), the $j$th observation is suspected to have an outlier, when

$$\begin{aligned} |w_j| &= \max_i |w_i| \geq k \, , \quad \text{or} \\ p_j &= \min_i p_i \leq \alpha \, , \end{aligned} \tag{24.67}$$

with critical value

$$k = \mathcal{N}_{\frac{1}{2}\alpha}(0, 1) \, ,$$

$p$-value $p_i = 2[1-\Phi(|w_i|)]$ and $\Phi(x)$ the standard normal distribution function. This procedure of screening each individual observation for the presence of an outlier is known as *data snooping* [24.34, 61]. In the special case of a diagonal variance matrix $\mathbf{Q}_{yy}$ it is sometimes also referred to as the *maximum residual technique* [24.27]. The adaptation step of data snooping can follow (24.65). Due to the special structure of $\mathbf{C} = \boldsymbol{c}_i$, this adaptation step in essence means that $\hat{\boldsymbol{x}}_a$ is computed with the measurement corresponding to the maximum $w$-statistic excluded.

Although formulation (24.66) assumes the presence of a single outlier, (iterated) data snooping is also used to find multiple outliers. For a discussion on multiple outlier testing, see for example [24.74–82]. Also note that one can generalize the constant critical value $k$ of (24.67) to a variable setting, i. e., a critical value $k_i$ per $w_i$-test, thus allowing for extra flexibility in testing.

When evaluating a multiple testing procedure, one can in principle not work anymore with the binary probabilities of false alarm and missed detection of (24.24). That is, for a consideration of the error probabilities, one has to consider the complete partitioning of the multidimensional sample space into acceptance and rejection regions. In the case of the above data snooping with constant critical value $k$ this implies that the acceptance region is given by the origin centered hyper-cube

$$\mathcal{A} = \{x \in \mathbb{R}^m | \; |x_i| \leq k, i = 1, \ldots, m\} \; .$$

Defining the $m$-vector of $w_i$-statistics as

$$\boldsymbol{w} = (w_1, \ldots, w_m)^{\mathrm{T}} \; ,$$

the probabilities of false alarm and missed detection now read

$$\begin{aligned} P_{\mathrm{FA}} &= P(\boldsymbol{w} \notin \mathcal{A} \mid \mathcal{H}_0) \; , \\ P_{\mathrm{MD}_i} &= P(\boldsymbol{w} \in \mathcal{A} \mid \mathcal{H}_i) \; . \end{aligned} \tag{24.68}$$

These probabilities can be computed using Monte Carlo integration [24.60]. The binary missed detection probability $P(|w_i| \leq k \mid \mathcal{H}_i)$ is an upper bound for $P_{\mathrm{MD}_i}$. Thus if the binary probability of missed detection is acceptable so is the overall one. This is however not true for the false alarm. To get an idea of the multidimensionality effect, assume that the $m$ number of $w_i$-test statistics is independent and that all $m$ tests are executed with a level of significance $\alpha$. Then under $\mathcal{H}_0$, $(1-\alpha)^m$ is the probability that all tests are accepted and thus $P_{\mathrm{FA}} = 1-(1-\alpha)^m$. Hence, with a choice $\alpha = 5\%$, this would already give a false alarm probability of $P_{\mathrm{FA}} = 64\%$ if $m = 20$. This shows that care has to be taken in choosing the level of significance for the individual tests. The probability becomes an upper bound of the false alarm if the assumption of independence is dropped

$$P_{\mathrm{FA}} \leq 1-(1-\alpha)^m \approx m\alpha \; . \tag{24.69}$$

The approximation of the upper bound is sharp for small $\alpha$. This result can now be used to control the false alarm rate of data snooping. If one requires the overall false alarm rate of data snooping (DS) to be not greater than $P_{\mathrm{FA}} = \alpha_{\mathrm{DS}}$, then the level of significance for each individual test could be chosen as $\alpha = 1-(1-\alpha_{\mathrm{DS}})^{\frac{1}{m}} \approx \alpha_{\mathrm{DS}}/m$. The latter correction is known as the Bonferroni correction [24.83].

Although the above level-of-significance adjustment certainly controls the overall false alarm rate of data snooping, it may sometimes, when $m$ is large, also lead to too small values and therefore to larger probabilities of missed detection. This is due to the fact that the above upper bound discards the dependence among the $w_i$-test statistics. There do exist less conservative procedures, including those that take a somewhat different criterion for the multidimensional false alarm. The approach above is based on controlling the probability that one or more of the rejected hypotheses is true. An alternative is the false discovery rate approach. Instead of controlling the probability that one or more of the rejected hypotheses is true, it controls the *expected* number of false rejections from among the rejected hypotheses; see for example [24.63, 84–86].

The consequence of the multiple testing involved in data snooping is that for the evaluation of the probability of hazardous missed detection, one has next to the missed detection probability, $P_{\mathrm{MD}_i}$ (24.68), also a corresponding probability of hazardous occurrence, $P_{\mathrm{H}_i} = P(P_n \geq \chi^2_\eta(n,0) \mid \mathcal{H}_i)$, for each alternative hypothesis $\mathcal{H}_i$. Hence, we have per alternative hypothesis, $P_{\mathrm{HMD}}(b_i) = P_{\mathrm{H}_i} \times P_{\mathrm{MD}_i}$. These conditional probabilities (i. e., conditioned on $\mathcal{H}_i$) can be evaluated individually, or unconditionally as a weighted average,

$$P_{\mathrm{HMD}}(\boldsymbol{b}) = \sum_{i=1}^{m} p_i P_{\mathrm{HMD}}(b_i) \; , \tag{24.70}$$

with the weights summing up to one, $\sum_{j=1}^{m} p_j = 1$. If the a priori probabilities for the occurrence of the individual alternative hypotheses, $P(\mathcal{H}_i)$ $i = 1, \ldots, m$ are available, then the weights are given by their relative frequencies,

$$p_i = P(\mathcal{H}_i) / \sum_{j=1}^{m} P(\mathcal{H}_j) \; .$$

In case one would like to include the hazardous occurrence under $\mathcal{H}_0$ as well in the evaluation, then (24.70)

**Table 24.2** Outliers $b$ (m) in PRN pseudoranges, epochs of their occurrence $k$ and their estimated values $\hat{b}$ (m)

| Epoch | PRN | $b$ | $\hat{b}$ |
|---|---|---|---|
| $k = 50$ | 22 | 10 | 9.5 |
| $k = 100$ | 31 | −10 | −9.3 |
| $k = 150$ | 19 | 10 | 9.4 |
| $k = 200$ | 17 | 5 | 5.1 |
| $k = 250$ | 23 | 2 | 2.1 |
| $k = 300$ | 31 | 2 | 2.2 |

needs extension with the probability $P_0 = \eta \times (1-\alpha)$, to give the probability of hazardous misleading information $P_{\mathrm{HMI}}(\boldsymbol{b}) = p_0 P_0 + (1-p_0) P_{\mathrm{HMD}}(\boldsymbol{b})$, with $p_0$ being the a priori occurrence probability of the null hypothesis [24.87]. Since the relative occurrences of the alternative hypotheses $\mathcal{H}_i$ (24.66) are often easier to specify than the probability of occurrence of the null hypothesis itself, it is usually easier to work with (24.70). As both probabilities show the same variability as function of the biases, both have the same *worst-case bias solution*.

### *Example 24.15 Differential GPS*

We now briefly discuss a Differential Global Positioning System (DGPS) testing example taken from [24.57]. The model on which this example is based is one of instantaneous relative positioning using single frequency code data. Both receivers tracked the same seven satellites every epoch using a sampling interval of ten seconds. Atmospheric delays were neglected because of the short baseline length ($\approx 3$ km). The standard deviation of the undifferenced code observable was set at $\sigma_p = 30$ cm in zenith. The skyplot over the observation period is shown in Fig. 24.14. At six different epochs over the observation period, one of the seven pseudoranges was artificially corrupted by an outlier. The epoch number ($k$), the corrupted pseudorange (PRN) and the size of the outlier ($b$) are shown in the first three columns of Table 24.2. The last column shows the least-squares estimate $\hat{b}$ of the outlier.

Over the observation period the MDBs were about 2–3 m. The results of the detection step are depicted in Fig. 24.15. Along the vertical axis the normalized test statistic

$$\frac{T_{q=3}}{\chi^2_\alpha(3,0)}$$

is shown. The null hypothesis is rejected when this value exceeds one. The figure clearly shows that model errors are indeed detected at the above given six different epochs. Identification of the model errors is therefore needed for these six epochs. For each epoch this is done with the identification test statistic $w_i$. For each epoch, there are seven of such test statistics, one for each (single differenced) pseudorange. The values of these test statistics are shown in Table 24.3. The in

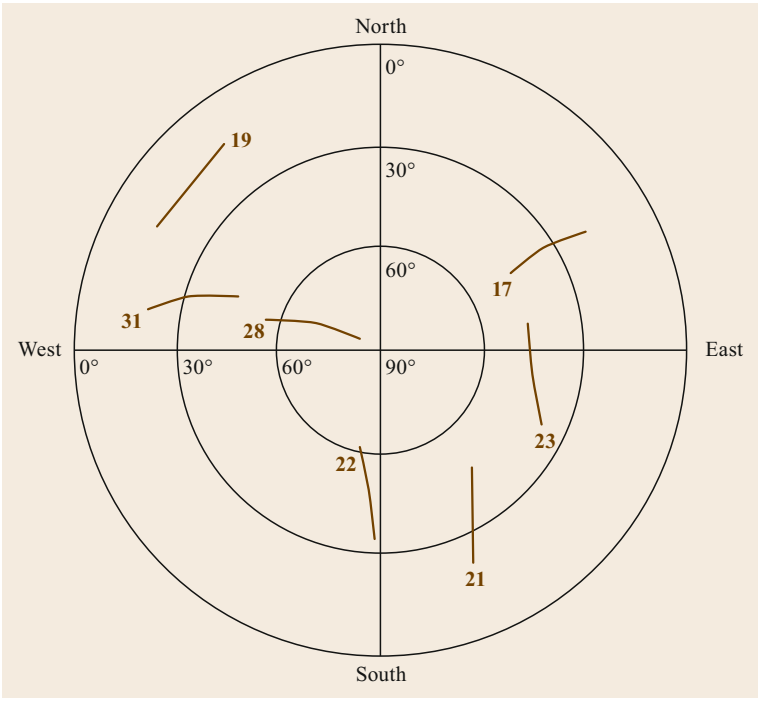

**Fig. 24.14** Skyplot of seven GPS satellites with their PRN numbers; (after [24.4])

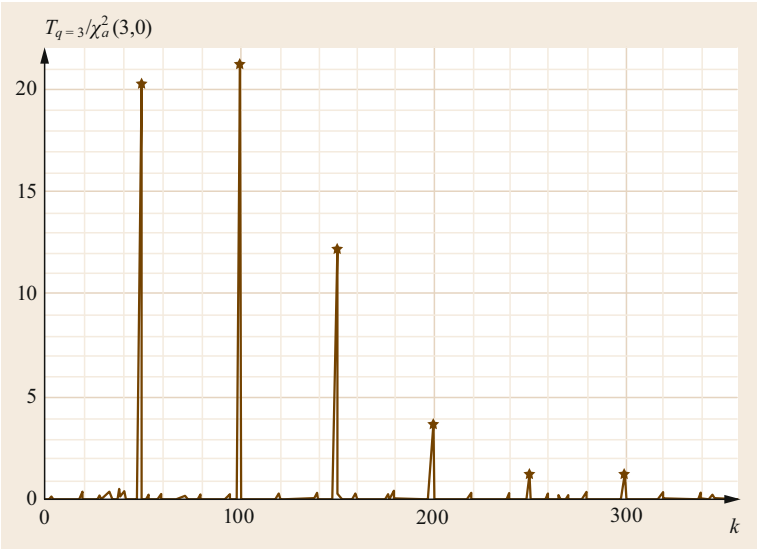

**Fig. 24.15** Time series of normalized test statistic $T_{q=3}/\chi^2_\alpha(3,0)$ (after [24.4])

**Table 24.3** Data snooping $w_i$-values $(i = 1,\ldots,7)$ for the seven pseudoranges at the six epochs $k = 50, 100, 150, 200, 250, 300$

| PRN/$k$ | 50 | 100 | 150 | 200 | 250 | 300 |
|---|---|---|---|---|---|---|
| 17 | 1.9 | –4.6 | –6.4 | *6.8* | –3.4 | 0.2 |
| 19 | 7.5 | –14.8 | *12.4* | –3.9 | 0.6 | –3.1 |
| 21 | –7.5 | 5.5 | –1.8 | –0.1 | –0.5 | 0.3 |
| 22 | *15.9* | 3.5 | 3.7 | 2.5 | –1.0 | –0.7 |
| 23 | –2.7 | –4.0 | 2.5 | –6.0 | *3.9* | 0.7 |
| 31 | –2.2 | *–16.3* | –11.4 | 1.7 | 1.1 | *3.9* |
| 28 | –13.9 | 6.8 | 3.5 | –0.4 | –2.7 | –3.6 |

absolute value largest test statistics are shown in *italics*. They indicate the pseudoranges that are most likely corrupted by outliers. The values in italic all exceed the critical value $\mathcal{N}_{\alpha/2}(0,1) = 3.29$. In this case all code outliers were correctly identified; compare Tables 24.2 and 24.3.

### 24.4.3 Unknowns in the Stochastic Model

So far we assumed the variance matrix of the observables to be known. In some applications it may happen however that the variance matrix $\mathbf{Q}_{yy}$ is only partly known. The simplest of such cases occurs if the variance matrix is known up to an unknown scale factor $\sigma^2$, the so-called *variance of unit weight*. Then

$$\mathbf{Q}_{yy} = \sigma^2 \mathbf{C}_{yy} \,,$$

with known cofactor matrix $\mathbf{C}_{yy}$, but unknown scalar $\sigma^2$. If this is the case, then none of the previously discussed test statistics can be computed, since (24.30)

$$T_q = \frac{||\hat{\boldsymbol{b}}||^2_{\mathbf{C}_{\hat{b}\hat{b}}}}{\sigma^2} \,. \tag{24.71}$$

To cope with this situation, the idea is to replace the unknown $\sigma^2$ with an unbiased estimator of it. There are two such candidates, namely

$$\hat{\sigma}^2 = \frac{||\hat{\boldsymbol{e}}||^2_{\mathbf{C}_{yy}}}{m-n} \quad \text{and} \quad \hat{\sigma}^2_{\mathrm{a}} = \frac{||\hat{\boldsymbol{e}}_{\mathrm{a}}||^2_{\mathbf{C}_{yy}}}{m-n-q} \,. \tag{24.72}$$

Thus if $\sigma^2$ is unknown, one can work, instead of with (24.71), with either one of the following two test statistics

$$T'_q = \frac{||\hat{\boldsymbol{b}}||^2_{\mathbf{C}_{\hat{b}\hat{b}}}}{q\hat{\sigma}^2} \,, \quad T''_q = \frac{||\hat{\boldsymbol{b}}||^2_{\mathbf{C}_{\hat{b}\hat{b}}}}{q\hat{\sigma}^2_{\mathrm{a}}} \,. \tag{24.73}$$

The statistic $T''_q$ has an $F$-distribution with $q$ and $(m-n-q)$ degrees of freedom, while $q/(m-n)T'_q$ has a beta distribution with $q/2$ and $(m-n-q)/2$ degrees of freedom [24.31, 88]. The two test statistics are functionally related as

$$T'_q = \frac{(m-n)T''_q}{(m-n-q)+qT''_q} \,. \tag{24.74}$$

Note that they cannot be used for

$$q = m - n \,,$$

since then $T'_q = 1$ and $T''_q$ is undefined. Hence, no detection test (24.61) exists when $\sigma^2$ is unknown. For the one-dimensional case $q = 1$, we have

$$\begin{aligned} T'_{q=1} &= (w')^2 \quad \text{and} \\ T''_{q=1} &= (w'')^2 \,, \end{aligned} \tag{24.75}$$

with

$$w' = \frac{\sigma}{\hat{\sigma}} w \,, \; w'' = \frac{\sigma}{\hat{\sigma}_\mathrm{a}} w \,. \tag{24.76}$$

Thus in the case where $\sigma^2$ is unknown, $w'$ or $w''$ can be used instead of $w$. They have a $\tau$- and Student $t$-distribution respectively [24.64, 89]. In the case where $\mathbf{C}_{yy}$ is diagonal and $\boldsymbol{c}$ is the canonical unit-vector, $w'$ and $w''$ are referred to as the *internal* and *external* Studentized residuals respectively [24.65, 70].

## 24.5 Recursive Model Validation

### 24.5.1 Model and Filter

In the previous section the parameter vector $\boldsymbol{x}$ was assumed to be time invariant and completely unknown. In the present section we will relax these assumptions. First, the parameter vector $\boldsymbol{x}$ (from now on referred to as the state vector) will be allowed to vary with time. Thus instead of the notation $\boldsymbol{x}$, we will now use the notation $\boldsymbol{x}_k$ to indicate the (discrete) time epoch $k$ to which $\boldsymbol{x}$ refers. Secondly, we will assume that the parameter vector, instead of being deterministic, is now a random vector as well.

The model on which the filter is based consists of two parts (Chap. 22). As before we have an observational model that links the observables to the state vector. But in addition we now also have a dynamic model, describing the variability of the state vector over time. Both the measurement model and dynamic model constitute the null hypothesis $\mathcal{H}_0$.

*Measurement model*: The link between the vector of observables $\boldsymbol{y}_k \in \mathbb{R}^{m_k}$ and the state-vector $\boldsymbol{x}_k \in \mathbb{R}^n$ is assumed given as

$$\boldsymbol{y}_k = \mathbf{A}_k \boldsymbol{x}_k + \boldsymbol{n}_k, \; k = 0, \ldots \,, \tag{24.77}$$

with

$$\begin{aligned} E(\boldsymbol{x}_0) &= \bar{\boldsymbol{x}}_0 \,, \\ E(\boldsymbol{n}_k) &= \mathbf{0} \,, \\ C(\boldsymbol{x}_0, \boldsymbol{n}_k) &= \mathbf{0} \,, \quad \text{and} \\ C(\boldsymbol{n}_k, \boldsymbol{n}_l) &= \mathbf{R}_k \delta_{k,l} \,, \end{aligned}$$

where $C(\boldsymbol{u}, \boldsymbol{v})$ denotes the covariance between two random vectors $\boldsymbol{u}$ and $\boldsymbol{v}$, $\mathbf{R}_k$ is the variance matrix of the measurement noise $\boldsymbol{n}_k$ and $\delta_{k,l}$ is the Kronecker delta. Thus the zero-mean measurement noise $\boldsymbol{n}_k$ is assumed to be uncorrelated in time and to be uncorrelated with the initial state-vector $\boldsymbol{x}_0$.

*Dynamic model*: The linear dynamic model, describing the time evolution of $\boldsymbol{x}_k$, is given as

$$\boldsymbol{x}_k = \boldsymbol{\Phi}_{k,k-1} \boldsymbol{x}_{k-1} + \boldsymbol{d}_k, k = 1, \ldots \,, \tag{24.78}$$

with

$$\begin{aligned} E(\boldsymbol{d}_k) &= \mathbf{0} \,, \\ C(\boldsymbol{x}_0, \boldsymbol{d}_k) &= \mathbf{0} \,, \\ C(\boldsymbol{d}_k, \boldsymbol{n}_l) &= \mathbf{0} \,, \\ C(\boldsymbol{d}_k, \boldsymbol{d}_l) &= \mathbf{S}_k \delta_{k,l} \,, \end{aligned}$$

where $\boldsymbol{\Phi}_{k,k-1}$ denotes the transition matrix and $\mathbf{S}_k$ the variance matrix of the system noise $\boldsymbol{d}_k \in \mathbb{R}^n$. The system noise $\boldsymbol{d}_k$ is thus also assumed to have a zero mean, to be uncorrelated in time and to be uncorrelated with the initial state-vector and the measurement noise.

If the mean of the initial state, $E(\boldsymbol{x}_0)$, is assumed unknown, it first needs to be estimated. Since we will assume here that the initial state $\hat{\boldsymbol{x}}_{0|0}$ and its error-variance matrix $\mathbf{P}_{0|0}$ are known, we start the recursion from these initial values. The recursive procedure consists then of two steps for every epoch, a time update (TU) and a measurement update (MU)

$$\begin{aligned} \hat{\boldsymbol{x}}_{k|k-1} &= \boldsymbol{\Phi}_{k,k-1} \hat{\boldsymbol{x}}_{k-1|k-1} \,, \\ \hat{\boldsymbol{x}}_{k|k} &= \hat{\boldsymbol{x}}_{k|k-1} + \mathbf{K}_k (\boldsymbol{y}_k - \mathbf{A}_k \hat{\boldsymbol{x}}_{k|k-1}) \,. \end{aligned} \tag{24.79}$$

The time update propagates the state vector estimate of epoch $k-1$ to the next epoch $k$, thus giving the predicted state vector of epoch $k$. The measurement update combines in a least-squares sense the predicted state vector with the observations of epoch $k$ to produce the filtered state vector at that epoch. The above pair of equations is often referred to as the Kalman filter and matrix $\mathbf{K}_k$ as the Kalman gain matrix [24.90–93]. The (error) variance matrices of the predicted and filtered state vector

are given as

$$\begin{aligned}\mathbf{P}_{k|k-1} &= \boldsymbol{\Phi}_{k,k-1}\mathbf{P}_{k-1|k-1}\boldsymbol{\Phi}_{k,k-1}^{\top} + \mathbf{S}_k \,, \\ \mathbf{P}_{k|k} &= (\mathbf{I}_n - \mathbf{K}_k\mathbf{A}_k)\mathbf{P}_{k|k-1} \,. \end{aligned} \tag{24.80}$$

Due to the presence of the system's noise, we usually have a worsening of the precision in the time-update step, $\mathbf{P}_{k|k-1} > \mathbf{P}_{k-1|k-1}$, while in the measurement-update, with the additional measurements, the precision improves again such that $\mathbf{P}_{k|k} < \mathbf{P}_{k|k-1}$.

An important role in the process of recursive model validation is played by the so-called predicted residuals. They play a role that is similar to that of the least-squares residuals in the previous sections. The predicted residual and its variance matrix are given as

$$\begin{aligned}\boldsymbol{v}_k &= \boldsymbol{y}_k - \mathbf{A}_k\hat{\boldsymbol{x}}_{k|k-1} \,, \\ \mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k} &= \mathbf{R}_k + \mathbf{A}_k\mathbf{P}_{k|k-1}\mathbf{A}_k^{\top} \,. \end{aligned} \tag{24.81}$$

The predicted residuals have the important property that they are zero-mean and uncorrelated in time

$$E(\boldsymbol{v}_k) = \mathbf{0} \,, \; C(\boldsymbol{v}_k, \boldsymbol{v}_l) = \mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k}\delta_{k,l} \,. \tag{24.82}$$

It are these properties that make it possible to formulate a recursive testing procedure that can be executed in parallel to the Kalman filter [24.10, 25, 57, 75, 94, 95],

### 24.5.2 Models and UMPI Test Statistic

The above Kalman filter produces optimal estimators of the state vector with well-defined statistical properties. This optimality is only guaranteed however as long as the assumptions underlying the model, i. e., the null hypothesis $\mathcal{H}_0$, hold. Misspecifications in $\mathcal{H}_0$ will invalidate the results of estimation and thus also any conclusions based on them. In the following we restrict attention, as before, to misspecifications in the mean. This implies that the predicted residuals have a zero-mean under $\mathcal{H}_0$, but not so under $\mathcal{H}_\mathrm{a}$. Thus if we collect all $k$ vectors of predicted residuals in one vector $\boldsymbol{v} = (\boldsymbol{v}_1^{\mathrm{T}}, \ldots, \boldsymbol{v}_k^{\mathrm{T}})^{\mathrm{T}}$, the null and alternative hypotheses can be expressed in terms of the predicted residuals as

$$\mathcal{H}_0 : E(\boldsymbol{v}) = \mathbf{0} \text{ versus } \mathcal{H}_\mathrm{a} : E(\boldsymbol{v}) = \mathbf{C}_{\boldsymbol{v}}\boldsymbol{b} \,. \tag{24.83}$$

The $\mathbf{C}_{\boldsymbol{v}}$-matrix is of order $\sum_{i=1}^{k} m_i \times q$ and follows from propagating the assumed misspecifications in the mean through the time update and measurement update respectively.

As before one can now estimate $\boldsymbol{b}$ under $\mathcal{H}_\mathrm{a}$ and test its significance using the UMPI test statistic

$$T_q = \hat{\boldsymbol{b}}^{\mathrm{T}}\mathbf{Q}_{\hat{\boldsymbol{b}}\hat{\boldsymbol{b}}}^{-1}\hat{\boldsymbol{b}} \overset{\mathcal{H}_0}{\sim} \chi^2(q, 0) \tag{24.84}$$

in which the bias estimator $\hat{\boldsymbol{b}}$ and its variance matrix $\mathbf{Q}_{\hat{\boldsymbol{b}}\hat{\boldsymbol{b}}}$ are computed from the vector of predicted residuals $\boldsymbol{v}$ as

$$\begin{aligned}\hat{\boldsymbol{b}} &= (\mathbf{C}_{\boldsymbol{v}}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}\boldsymbol{v}}^{-1}\mathbf{C}_{\boldsymbol{v}})^{-1}\mathbf{C}_{\boldsymbol{v}}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}\boldsymbol{v}}^{-1}\boldsymbol{v} \,, \\ \mathbf{Q}_{\hat{\boldsymbol{b}}\hat{\boldsymbol{b}}} &= (\mathbf{C}_{\boldsymbol{v}}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}\boldsymbol{v}}^{-1}\mathbf{C}_{\boldsymbol{v}})^{-1} \,. \end{aligned} \tag{24.85}$$

Using this result one can express the test statistic (24.84) also directly in the predicted residuals

$$T_q = \boldsymbol{v}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}\boldsymbol{v}}^{-1}\mathbf{C}_{\boldsymbol{v}}(\mathbf{C}_{\boldsymbol{v}}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}\boldsymbol{v}}^{-1}\mathbf{C}_{\boldsymbol{v}})^{-1}\mathbf{C}_{\boldsymbol{v}}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}\boldsymbol{v}}^{-1}\boldsymbol{v} \,. \tag{24.86}$$

Although this form is the equivalent of (24.32), it has the advantage of being expressed in the predicted residuals which, after all, are readily available at each measurement update (cf. (24.79) and (24.81)).

The above expressions form the basis for Kalman-filter model validation. They are however not yet in a form that facilitates *recursive* testing. This will become possible though if we make use of the block diagonal structure of the variance matrix of the vector of predicted residuals,

$$D(\boldsymbol{v}) = \mathbf{Q}_{\boldsymbol{v}\boldsymbol{v}} = \mathrm{blockdiag}(\mathbf{Q}_{\boldsymbol{v}_1\boldsymbol{v}_1}, \ldots, \mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k}) \,. \tag{24.87}$$

With the use of this block diagonal structure, the test statistic (24.86) can be written as

$$\begin{aligned}T_q = &\left(\sum_{i=1}^{k} \boldsymbol{v}_i^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}_i\boldsymbol{v}_i}^{-1}\mathbf{C}_{\boldsymbol{v}_i}\right)\left(\sum_{i=1}^{k} \mathbf{C}_{\boldsymbol{v}_i}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}_i\boldsymbol{v}_i}^{-1}\mathbf{C}_{\boldsymbol{v}_i}\right)^{-1} \\ &\times \left(\sum_{i=1}^{k} \mathbf{C}_{\boldsymbol{v}_i}^{\mathrm{T}}\mathbf{Q}_{\boldsymbol{v}_i\boldsymbol{v}_i}^{-1}\boldsymbol{v}_i\right) \,. \end{aligned} \tag{24.88}$$

It is this expression that we will use in the following as basis for the recursive detection, identification and adaptation. The design and performance analysis of recursive testing (e.g., MDB and BNR analyses) can be done in a way that is similar to what has been discussed earlier for the batch model; see for example [24.26, 35, 53, 96–98].

### 24.5.3 Local and Global Testing

We make a distinction between *local* model testing and *global* model testing (Fig. 24.16). We speak of local model testing when the tests performed at time $k$ only depend on the predicted state vector at time $k$ and the observations of time $k$. Thus for the local case we assume that no invalidation of the model has taken place

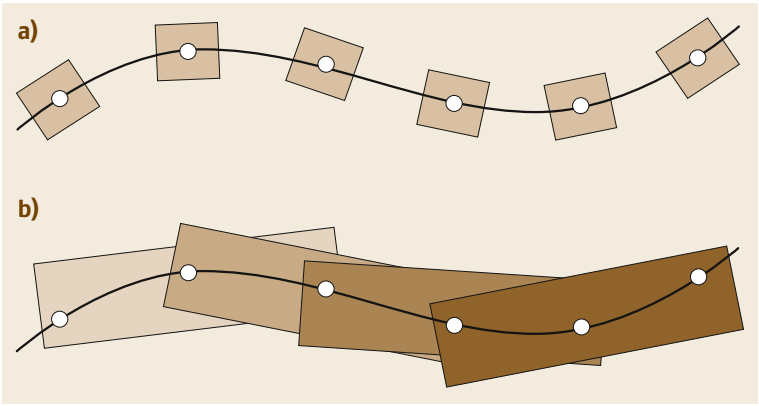

**Fig. 24.16** Local (top) and global (bottom) testing (after [24.25])

prior to the present time of testing $k$. This implies that attention can be restricted to the following *local* hypotheses

$$\mathcal{H}_0^k : E(\boldsymbol{v}_k) = \mathbf{0} \text{ versus } \mathcal{H}_\mathrm{a}^k : E(\boldsymbol{v}_k) = \mathbf{C}_{v_k}\boldsymbol{b} \tag{24.89}$$

in which the type of model error occurring at epoch $k$ is specified through the $m_k \times q$ matrix $\mathbf{C}_{v_k}$.

If the test takes more than one epoch into account we speak of global testing. For those cases we consider the following *global* hypotheses

$$\mathcal{H}_0^{l,k} : E(\boldsymbol{v}^{l,k}) = \mathbf{0} \text{ versus } \mathcal{H}_\mathrm{a}^{l,k} : E(\boldsymbol{v}^{l,k}) = \mathbf{C}_{\boldsymbol{v}}^{l,k}\boldsymbol{b}\,, \tag{24.90}$$

with $l$ the epoch the assumed model error is supposed to have started, $k$ the current epoch,

$$\boldsymbol{v}^{l,k} = (\boldsymbol{v}_l^\mathrm{T}, \ldots, \boldsymbol{v}_k^\mathrm{T})^\mathrm{T}\,,$$

and

$$\mathbf{C}_{\boldsymbol{v}}^{l,k} = (\mathbf{C}_{\boldsymbol{v}_l}^\mathrm{T}, \ldots, \mathbf{C}_{\boldsymbol{v}_k}^\mathrm{T})^\mathrm{T}\,.$$

This distinction between local and global is introduced in order to discriminate between model errors that have either a local or a more global character. By definition, the local procedure can be executed in real time. That is, the corrective action of the adaptation step is designed to coincide with the moment the model error occurred.

Global testing is of course more powerful than local testing. Hence, for certain model errors local testing may be too insensitive. Model errors that slowly build up as time proceeds may have a high probability of passing the local tests unnoticed. For such type of errors global testing is needed, due to their built-in memory capabilities. The price paid for the higher power of the global tests is the delay between the time the model error started to occur and the time of detection. But such a delay will be acceptable if it is considered more important to detect the model error than to not detect it at all.

### 24.5.4 Recursive Detection

#### Local Detection

Local detection applies when one assumes the most relaxed version of the alternative in (24.89),

$$\mathcal{H}_0^k : E(\boldsymbol{v}_k) = \mathbf{0} \text{ versus } \mathcal{H}_\mathrm{a}^k : E(\boldsymbol{v}_k) \in \mathbb{R}^{m_k}\,. \tag{24.91}$$

As no restrictions are imposed on the mean of the predicted residual under $\mathcal{H}_\mathrm{a}^k$, the matrix $\mathbf{C}_{v_k}$ in (24.89) is chosen as a square and regular matrix and thus $q = m_k$. Since $\mathbf{C}_{v_i} = \mathbf{0}$ for $i < k$, the corresponding test statistic for the *local overall model* (LOM) test follows from (24.88) as

$$T_\mathrm{LOM}^k = \frac{\boldsymbol{v}_k^\mathrm{T}\mathbf{Q}_{v_k v_k}^{-1}\boldsymbol{v}_k}{m_k} \overset{\mathcal{H}_0^k}{\sim} F(m_k, \infty, 0)\,. \tag{24.92}$$

An unspecified model error is considered present at time $k$ when $T_\mathrm{LOM}^k > F_\alpha(m_k, \infty, 0)$. Note that we divided the quadratic form in (24.92) by the local redundancy $m_k$. This is not essential, but is merely done for practical reasons so as to have a graphical display of the time series of $T_\mathrm{LOM}^k$ fluctuate around the value of one, since

$$E(T_\mathrm{LOM}^k | \mathcal{H}_0) = 1\,.$$

The normalization by $m_k$ changes the distribution from a $\chi^2$-distribution into an $F$-distribution. A similar normalization is done in the case of the global detector.

### Global Detection

The above LOM test may turn out to be too insensitive to detect global unmodeled trends. For those cases we consider the following *global* hypotheses

$$\mathcal{H}_0^{l,k} : E(\boldsymbol{v}^{l,k}) = \mathbf{0} \text{ versus } \mathcal{H}_a^{l,k} : E(\boldsymbol{v}^{l,k}) \in \mathbb{R}^{\sum_{i=l}^{k} m_i} . \tag{24.93}$$

Thus matrix $\mathbf{C}_{\boldsymbol{v}}^{l,k}$ of (24.90) is chosen as a square and regular matrix and

$$q = \sum_{i=l}^{k} m_i .$$

The corresponding *global overall model* (GOM) test statistic can be written in recursive form as

$$T_{\text{GOM}}^{l,k} = T_{\text{GOM}}^{l,k-1} + g_k \left( T^k - m_k T_{\text{GOM}}^{l,k-1} \right) , \tag{24.94}$$

with

$$T^k = \boldsymbol{v}_k^{\mathrm{T}} \mathbf{Q}_{\boldsymbol{v}_k \boldsymbol{v}_k}^{-1} \boldsymbol{v}_k$$

and the scalar gain (Fig. 24.17)

$$g_k = \frac{1}{\sum_{i=l}^{k} m_i} .$$

The recursion is initialized with $T_{\text{GOM}}^{l,l} = T_{\text{LOM}}^{l}$. An unspecified model error within the interval $[l, k]$ is considered detected at time $k$ when

$$T_{\text{LOM}}^{l,k} > F_\alpha \left( \sum_{i=l}^{k} m_k, \infty, 0 \right) .$$

Note that this test reduces to its local counterpart when $l = k$.

A practical problem with the above test is the choice of $l$, the time that the model error is assumed to have started to occur. Since the starting time of the model error is unknown a priori, one has to start in principle with $l = 1$. A fixed value of $l$ however implies a growing memory recursion, with the practical problem of a possible long delay in time of detection. Rejection of $H_0$ at time $k$ with the GOM test may imply namely that a global model error started to occur as early as time $l = 1$. In order to reduce the time of delay, it is worthwhile to consider a moving window of length $N$ by constraining $l$ to $k - N + 1 \leq l \leq k$. When choosing $N$ one of course has to make sure that the detection power of the test is still sufficient. This is typically a problem one should take into consideration when designing the filter. With the finite window of length $N$, the recursion (24.94) essentially reduces to a *finite-memory* filter.

Instead of using a finite window, one could also consider using a fading window [24.93, 99, 100]. By setting $l = 1$ and replacing the gain $g_k$ by

$$\frac{\omega^k}{\sum_{i=l}^{k} m_i \omega^i} ,$$

with weight $\omega > 1$, the recursion reduces to a *fading-memory* filter. Note that with the fading window we still have $E(T_{\text{GOM}}^{l,k} | H_0) = 1$. Instead of a central $F$-distribution, the fading GOM-test statistic will now follow a linear combination of independent $\chi^2$-distributions. With the fading window, the same recursion (24.94) is retained. This becomes advantageous when compared to the finite window if a particular application requires the use of long windows. The weight $\omega$, which determines the nominal length of the fading window, is chosen on the basis of the detection power of the GOM test.

## 24.5.5 Recursive Identification

### Local Identification

Recall that the local alternative is of the form (24.89)

$$\mathcal{H}_a^k : E(\boldsymbol{v}_k) = \mathbf{C}_{\boldsymbol{v}_k} \boldsymbol{b} . \tag{24.95}$$

The type of model error considered is determined by the choice of the $m_k \times q$ matrix $\mathbf{C}_{\boldsymbol{v}_k}$. Any model error that biases $\boldsymbol{v}_k$ can be considered. These could be biases in the vector of observables $\boldsymbol{y}_k$ and/or in the predicted state

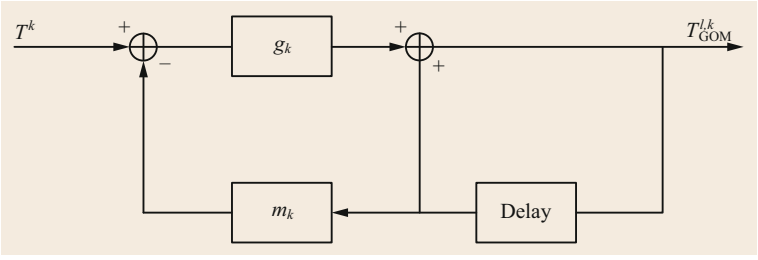

**Fig. 24.17** The recursion of the GOM test statistic

$\hat{\boldsymbol{x}}_{k|k-1}$. For an outlier in the $i$th entry of $\boldsymbol{y}_k$, for instance, the matrix $\mathbf{C}_{\boldsymbol{v}_k}$ reduces to the canonical unit vector having a one as its $i$th entry.

All test statistics for (24.95) follow from (24.88) by setting $\mathbf{C}_{\boldsymbol{v}_i} = \mathbf{0}$ for $i < k$. For the case $q = 1$, for example for data snooping at epoch $k$, one can make use of the normally distributed statistic

$$t^k = \frac{\boldsymbol{c}_{\boldsymbol{v}_k}^{\mathrm{T}} \mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k}^{-1} \boldsymbol{v}_k}{\sqrt{\boldsymbol{c}_{\boldsymbol{v}_k}^{\mathrm{T}} \mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k}^{-1} \boldsymbol{c}_{\boldsymbol{v}_k}}} \overset{\mathcal{H}_0}{\sim} \mathcal{N}(0,1) \tag{24.96}$$

since $T_{q=1}^k = (t^k)^2$.

### Global Identification

The global alternative is of the form (24.90)

$$\mathcal{H}_{\mathrm{a}}^{l,k} : E(\boldsymbol{v}^{l,k}) = \mathbf{C}_{\boldsymbol{v}}^{l,k} \boldsymbol{b} \,. \tag{24.97}$$

All test statistics for this global alternative follow from (24.88) by setting $\mathbf{C}_{\boldsymbol{v}_i} = \mathbf{0}$ for $i < l$. As they will be expressed in

$$\mathbf{C}_{\boldsymbol{v}}^{l,k} = (\mathbf{C}_{\boldsymbol{v}_l}^{\mathrm{T}}, \ldots, \mathbf{C}_{\boldsymbol{v}_k}^{\mathrm{T}})^{\mathrm{T}} \,,$$

we need a recursion for computing the entries of $\mathbf{C}_{\boldsymbol{v}}^{l,k}$ so as to be able to perform the testing recursively. The recursion of $\mathbf{C}_{\boldsymbol{v}_i}$, $i = l, \ldots, k$, can be determined from the way the assumed bias propagates itself through the time and measurement updates of the Kalman filter. For instance, if it is assumed that the means of the observables are biased in the interval $[l, k]$, then we have under the alternative

$$\mathcal{H}_{\mathrm{a}}^{l,k} : E(\boldsymbol{y}_i) = \mathbf{A}_i \boldsymbol{x}_i + \mathbf{C}_i \boldsymbol{b} \,, \; i \in [l, k] \,. \tag{24.98}$$

As the bias $\mathbf{C}_i \boldsymbol{b}$ propagates through the Kalman filter, it biases the predicted residuals and the predicted state as $\mathbf{C}_{\boldsymbol{v}_i} \boldsymbol{b}$ and $\mathbf{C}_{\hat{\boldsymbol{x}}_{i|i-1}} \boldsymbol{b}$ respectively, with the response matrices satisfying the recursion (Fig. 24.18)

$$\begin{cases} \mathbf{C}_{\boldsymbol{v}_i} = \mathbf{C}_i - \mathbf{A}_i \mathbf{C}_{\hat{\boldsymbol{x}}_{i|i-1}} \,, \; \mathbf{C}_{\hat{\boldsymbol{x}}_{l|l-1}} = 0 \,, \\ \mathbf{C}_{\hat{\boldsymbol{x}}_{i+1|i}} = \boldsymbol{\Phi}_{i+1,i} (\mathbf{C}_{\hat{\boldsymbol{x}}_{i|i-1}} + \mathbf{K}_i \mathbf{C}_{\boldsymbol{v}_i}) \,, i \geq l \,. \end{cases} \tag{24.99}$$

A likewise recursion can be found if, instead of the alternative (24.98), biases in the system noise are assumed present, for example due to an underparametrization of the dynamic model; see for example [24.25, 94].

As in the case of detection, the global identification test statistic can also be computed in recursive form. For $q = 1$, we have

$$\left(t^{l,k}\right)^2 = \left(t^{l,k-1}\right)^2 + h_{l,k} \left[ (t^k)^2 - \left(t^{l,k-1}\right)^2 \right] \,, \tag{24.100}$$

with gain

$$h_{l,k} = \frac{\boldsymbol{c}_{\boldsymbol{v}_k}^{\mathrm{T}} \mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k}^{-1} \boldsymbol{c}_{\boldsymbol{v}_k}}{\sum_{i=l}^k \boldsymbol{c}_{\boldsymbol{v}_i}^{\mathrm{T}} \mathbf{Q}_{\boldsymbol{v}_i\boldsymbol{v}_i}^{-1} \boldsymbol{c}_{\boldsymbol{v}_i}} \,.$$

Note that the local statistic $t^k$ of (24.96) is used as input for each new epoch.

Strictly speaking the above test statistic has to be computed for each alternative hypothesis considered and for each epoch $k > l$. However, since $l$ is unknown, one has to start in principle with $l = 1$. This implies that one has to compute $k$ number of test statistics per alternative hypothesis at the time of testing $k$. As a result one obtains a test matrix of increasing order with $t^{l,k}$ as its entries. An example is shown in Fig. 24.19.

Such an increase in the number of test statistics is clearly unpractical, both from a computational point of view and because of the potential delay in time of identification. Fortunately not all entries of the test matrix may be necessary if one studies the power of the test statistics. Although the power will increase for longer intervals $[l, k]$, at a certain stage the gain in power may become negligible for all practical purposes. This motivates, in accordance with our discussion of detection, the use of a moving window. This is shown in Fig. 24.19b for the case $l \in [k-N+1, k]$, with $N = 2$, and in Fig. 24.19c for the case $l \in [k-N+1, k-M]$, with $N = 2$ and $M = 1$. The rationale behind this last constraint is that in some applications the test statistic may be too insensitive for global identification if $l > k-M$.

Once the test matrix has been defined, the identification procedure can proceed as follows. At the time of testing $k$, one first determines per alternative hypothesis the value of $l$ in the window for which $|t^{l,k}|$ is at its maximum. Hence, the $k$th column of the test matrix is searched for the largest entry in absolute value. The corresponding matrix row number then identifies $l$ as the most likely time of occurrence of the model error if the corresponding alternative hypothesis would be true. In order to find both the most likely alternative hypothesis and most likely value of $l$, the values of $\max_{l \in [k-N+1, k-M]} |t^{l,k}|$ for the different alternative hypotheses are compared. The maximum of this set finally identifies the most likely time of occurrence $l$ and the most likely alternative hypothesis. Its likelihood is then tested against the chosen critical value or $p$-value.

## 24.5.6 Recursive Adaptation: General Case

After identification of the most likely model error, adaptation of the recursive filter is needed so as to reduce the presence of biases in the filtered state. If we assume that (24.97) has been identified as the most likely hypothesis, then – in analogy with (24.65) – the adaptation step

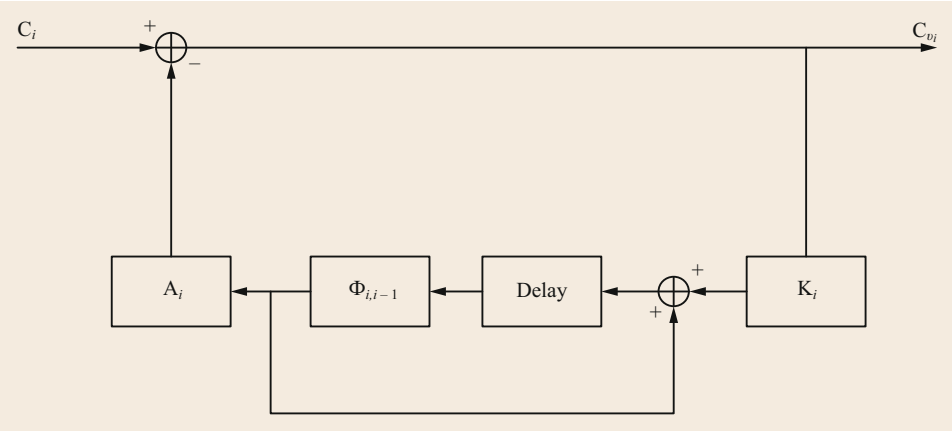

**Fig. 24.18** Recursion of $\mathbf{C}_{\boldsymbol{v}_i}$ in response to observation biases $\mathbf{C}_i\boldsymbol{b}$, with $i \in [l,k]$

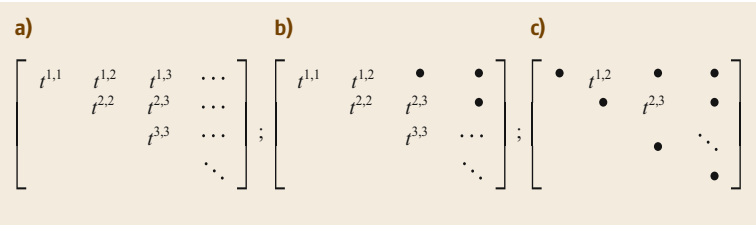

**Fig. 24.19a–c** Test matrices $t^{l,k}$ $(l \le k)$ for identification, with **(a)** no window, **(b)** moving window $l \in [k-1,k]$, and **(c)** moving window $l \in [k-1,k-1]$

is given as

$$\begin{aligned}\hat{\boldsymbol{x}}^a_{k|k} &= \hat{\boldsymbol{x}}_{k|k} - \mathbf{C}_{\hat{\boldsymbol{x}}_{k|k}}\hat{\boldsymbol{b}}_{l|k}\,,\\ \mathbf{P}^a_{k|k} &= \mathbf{P}_{k|k} + \mathbf{C}_{\hat{\boldsymbol{x}}_{k|k}}\mathbf{Q}_{l|k}\mathbf{C}^{\mathrm{T}}_{\hat{\boldsymbol{x}}_{k|k}}\,,\end{aligned} \tag{24.101}$$

with $\hat{\boldsymbol{b}}_{l|k}$ the least-squares solution of (24.97), $\mathbf{Q}_{l|k}$ its variance matrix, and $\mathbf{C}_{\hat{\boldsymbol{x}}_{k|k}}$ the bias-response matrix of the filter state. By again making use of the block diagonal structure of the predicted residual vector's variance matrix, the bias estimator can be formulated in recursive form as

$$\begin{aligned}\hat{\boldsymbol{b}}_{l|k} &= \hat{\boldsymbol{b}}_{l|k-1} + \mathbf{G}_k(\boldsymbol{v}_k - \mathbf{C}_{\boldsymbol{v}_k}\hat{\boldsymbol{b}}_{l|k-1})\,,\\ \mathbf{Q}_{l|k} &= (\mathbf{I}_q - \mathbf{G}_k\mathbf{C}_{\boldsymbol{v}_k})\mathbf{Q}_{l|k-1}\,,\end{aligned} \tag{24.102}$$

with gain matrix

$$\mathbf{G}_k = \mathbf{Q}_{l|k-1}\mathbf{C}^{\mathrm{T}}_{\boldsymbol{v}_k}\left(\mathbf{Q}_{\boldsymbol{v}_k\boldsymbol{v}_k} + \mathbf{C}_{\boldsymbol{v}_k}\mathbf{Q}_{l|k-1}\mathbf{C}^{\mathrm{T}}_{\boldsymbol{v}_k}\right)^{-1}\,. \tag{24.103}$$

Hence, since both the bias estimator $\hat{\boldsymbol{b}}_{l|k}$ and the filtered response matrix $\mathbf{C}_{\hat{\boldsymbol{x}}_{k|k}} = \boldsymbol{\Phi}_{k,k+1}\mathbf{C}_{\hat{\boldsymbol{x}}_{k+1|k}}$ (cf. (24.99)) can be computed recursively, the adaptation (24.101) can be executed recursively as well. The recursion of the bias estimator and filtered response matrix is shown in Fig. 24.20.

The adaptation (24.101) reduces to the adaptation for (24.95) in the case where $l = k$. Thus if local identification can be done successfully, it has the advantage that immediate corrective action is possible by adapting the filter at the same time that the model error occurred. This is not possible in the case of global identification. As one is then confronted with a delay in time of identification (i. e., identifying at epoch $k$ of an error that occurred at a previous epoch $l < k$), the filtered state will remain biased within the interval $[l,k)$. Whether this is considered acceptable depends on the application at hand. Correcting these filtered states would involve smoothing, which can be done recursively, but which may not be needed in real-time applications as it is a corrective action after the fact.

As adaptation implies that the identified alternative hypothesis takes over the role of the null hypothesis, the filtering from time $k$ onwards will be based on the extended state vector and variance matrix

$$\begin{bmatrix}\hat{\boldsymbol{x}}^a_{k|k}\\ \hat{\boldsymbol{b}}_{l|k}\end{bmatrix}\,,\ \begin{bmatrix}\mathbf{P}^a_{k|k} & -\mathbf{C}_{\hat{\boldsymbol{x}}_{k|k}}\mathbf{Q}_{l|k}\\ -\mathbf{Q}_{l|k}\mathbf{C}^{\mathrm{T}}_{\hat{\boldsymbol{x}}_{k|k}} & \mathbf{Q}_{l|k}\end{bmatrix} \tag{24.104}$$

the recursion of which is given by (24.101) and (24.102) respectively [24.75, 101].

### 24.5.7 Recursive Adaptation: Special GNSS Case

Not in all cases does the filtering after the adaptation step need to continue with an extended state vector as

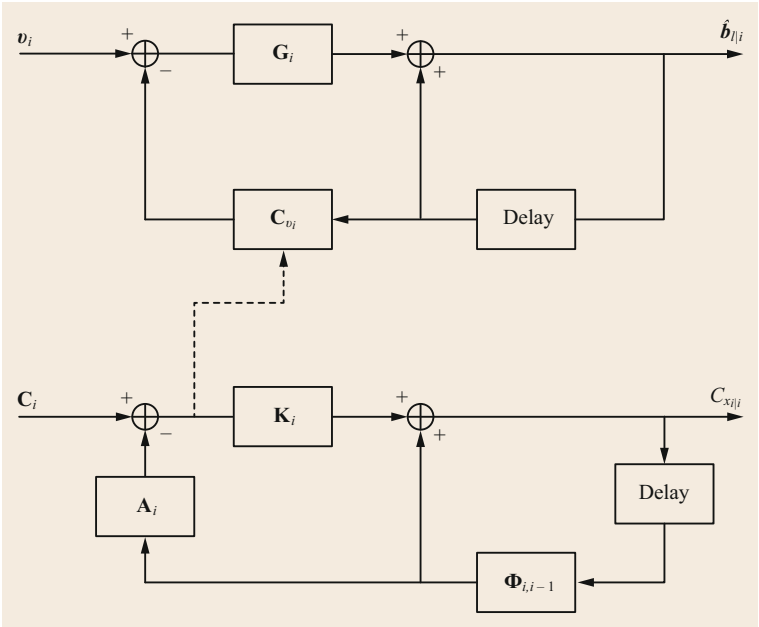

**Fig. 24.20** Recursion of the bias estimator $\hat{\boldsymbol{b}}_{l|i}$ and filtered response matrix $\mathbf{C}_{\hat{\boldsymbol{x}}_{i|i}}$

in (24.104). There are two important GNSS biases for which this is not needed. They are the biases due to code outliers and the biases due to carrier-phase slips. In both cases the adaptation needs to be performed only once, after which one can revert back again to the standard filtering under the null hypothesis.

### Code Outliers

Consider the case that the assumed modeling error in the observables is confined to a single epoch $l$. The $\mathbf{C}_i$-matrix of (24.98) is then given as

$$\mathbf{C}_i = \mathbf{C}_l \delta_{i,l} \,, \; i = 1, \ldots, k \,. \tag{24.105}$$

A special case of this structure is the occurrence of a code outlier, for which matrix $\mathbf{C}_l$ becomes the canonical unit vector having its nonzero entry at the place of the suspected code observable.

As spike-like modeling errors of the type (24.105) are not persistent, but instead confined to a single epoch, their adaptation only needs to be done once. After such adaptation one can then simply proceed again with the filtering under $\mathcal{H}_0$. The adapted state and its (error) variance matrix, $\hat{\boldsymbol{x}}^a_{k|k}$ and $\mathbf{P}^a_{k|k}$, are then in fact treated as a new initialization of the standard filter.

### Carrier-Phase Slips

For a slip, the $\mathbf{C}_i$-matrix of (24.98) is given as

$$\mathbf{C}_i = \mathbf{C}_l s_{i,l} \,, \; i = 1, \ldots, k \,, \tag{24.106}$$

with the step function $s_{i,l} = 0$ for $i < l$ and $s_{i,l} = 1$ for $i \geq l$. Since slips are persistent, one generally will have to work with the extended state vector (24.104) for all following epochs. However, an important exception exists for GNSS carrier-phase slips, where filtering under $\mathcal{H}_0$ is possible after a single adaptation step. This property is a consequence of the fact that one can show that reverting back to filtering under $\mathcal{H}_0$ is possible for any slip that can be parametrized as

$$\mathbf{C}_i = \mathbf{A}_i \boldsymbol{\Phi}_{i,l} \mathbf{X}_l s_{i,l} \;\text{ for some } \mathbf{X}_l \in \mathbb{R}^{n \times q} \,. \tag{24.107}$$

By then reparametrizing the state vector under $\mathcal{H}_\mathrm{a}$ as

$$\begin{bmatrix} \bar{\boldsymbol{x}}_i \\ \boldsymbol{b} \end{bmatrix} = \begin{bmatrix} \mathbf{I}_n & \boldsymbol{\Phi}_{i,l} \mathbf{X}_l \\ \mathbf{0} & \mathbf{I}_q \end{bmatrix} \begin{bmatrix} \boldsymbol{x}_i \\ \boldsymbol{b} \end{bmatrix} \tag{24.108}$$

the adaptation at epoch $k$ takes the form

$$\begin{aligned} \hat{\bar{\boldsymbol{x}}}^a_{k|k} &= \hat{\boldsymbol{x}}_{k|k} - \bar{\mathbf{C}}_{\hat{\boldsymbol{x}}_{k|k}} \hat{\boldsymbol{b}}_{l|k} \,, \\ \bar{\mathbf{P}}^a_{k|k} &= \mathbf{P}_{k|k} + \bar{\mathbf{C}}_{\hat{\boldsymbol{x}}_{k|k}} \mathbf{Q}_{l|k} \bar{\mathbf{C}}^{\mathrm{T}}_{\hat{\boldsymbol{x}}_{k|k}} \,, \end{aligned} \tag{24.109}$$

with $\bar{\mathbf{C}}_{\hat{\boldsymbol{x}}_{k|k}} = (\mathbf{C}_{\hat{\boldsymbol{x}}_{k|k}} - \boldsymbol{\Phi}_{k,l} \mathbf{X}_l)$. Compare with (24.101).

Since the reparametrization (24.108) compensates rigorously for the bias effect of $\boldsymbol{b}$, the adaptation step (24.109) only needs to be done once, after which one can continue with the filtering under $\mathcal{H}_0$. Thus with the new initialization, $\hat{\bar{\boldsymbol{x}}}^a_{k|k}$ and $\bar{\mathbf{P}}^a_{k|k}$, one can continue with the standard filter under $\mathcal{H}_0$, thereby recognizing

of course that the state vector $\boldsymbol{x}_i$ has now been replaced by its reparametrized version $\bar{\boldsymbol{x}}_i$ for $i \geq k$.

The above results directly apply to the case of GNSS carrier-phase slips. To see this, let $\boldsymbol{y}_i = [\boldsymbol{p}_i^{\mathrm{T}}, \boldsymbol{\phi}_i^{\mathrm{T}}]^{\mathrm{T}}$ be the code ($\boldsymbol{p}_i$) and phase ($\boldsymbol{\phi}_i$ in cycles) observation vector at epoch $i$, with partitioned design matrix and state vector, $\mathbf{A}_i = [\mathbf{A}_{1i}, \mathbf{A}_{2i}]$ and $\boldsymbol{x}_i = [\boldsymbol{x}_{1i}^{\mathrm{T}}, \boldsymbol{x}_2^{\mathrm{T}}]^{\mathrm{T}}$ respectively, in which $\boldsymbol{x}_2$ is the time-constant ambiguity vector in cycles. Then $\mathbf{A}_{2i} = [\mathbf{0}, \mathbf{I}_p]^{\mathrm{T}}$ and $\boldsymbol{\Phi}_{i,l} = \mathrm{blockdiag}[\boldsymbol{\Phi}_{1i,l}, \mathbf{I}_p]$. With a cycle slip at epoch $l$ in the $j$th phase observable, we have $\mathbf{C}_i = [\mathbf{0}, \boldsymbol{c}_j^{\mathrm{T}}]^{\mathrm{T}} s_{i,l}$, thus showing that (24.107) is satisfied for $\mathbf{X}_l = [\mathbf{0}, \boldsymbol{c}_j^{\mathrm{T}}]^{\mathrm{T}}$. With $\boldsymbol{\Phi}_{i,l}\mathbf{X}_l = [\mathbf{0}, \boldsymbol{c}_j^{\mathrm{T}}]^{\mathrm{T}}$, the reparametrization (24.108) for $\bar{\boldsymbol{x}}_i$ then simplifies to

$$\begin{bmatrix} \bar{\boldsymbol{x}}_{1i} \\ \bar{\boldsymbol{x}}_{2i} \end{bmatrix} = \begin{bmatrix} \boldsymbol{x}_{1i} \\ \boldsymbol{x}_{2i} \end{bmatrix} + \begin{bmatrix} \mathbf{0} \\ \boldsymbol{c}_j \end{bmatrix} b \,, \tag{24.110}$$

thus showing that in this case it only affects the ambiguities and not the other state vector entries.

With $\bar{\mathbf{C}}_{\hat{\boldsymbol{x}}_{k|k}} = [\mathbf{C}_{\hat{\boldsymbol{x}}_{k|k}} - [\mathbf{0}, \boldsymbol{c}_j^{\mathrm{T}}]^{\mathrm{T}}]$, the carrier-phase slip adaptation then takes the simple form

$$\begin{bmatrix} \hat{\boldsymbol{x}}_{1k|k} \\ \hat{\bar{\boldsymbol{x}}}_{2k|k} \end{bmatrix}^a = \begin{bmatrix} \hat{\boldsymbol{x}}_{1k|k} \\ \hat{\boldsymbol{x}}_{2k|k} \end{bmatrix} + \begin{bmatrix} \mathbf{C}_{1\hat{\boldsymbol{x}}_{k|k}} \\ \mathbf{C}_{2\hat{\boldsymbol{x}}_{k|k}} - \boldsymbol{c}_j \end{bmatrix} \hat{b}_{l|k} \,, \tag{24.111}$$

in which $\hat{b}_{l|k}$ is the estimated slip. Thus when after adaptation one reverts back to the standard filter under $\mathcal{H}_0$, the interpretation of all state vector entries remains the same except for the ambiguities. The adapted ambiguities differ from the original ambiguities by the slip.

# 25. Precise Point Positioning

Jan Kouba, François Lahaye, Pierre Tétreault

Since its introduction in 1997, precise point positioning (PPP) offers an attractive alternative to differential global navigation satellite system (GNSS) positioning. The PPP approach uses undifferenced, dual-frequency, pseudorange and carrier-phase observations along with precise satellite orbit and clock products, for standalone static or kinematic geodetic point positioning with centimeter precision. This chapter introduces the PPP concept and specifies the required models needed to correct for systematic effects causing centimeter-level variations in the satellite-to-user range. For completeness, models and methods for processing single-frequency GNSS data are presented and specific aspects of GLONASS (Global'naya Navigatsionnaya Sputnikova Sistema) and new GNSSs are also described. Furthermore, recent developments in fixing undifferenced carrier-phase ambiguities, which can considerably shorten or nearly eliminate the initial delay for PPP convergence, are highlighted. Existing web applications and real-time corrections services enabling post-mission and real-time PPP are presented. Finally, typical PPP precision and accuracy estimates are discussed, including the solution of station tropospheric zenith path delays and receiver clocks, with millimeter and nanosecond precision respectively.

The potential of GNSS for geodetic positioning applications was realized quite early during the Global Positioning System (GPS) implementation stage [25.1]. A relative positioning method, utilizing carrier-phase measurements made simultaneously and doubly differenced (DD) between two observing stations and two satellites, was proposed to eliminate the satellite and receiver clock offsets. Until the mid-1990s, practically all geodetic GPS applications employed relative baseline positioning with DD carrier-phase observations (Chap. 26).

In 1997, a new approach called precise point positioning (PPP), utilizing undifferenced carrier-phase and pseudorange observations was introduced by *Zumberge* et al. [25.2]. Unlike the traditional DD relative baseline positioning, PPP does not require simultaneous observations at two stations. PPP, in fact, is a logical extension of the GNSS pseudorange navigation, which replaces the broadcast satellite orbits and clocks with precise estimates, and includes the precise carrier-phase observations in addition to the pseudoranges. This, however, necessitates the introduction of additional initial phase ambiguity unknowns, causing a fairly long (up to 15 min or longer) initial convergence of PPP solutions. It also entails careful modeling and data screening for outliers and carrier-phase cycle

slips, which is more challenging than for the DD approach.

PPP also requires much more careful modeling of local station and environmental effects than DD relative positioning. However, in addition to precise position solutions, PPP provides precise station clocks and tropospheric zenith path delays (ZTDs), which are either unavailable or less precise in the case of DD positioning. The greater availability of precise orbit and clock solution products in late 1990s, thanks in great part to the organized efforts of the International GNSS Service (IGS); (Chap. 33), increased the popularity of PPP for geodetic and many other applications, for example in geodynamics, meteorology, metrology [25.3] and so on. This is clearly demonstrated by the popularity of the several online PPP services and PPP software packages now available.

The purpose of this chapter is to provide an overview of the PPP concept, state-of-the art PPP modeling techniques and the achievable performances. In Sect. 25.1 the PPP concept is introduced, followed by Sect. 25.2, which discusses conventional correction models and compatibility aspects. This is complemented by a review of specific processing aspects such as single-frequency and multi-GNSS PPP as well as the recent developments of precise point positioning using undifferenced phase ambiguity fixing (Sect. 25.3). The last two sections, 25.4 and 25.5, respectively list available PPP implementations and services and provide more detailed examples of recent PPP results.

## 25.1 PPP Concept

The PPP approach assumes that globally consistent satellite orbits and clocks are fixed or heavily constrained, and that PPP mathematical models are consistent with those applied in the global network solutions from which the orbit/clock products were estimated. In general, this consistency can be readily achieved if both the global orbit/clock and PPP solutions adhere to the same international standards, such as the current International Earth Rotation and Reference Systems Service (IERS) conventions. Since carrier-phase observations are used, PPP must estimate initial phase ambiguities to all satellites, in addition to the station position, station clock offsets and tropospheric zenith path delays (ZTD). The PPP method can be conceptualized as a back substitution of single station data into a global solution condensed in the form of the global satellite orbits and clocks and associated conventions and standards. Although PPP itself uses data from a single station only, computation of the satellite orbits and clocks needed for its implementation require the use of a global tracking network.

### 25.1.1 Observation Equations

For PPP, typically dual-frequency data is combined in order to eliminate nearly all of the ionospheric propagation delays. The ionosphere-free (IF) combinations (Chap. 19) of dual-frequency GNSS pseudorange ($p_{\mathrm{IF}}$) and carrier-phase observations ($\varphi_{\mathrm{IF}}$) are related to the user position, clock, troposphere and ambiguity parameters according to the following simplified observation equations (Chap. 19)

$$\begin{aligned} p^{\mathrm{s}}_{\mathrm{r,IF}} &= \rho^{\mathrm{s}}_{\mathrm{r}} + c\,(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + T^{\mathrm{s}}_{\mathrm{r}} + e_{\mathrm{IF}}\,, \\ \varphi^{\mathrm{s}}_{\mathrm{r,IF}} &= \rho^{\mathrm{s}}_{\mathrm{r}} + c\,(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + T^{\mathrm{s}}_{\mathrm{r}} + \lambda_{\mathrm{IF}} A_{\mathrm{IF}} + \epsilon_{\mathrm{IF}}\,, \end{aligned} \quad (25.1)$$

where:

- $p^{\mathrm{s}}_{\mathrm{r,IF}}$ is the ionosphere-free combination $(f_{\mathrm{A}}^2 p_{\mathrm{A}} - f_{\mathrm{B}}^2 p_{\mathrm{B}})/(f_{\mathrm{A}}^2 - f_{\mathrm{B}}^2)$ of pseudoranges $p_{\mathrm{A}}$ and $p_{\mathrm{B}}$ observed at two distinct signal frequencies $f_{\mathrm{A}}$ and $f_{\mathrm{B}}$.
- $\varphi^{\mathrm{s}}_{\mathrm{r,IF}}$ is the ionosphere-free combination $(f_{\mathrm{A}}^2 \varphi_{\mathrm{A}} - f_{\mathrm{B}}^2 \varphi_{\mathrm{B}})/(f_{\mathrm{A}}^2 - f_{\mathrm{B}}^2)$ of the corresponding carrier-phases $\varphi_{\mathrm{A}}$ and $\varphi_{\mathrm{B}}$.
- $\rho^{\mathrm{s}}_{\mathrm{r}}$ is the geometrical range $||\boldsymbol{x}^{\mathrm{s}} - \boldsymbol{x}_{\mathrm{r}}||$ from the satellite position $\boldsymbol{x}^{\mathrm{s}} = (x^{\mathrm{s}}, y^{\mathrm{s}}, z^{\mathrm{s}})^{\top}$ at the signal emission epoch $t_{\mathrm{E}}$ to the receiver position $\boldsymbol{x}_{\mathrm{r}} = (x_{\mathrm{r}}, y_{\mathrm{r}}, z_{\mathrm{r}})^{\top}$ at its reception (arrival) epoch $t_{\mathrm{A}} \cong t_{\mathrm{E}} + \rho^{\mathrm{s}}_{\mathrm{r}}/c$.
- $dt_{\mathrm{r}}$ is the receiver clock offset from the GNSS time (including receiver code biases and delays).
- $dt^{\mathrm{s}}$ is the satellite clock offset from the GNSS system time (including satellite code biases and delays).
- $c$ is the vacuum speed of light.
- $T^{\mathrm{s}}_{\mathrm{r}}$ is the signal path delay due to the neutral atmosphere (primarily the troposphere).
- $A_{\mathrm{IF}}$ is the *noninteger* ambiguity of the IF carrier-phase combination, actually the IF combination of the $\varphi_{\mathrm{A}}$ and $\varphi_{\mathrm{B}}$ integer ambiguities and noninteger initial phase delays.
- $\lambda_{\mathrm{IF}}$ is the IF combination of the carrier-phase wavelengths $\lambda_{\mathrm{A}}$ and $\lambda_{\mathrm{B}}$ of signals A and B (e.g., 10.7 cm for GPS L1 and L2).
- $e_{\mathrm{IF}}, \epsilon_{\mathrm{IF}}$ are the relevant measurement noise components, including multipath of the IF pseudorange and carrier-phase combinations.

Since the global GNSS orbit/clock parameters are held fixed, the satellite coordinates $(x^{\mathrm{s}}, y^{\mathrm{s}}, z^{\mathrm{s}})$ and the satellite clocks $dt^{\mathrm{s}}$ in (25.1) are considered known.

Furthermore, the unknown wet part of the tropospheric delay is usually expressed as a product of the wet zenith tropospheric delay $ZTD_w$ and a mapping function that relates the slant wet delay to the zenith delay. As a result, the unknown parameters of a typical PPP model are: receiver position coordinates $(x_r, y_r, z_r)$, receiver clock $(dt_r)$, zenith troposphere delay $(ZTD_w)$ and (noninteger) IF carrier-phase ambiguities $(A_{IF})$.

After fixing the known satellite clocks and positions, the above observation equations contain observations and unknowns pertaining to a single station only. Note that satellite clock and orbit weighting does not require the satellite clock and position parameterizations, since they can be effectively accounted for by satellite-specific pseudorange/phase observation weighting. When fixing orbits/clocks, it makes little or no sense to solve (25.1) in a network solution, as it would still result in uncorrelated station solutions that are exactly identical to independent, single station, PPP solutions. Also note that, unlike relative or network solutions utilizing DD phase observations, it is not possible to fix individual integer ambiguities for the two signals A and B in single point positioning solutions without additional parameterization of measurement biases (Sect. 25.3.4).

It is worth noting that PPP provides position, ZTD and receiver-clock estimates that are consistent with the global reference system implied by the fixed global GNSS orbit/clock solutions. The DD approach, on the other hand, does not offer any clock solutions, and the ZTD solutions may be biased by a constant (datum) offset, in particular for regional or local network, or single baseline ($< 500$ km) solutions. This ZTD bias, in turn, may cause a small-scale error in relative height solutions. Thus, such regional or local ZTD solutions, based on DD analyses, require external tropospheric ZTD calibration (at least at one station of the network), for example by means of the IGS tropospheric combined ZTD products (Chaps. 38 and 33).

Traditionally, GPS L1 and L2 observation pairs have been used in PPP applications in view of the availability of highest precision orbit and clock products compatible with these signals. However, some GNSS, like the emerging Galileo or the modernized GPS systems, may also provide E5 or L5 carrier-phase observations instead of, or in addition to, those on the L2 frequency. The above dual-frequency PPP discussion is generically valid for any pair of (sufficiently spaced) signal frequencies $f_A$ and $f_B$. The possible use and impact of three frequency observations, which are also becoming available for new or modernized GNSSs, are briefly discussed below in Sects. 25.2.1 and 25.3.4.

## 25.1.2 Adjustment and Quality Control

The design matrix needed for the adjustment follows from a linearization of the observation equations around the approximate parameter values (Chap. 21). It consists of the partial derivatives of (25.1) with respect to the four types of PPP parameters: station position, receiver clock, zenith troposphere delay, and (noninteger) IF carrier-phase ambiguities.

### Batch versus Sequential

The adjustment can be done in a single step, the so-called batch adjustment (with iterations), or alternatively within a sequential adjustment or filter (with or without iterations) that can be adapted to varying user dynamics (Chap. 22). The disadvantage of a batch adjustment is that it may become too large even for modern and powerful computers, in particular for a very large number of undifferenced observations. However, no back substitutions or back smoothing is necessary in this case, which makes batch adjustment attractive in particular for DD approaches. Filter implementations for GNSS positioning are equivalent to sequential adjustments with steps coinciding with observation epochs. They are usually much more efficient and of smaller size than the batch adjustment implementations, at least as far as the position solutions with undifferenced observations are concerned. This is so, since parameters that appear only at a particular observation epoch, such as station clock and even ZTD parameters, can be preeliminated. However, filter (sequential adjustment) implementations require backward smoothing (back substitutions) for the parameters that are not retained from epoch to epoch (e.g., the station clock and ZTD parameters).

Furthermore, filter or sequential approaches can also model variations in the states of the parameters between observation epochs with appropriate stochastic processes that also update parameter variances from epoch to epoch. For example, the PPP observation model involves four types of parameters: station position $(x_r, y_r, z_r)$, receiver clock $(dt_r)$, troposphere zenith path delay $(ZTD_w)$ and noninteger carrier-phase ambiguities $(A_{IF})$. The station position may be constant or change over time depending on the user dynamics. These dynamics could vary from tens of meters per second in the case of a land vehicle to a few kilometers per second for a low Earth orbiter (LEO). The receiver clock may drift and will have noise characteristics according to the quality of its oscillator, for example about 0.1 ns/s (equivalent to several cm/s) in the case of an internal quartz clock with frequency stability of about $10^{-10}$. Comparatively, for a stationary receiver, the tropospheric ZTD will vary in time by a relatively small

amount, in the order of a few cm/h. Finally, the carrier-phase ambiguities will remain constant as long as the satellite is not being reoriented (e.g., during an eclipsing period, see the phase wind-up correction, Chap. 19 and Sect. 25.2.2) and the carrier phases are free of cycle slips, a condition that requires close monitoring. Note that only for DD data, i. e., two satellites observed from two stations, all clocks including the receiver-clock corrections are practically eliminated by the double differencing operation.

The system or process noise can be adjusted according to user dynamics, receiver-clock characteristics and atmospheric activity. In all instances the ambiguity process noise is set to zero, since the carrier-phase ambiguities remain constant over time. In static mode, the user position is also constant and consequently the coordinate process noise is also zero. In kinematic mode, it can be increased as a function of user dynamics, though usually the coordinate process noise values are set to a very large value to accommodate all possible user dynamics (including LEO satellites), effectively forcing independent position solutions for every epoch. The receiver-clock process noise can vary as a function of its frequency stability but is usually set to white noise with a large process noise variance to accommodate the unpredictable occurrence of clock resets. A random walk process noise of about 2–5 mm/$\sqrt{\text{h}}$ is usually assigned and used to drive the process noise variance of the ZTD. Note that for the most precise PPP applications, ZTD modeling typically also includes two additional stochastic (e.g., random walk) unknown parameters pertaining to the north-south and east-west ZTD gradients (Sect. 25.2.1).

### Data Screening and Editing

When undifferenced code and phase observations are used, such as is the case for PPP, data testing and editing is quite essential (Chap. 24). For undifferenced, single-station observations this is a major challenge, in particular during periods of high ionospheric activity and/or station in the ionospherically disturbed subauroral or equatorial regions. This is because the difference between the phase observations on the two frequencies (e.g., GPS L1 and L2) along with widelane pseudorange/phase combinations (Chap. 20) are commonly used to check and edit cycle slips and outliers. Under quiet ionospheric conditions it is possible to detect and correct cycle slips even for data breaks exceeding 1 min, in particular when changes in ionospheric delays are taken into account [25.4]. When it is not possible to correct cycle slips a new initial ambiguity unknown has to be introduced. However, in the extreme cases of a highly active and scintillating ionosphere, this cycle slip editing approach would need data sampling higher than 1 Hz in order to safely edit or correct cycle slips or outliers. Due to memory constraints, data cannot always be sampled or processed at a rate of 1 Hz or higher. Within a geodetic receiver, however, it should be possible (at least in principle), to do efficient and reliable data cleaning and editing based on fitting the individual carriers phase measurements (e.g., $\varphi_{\text{L1}}$ and $\varphi_{\text{L2}}$) or their difference ($\varphi_{\text{L1}} - \varphi_{\text{L2}}$), since data samplings much higher than 1 Hz are internally available. Most IGS stations have data sampling of only 30 s, which is why efficient statistical editing and error detection tests are critical, in particular for undifferenced, single station observation analyses.

On the other hand, the double-difference carrier-phase observations on the individual frequencies or even the DD ionosphere-free measurement combinations are much easier to edit or correct for cycle slips and outliers, consequently making statistical error detection and corrections less critical or even unnecessary. An attractive alternative for undifferenced observation network analyses is cycle slip detection and editing based on DD observations, which could also facilitate the resolution of the initial DD phase ambiguities. Resolved phase ambiguities are then reintroduced into the undifferenced analysis as the condition equations of the new undifferenced observations, formed from the reconstructed, unambiguous and edited DD observations, previously obtained.

## 25.2 Precise Positioning Correction Models

GNSS software must apply corrections to pseudorange observations in order to eliminate effects such as special and general relativity, Sagnac delay, satellite clock offsets, atmospheric delays, and so on (e.g., [25.7]; Chap. 19). Since these effects are quite large, exceeding several meters, they must be considered even for pseudorange positioning at the meter precision level. When attempting to combine satellite positions and clocks precise to a few cm with IF carrier-phase observations (with mm precision), or for the most precise differential phase processing mode, it is important to account for additional effects that are not normally considered for pseudorange positioning. An overview of the various model components and corrections in PPP applications is provided in Table 25.1.

**Table 25.1** PPP a priori correction models. Magnitude and uncertainty values should be considered as approximate and may differ from case to case (after [25.27])

| Model component | | Magnitude | Uncertainty | Notes |
|---|---|---|---|---|
| Satellite | Center-of-mass position | | 2.5 cm (GPS) | Interpolated from precise orbit product in standard product 3 (format) (SP3) format with typical sampling of 15 min |
| | Antenna phase center offset | 0.5–3 m | 10 cm | Antenna offset vector in spacecraft system (IGS antenna exchange (ANTEX)) and GNSS specific attitude models [25.5, 6] |
| | Phase center variations | 5–15 mm (GPS) | 0.2–1 mm | IGS ANTEX model [25.5] |
| | Clock offset | < 1 ms | 75 ps, 2 cm (GPS) | Interpolated from precise clock product with typical sampling of 30 s to 5 min |
| | Relativistic clock effects | 10–20 m | – | Eccentricity-dependent effect [25.7, 8] |
| | | 2 cm | – | $J_2$-dependent contribution [25.8]; consistently neglected in current precise GNSS clock products and PPP models |
| | Differential code biases | up to 15 ns, 5 m | 0.1–1 ns | Required biases depend on tracked signals and clock product [25.9, 10] |
| | Fractional phase biases | up to 0.5 cy | 0.01 cy | For undifferenced ambiguity resolution [25.11] |
| Atmosphere | Troposphere (dry) | 2.3 m | 5 mm | Vertical delay [25.12], up to 10× larger for low elevations. Models: see, e.g., [25.13, Sect. 9.2], [25.14, 15] |
| | Troposphere (wet) | up to 0.3 m | up to 100% | Vertical delay [25.12]; estimated due to insufficient a priori models |
| | Ionosphere ($1^{st}$-order) | up to 30 m | – / 1 m | Vertical delay, up to 3× larger for low elevations. Corrected through ionosphere-free combination (2-freq. PPP) or global ionosphere maps ([25.16]; 1-freq. PPP) |
| | Ionosphere (higher-order) | 0–2 cm | 1–2 mm | References [25.17] and [25.13, Sect. 9.4.1] |
| Site displacement | | | | Corrections for expressing measured positions in a conventional terrestrial reference frame |
| | Plate motion | up to 0.1 m/y | 0.3 mm/y | Reference [25.18] |
| | Solid Earth tide | up to 0.4 m | 1 mm | References [25.19] and [25.13, Sect. 7.1.1] |
| | Ocean loading (tidal) | 1–10 cm | 1–2 mm | References [25.13, Sect. 7.1.2], [25.20, 21] |
| | Ocean loading (nontidal) | up to 15 mm | 1 mm | Nonconventional correction; [25.22] |
| | Pole tide | 25 mm | – | Reference [25.13, Sect. 7.1.4] |
| | Atmospheric loading (tidal) | up to 1.5 mm | – | Reference [25.13, Sect. 7.1.3] |
| | Atm. loading (nontidal) | up to 20 mm | 15% | Nonconventional correction; [25.23] |
| Receiver | Phase center offset | 5–15 cm | – | IGS ANTEX model (conventional values) |
| | Phase center variations | up to 3 cm | 1–2 mm | IGS ANTEX model; [25.24] |
| Others | Phase wind-up | 10 cm | see notes | Wavelength dependent; correction subject to knowledge of satellite/receiver antenna orientation; [25.25, 26] |

For relative positioning at the cm-precision level and baselines of less than 100 km, all the correction terms discussed below can be safely neglected. The following sections describe additional correction terms often neglected in local relative positioning, that are, however, significant for PPP and all precise global analyses (DD or undifferenced approaches).

In the following discussion of PPP models, the correction terms have been grouped under four subsections covering propagation delays (Sect. 25.2.1), antenna effects (Sect. 25.2.2), site displacements effects (Sect. 25.2.3) and differential code biases (Sect. 25.2.4). Furthermore, compatibility considerations are addressed in Sect. 25.2.5.

A number of the corrections listed below require positions for the Moon and Sun (e.g., for tide and attitude computations). The respective information can be obtained from readily available planetary ephemerides files [25.28, 29], or more conveniently from simple analytical formulas [25.30–32], since a relative precision

of about 1/1000 is sufficient for corrections at the mm precision level.

### 25.2.1 Atmospheric Propagation Delays

Propagation of radio waves through the Earth's atmosphere introduces significant delays, which must be taken into account even for GNSS positioning at the meter precision level. For a comprehensive description of GNSS signal propagation see Chap. 6. Below are summarized the propagation delay models required for the highest precision PPP and GNSS global solutions as outlined in the current IERS2010 conventions [25.13].

#### Higher-Order Ionospheric Delay Corrections

The IF linear combination of dual-frequency observations used in (25.1) can be subjected to cm-level systematic errors caused by the neglected higher-order ionospheric delays. The higher-order ionospheric delays are negligible with respect to pseudorange noise of about 0.1–1.0 m but need to be considered for phase observations [25.33].

Following [25.13], the higher-order ionospheric delay errors of IF carrier-phase observations can be described as

$$d\varphi^{s}_{r,IF} = -\frac{s_2}{f_A f_B (f_A + f_B)} - \frac{s_3}{f_A^2 f_B^2}\,, \qquad (25.2)$$

where $f_A$ and $f_B$ denote the two signal frequencies (Hz) used in the IF combination.

The third-order term $s_3$ is negligible (at the sub-mm level) for GNSS frequencies. However, for a very high intensity ionosphere (such as during peaks of solar activity cycles) an $s_3$ ray-bending contribution, $\Delta s_3$, may become significant. For a given elevation $E$ and slant total electron content (STEC), it can be approximated as

$$\Delta s_3 = b_1 \left( \frac{1}{\sqrt{1 - b_2 \cos^2(E)}} - 1 \right) \mathrm{STEC}^2 \qquad (25.3)$$

with $b_1 = 2.495 \cdot 10^8\,\mathrm{m\,MHz^4/TECU^2}$ and $b_2 = 0.8592$ [25.13, 34]. The slant total electron content can reach up to $\approx 300\,\mathrm{TECU}$ for a highly active ionosphere, where $1\,\mathrm{TECU} = 10^{16}\,\mathrm{electrons/m^2}$. Thus, $\Delta s_3 / f^4$ can reach up to 10 mm and should be considered here, along with the second-order term $s_2$, at least for the most precise GNSS solutions.

The $s_2$ coefficient of the second-order term can be approximated by

$$s_2 = 1.1284 \cdot 10^{12}\, B_p \cos(\Theta)\,\mathrm{STEC}\,, \qquad (25.4)$$

where $B_p \cos(\Theta)$ is the projection of the Earth's magnetic field intensity onto the satellite-station (i. e., satellite signal propagation) direction [25.13]. Equation (25.4) yields the value of $s_2$ in units of $\mathrm{m\,Hz^3}$ for STEC measured in electrons/$\mathrm{m^2}$ and $B_p$ expressed in Tesla. The magnetic field strength required for the second-order correction can readily be obtained from models such as the international geomagnetic reference field (IGRF). Both the magnetic field $B_p$ and the satellite station direction are taken at the piercing point on the adopted ionospheric shell (typically at a height of 450 km).

The STEC in (25.3) and (25.4) can be obtained from global ionosphere maps (GIMs) providing the vertical total electron content (VTEC) and a thin-shell mapping function (Chaps. 6 and 19). Such maps are, for example, generated by the IGS on a daily basis and distributed in the standardized ionosphere exchange format (IONEX); (Annex A). Alternatively, STEC can be evaluated from dual-frequency pseudorange-leveled carrier-phase observations after proper consideration of satellite- and receiver-specific differential code biases for the employed signals.

From (25.4) one can see that the second-order correction is highly geographically correlated, since it is a projection on the direction of the Earth's magnetic field, which is nearly the same within a wide area around the station. Furthermore, the direction of the Earth's magnetic field (mainly pointing north-south) is changing very slowly in time (nearly constant even over a decade). Therefore due to periodical changes of satellite geometry the second-order ionospheric refraction will cause small periodical errors, mainly in latitude. However, as seen from (25.4), the second-order ionospheric correction is also proportional to STEC, so it changes during the day (small at night, larger during the day). Finally, it can also be an order or even two orders of magnitude smaller (thus insignificant) during periods of low ionospheric activity than during periods of very active ionosphere.

In principle, the availability of three signal frequencies (such as GPS L1, L2, and L5) opens the possibility to eliminate the second-order ionospheric delay by an appropriate combination of the triple frequency observations [25.35]. However, in that case, because of additional biases connected with the third frequency observations, the compatibility with the standard dual-frequency solutions as well as a significant amplification of the observation noise [25.13] also need to be considered.

#### Tropospheric Delay Modeling

The tropospheric delay in (25.1) is commonly expressed as the product $T^s_r = M\,\mathrm{ZTD}$ of an elevation-dependent mapping function $M$ and the zenith tro-

posphere delay ZTD. For all GNSS frequencies, the tropospheric delay $T_r^s$ of (25.1) does not depend on frequency and the ZTD amounts to about 2.3 m at sea level. The ZTD can conveniently be divided into hydrostatic (dry) and wet components. The hydrostatic delay is caused mainly by the refractivity of the dry gases in the troposphere. The water vapor refractivity is responsible for most of the wet delay. Typically the hydrostatic delay component accounts for about 90% of the total delay (Chap. 6).

The hydrostatic delay ($ZTD_h$) can be accurately computed a priori from surface pressure $p$, station latitude $\varphi$ and height $h$, using the formula of *Saastamoinen* [25.36] as given by [25.37]

$$ZTD_h = \frac{0.0022768\,\mathrm{m/hPa}\,p}{1-0.00266\cos(2\varphi)-2.8\cdot10^{-7}\,\mathrm{m}^{-1}\,h}\,. \tag{25.5}$$

For the smaller wet zenith delay ($ZTD_w$), there is no reliable model to obtain an a priori value. Because measuring the wet delay using water vapor radiometers is expensive and impractical for GNSS, it is normally estimated from the data. Standard GNSS navigation, utilizing pseudorange measurements or relative positioning over short baselines of a few tens of km, require only a simple mapping function $M$ and a single a priori ZTD. In such cases, ZTD estimation is usually unnecessary or impossible. On the other hand, PPP and precise global solutions (Chap. 34) require that the ZTD mapping function $M$ also be separated into a hydrostatic (dry) part ($M_h$) and a wet part ($M_w$). For the most precise GNSS applications, the ZTD north and east gradients ($G_N$, $G_E$) are also used, along with a gradient mapping function $M_g$. More specifically, the tropospheric delays of (25.1) are parameterized as

$$\begin{aligned} T_r^s = {} & M_h(E)\,ZTD_h + M_w(E)\,ZTD_w \\ & + M_g(E)\,[G_N\cos(A) + G_E\sin(A)]\,, \end{aligned} \tag{25.6}$$

where $A$ is the azimuth of the satellite direction and the gradient mapping function

$$M_g(E) = \frac{1}{(\sin(E)\,\tan(E)+0.0032)} \tag{25.7}$$

as suggested by [25.38] is typically used. The horizontal gradients ($G_N$, $G_E$) are needed to account for north-south atmospheric bulge and weather systems, since both can reach up to 1 mm [25.39].

Practically all the modern mapping functions use continued fractions

$$M(E,a,b,c) = \frac{1+\frac{a}{1+\left(\frac{b}{1+c}\right)}}{\sin E+\frac{a}{\sin E+\left(\frac{b}{\sin E+c}\right)}} \tag{25.8}$$

in terms of $\sin(E)$ as introduced by [25.40], where the coefficients $a$, $b$ and $c$ are small ($<<1$) constants. Different sets of coefficients ($a_h$, $b_h$, $c_h$) and ($a_w$, $b_w$, $c_w$) are required for the hydrostatic $M_h$ and wet $M_w$ mapping functions, respectively. Only the variation of the most significant coefficients $a_h$ and $a_w$ needs to be considered. The remaining and smaller coefficients ($b$ and $c$) can use functional, mainly seasonal, representations.

For a self-contained PPP application with no external information input, the coefficients $a_h$ and $a_w$ can be obtained from global spherical harmonics expansions of mean geographical and seasonal variations, which is the case of the global mapping function (GMF) [25.14]. The more recent mapping function of the GPT2 (global pressure and temperature) model [25.41] uses global grids of mean values and mean seasonal or semiseasonal variations. The most precise PPP and GNSS applications use the Vienna mapping function 1 (VMF1) [25.42], which requires actual temporal and geographical variations of $a_h$ and $a_w$, either site-specific or geographical grid files (with $2^\circ \times 2.5^\circ$ resolution). The VMF1 site-specific or grid files contain four sets of $a_h$ and $a_w$ coefficients per day (i. e., every 6 h), fitted to ray-tracing through the numerical weather model (NWM) of the European Centre for Medium-Range Weather Forecasts (ECMWF). The VMF1 site-specific or grid files, and alternatively those generated by the University of New Brunswick (UNB) and based on the US and Canadian NWMs [25.43], are readily available at [25.44] and [25.45], respectively.

Even though errors of the a priori $ZTD_h$ (25.5) can be largely compensated by the $ZTD_w$ estimation, for the most precise PPP and GNSS applications, $ZTD_h$ needs to be known fairly accurately in order to properly separate the dry and wet ZTD mapping (25.6). According to [25.42], for a 5° elevation cutoff angle, the hydrostatic/wet mapping separation causes height errors of about one tenth of the $ZTD_h$ error. This means that to reduce height errors below the mm level, the a priori $ZTD_h$ has to be known at the cm-precision level, which in turn means that $ZTD_h$ has to be based on measured pressure $p$, or more conveniently on $p$ obtained from a NWM, for example the ones in the VMF1 grid files. The NWM grid files also contain $ZTD_w$, however, its uncertainty is at the 2 cm level, which is not sufficient for most PPP applications, and thus $ZTD_w$ estimations are still required. Nevertheless, the NWM-based a priori $ZTD_w$ can be used to significantly constrain $ZTD_w$

estimates, which may shorten the initial PPP solution convergence.

The VMF1 and UNB grid files require spatial and temporal interpolations of $a_h$, $a_w$ and $ZTD_h$, $ZTD_w$ for a specific station location and epoch [25.46]. Less precise, self-contained PPP solutions can use a constant $ZTD_h$, or one evaluated from (25.5) for a specific station location and epoch using the global pressure and temperature (GPT) model pressure [25.15]. Alternatively it can be obtained directly from the more recent GPT2 routine. Both GPT and GPT2 are based on global averages of NWM values and their seasonal variations. [25.47] investigated GMF and GPT performance and [25.43] compared GPT2-based PPP solutions with those using the VMF1 and UNB grid mapping functions and $ZTD_h$. Using a constant $ZTD_h$ instead of a GPT- or GPT2-derived one may result in significant height errors due to hydrostatic/wet mapping separation errors. This is true in particular at high latitudes with large atmospheric pressure variations, where height errors can exceed 10 mm. It is interesting to note that a constant or GPT-derived $ZTD_h$ and GMF, and to a smaller extend also the GPT2-derived values, tend to compensate the atmospheric loading effects on heights [25.46]. This explains why prior to atmospheric loading corrections, PPP solutions utilizing constant or GPT/GPT2 a priori $ZTD_h$, and/or GMF/GPT2 mapping functions may show slightly better height repeatability than the more accurate gridded VMF1 PPP solutions.

## 25.2.2 Antenna Effects

### Phase Center Offsets and Variations

The ephemerides broadcast by today's GNSS satellites provide the position of the satellite antenna for direct use within the position computation. Here, no knowledge of the spacecraft orientation and antenna accommodation is required, but the achievable accuracy is limited in accord with the needs of pseudorange-based navigation. High-accuracy orbit products for PPP applications, in contrast, are referred to the spacecraft center of mass (CoM), which is the primary reference point for the orbit modeling. However, since GNSS measurements are effectively made between the phase centers of the transmitting and receiving antennas, it is necessary to account for the CoM offset of the satellite antenna and the orientation of the offset vector in space.

Representative values of the satellite antenna phase center offsets are summarized in Table 25.2 for the various constellations. The phase centers of all the GNSS satellites are offset by about one to a few meters in the body $z$-coordinate direction (towards the Earth) and some are also offset in the body $x$-coordinate direction, which is nominally in the plane containing the Sun, satellite and Earth.

In addition to the phase center offset in the spacecraft body frame, the orientation (attitude) of the spacecraft body relative to the terrestrial reference frame must be known to obtain the phase center position for given CoM coordinates of the GNSS satellite. Nominal attitude laws for the individual constellations and satellite types are discussed in [25.6] and Chap. 3. They allow computation of the satellite orientation for given orbital position and Sun direction and offer a good approximation of the true attitude except for short periods of noon and midnight turns during the eclipse season.

Since the assumption of a common phase center for all signals and line-of-sight directions is only approximately true for real antennas, complementary phase center variations (PCVs) need to be considered for high-precision carrier-phase modeling (Chaps. 17 and 19). Since November 5, 2006 (GPS Week 1400) the IGS has adopted calibration tables of absolute antenna PCV for both satellite and receiver antennas [25.5], which are readily available from the IGS [25.48] and updated as needed. The absolute PCV files (e.g., *igs08.atx* for consistent use with the IGS08/ITRF08 reference frame) contain PCV calibrations for all GNSS satellites and for practically all the receiver antenna models used by IGS. The receiver antenna PCV calibrations are usually based on antenna robot calibrations [25.24, 49] and include the measured phase center offsets (PCOs) together with elevation and azimuth dependent PCVs. The satellite portions of the absolute PCV file are based on solutions of several IGS analysis centers (ACs), which are consistent with the receiver antennas absolute PCVs and the IGS realization of the international reference frame.

It is advisable to use the absolute PCV convention in PPP solutions, for consistency with the orbits/clock computation process, but only when a receiver-absolute antenna PCV is available. If only a relative or no PCV calibration is available for the receiver antenna, then the nominal satellite antenna offsets and no satellite PCV should be used. PPP using absolute antenna PCV for satellite antennas with no or a relative receiver PCV may result in large (decimeter) solution errors and inconsistencies. Similarly, when orbits/clocks referred to satellite antenna phase center are generated from a network of ground stations (e.g., a commercial one) employing the same antenna types with no PCV, then PPP users with compatible antenna should not use any PCV either. However, when a user employs a different antenna than the one used to generate the orbits/clocks, the difference between the PCVs of the two antennas need to be accounted for.

**Table 25.2** Antenna phase center offset from the center of mass for different types of GNSS satellites (after [25.6]). The offsets refer to IGS-specific spacecraft body axes and serve for illustration only. Satellite- and frequency-specific values used in the generation of IGS precise orbit and clock products are provided as part of the IGS ANTEX model (after [25.5])

| Constellation | Type | $x$ (m) | $y$ (m) | $z$ (m) |
|---|---|---|---|---|
| GPS | II/IIA | +0.28 | 0.00 | +2.56 |
| | IIR-A | 0.00 | 0.00 | +1.31 |
| | IIR-B/M | 0.00 | 0.00 | +0.85 |
| | IIF | +0.39 | 0.00 | +1.60 |
| GLONASS | M | –0.55 | 0.00 | +2.30 |
| | K1 | 0.00 | 0.00 | +1.76 |
| Galileo | In-orbit validation (IOV) | –0.20 | 0.00 | +0.60 |
| | Full operational capability (FOC) | +0.15 | 0.00 | +1.00 |
| BeiDou-2 | | +0.60 | 0.00 | +1.10 |
| Quasi-Zenith Satellite System (QZSS) | QZS-1 | 0.00 | 0.00 | +3.20 |
| Indian Regional Navigation Satellite System (IRNSS/NavIC) | | +0.01 | 0.00 | +1.28 |

Some modern receivers allow input of a receiver antenna PCV and output PCV corrected data, in such a case only the satellite antenna PCV should be considered when orbits/clocks refer to satellite centers of mass. When using the receiver independent exchange format (RINEX [25.50, Annex A]) for GNSS observations, data from receivers applying PCV corrections will report *NULLANTENNA* in the file header.

### Phase Wind-Up

GNSS satellites employ right-hand circularly polarized (RHCP) electromagnetic waves for signal transmission, which means that the electric and magnetic field vectors perform a right-hand rotation about the propagation direction (Chap. 4). Other than linear polarization, the use of RHCP signals avoids restrictions on the relative orientation of the receive and transmit antenna and helps to mitigate multipath effects from reflected signals [25.51]. As a side effect, the measured carrier phase does not only change with the distance of the transmitter and receiver but also with the orientation of either of the two antennas relative to the line of sight. This is known as *phase wind-up* [25.25] and will, for example, result in a phase change by one cycle for a full rotation of the receive or transmit antenna about the boresight direction. It should be noted that only the carrier phase measurements are sensitive to wind-up effects, whereas the pseudorange observations remain unaffected (Chap. 19).

Phase wind-up effects have commonly been neglected in differential positioning applications since the effects are highly correlated for stationary receivers with a separation of less than a few hundred kilometers. For mobile receivers the phase wind-up caused by a rotation of the receiver antenna about a fixed axis is identical for all received satellites. Thus, it can partly be absorbed in the clock solution, but will give rise to a code-carrier inconsistency when processing both pseudorange and phase observations. Consideration of the user antenna orientation and the resulting phase wind-up is therefore essential for precise positioning on mobile platforms with continued attitude changes [25.26]. In particular, phase wind-up effects must be properly modeled for a toggling antenna [25.52], where the rotation vector varies over time.

Even for a presumably stationary position and alignment of the receiver antenna, phase wind-up effects arise from the slowly changing relative orientation of the satellite antenna, line of sight, and receiver antenna. Following [25.25] the resulting carrier phase change may differ by up to 4 cm for two stations separated by 4000 km.

GNSS satellites need to continuously change their orientation about the Earth-pointing antenna axis to orient their solar panels towards the Sun. Irrespective of the user antenna dynamics, these satellite attitude changes will results in a measurable phase wind-up effect. They are most pronounced during noon and midnight turns in the eclipse season, where the satellites may rotate by up to 180° (corresponding to a phase wind-up effect of half a wavelength) in 15–30 min. If ignored, these are fully absorbed into the estimated satellite clocks and thus are completely eliminated by double differencing. They become important, however, for undifferenced PPP applications and need to be consistently handled in the generation of orbit/clock products and the user positioning software. Within the IGS, phase wind-up effects are considered by all analysis centers and their respective products. Neglecting them and fixing IGS orbits/clocks in a PPP process may result in position and clock errors at the dm level.

Details of the phase wind-up modeling and the applicable satellite attitude models are provided in Chap. 19. Aside from nominal attitude laws, dedicated models have been developed for describing the noon or midnight turns of various types of satellites during the eclipse season [25.53–55]. Unless these models can be consistently applied by the user, the respective satellites and time intervals should be discarded in the PPP processing.

As an alternative to rigorous phase wind-up modeling, the use of a *decoupled clock model* has been suggested in [25.56]. Here unmodeled wind-up effects that otherwise result in a code-carrier inconsistency are absorbed in distinct clock offset parameters for the pseudorange and carrier-phase observation model. This approach can be applied if external attitude information for the receiver antenna is not available and the antenna is primarily rotating about a constant axis.

### 25.2.3 Site Displacement Effects

By its very nature, precise point positioning delivers coordinates in a global terrestrial reference frame such as the international terrestrial reference frame (ITRF) or the IGS-specific IGSyy frame. The realization of such a frame is complicated by the fact that the Earth and its crust are not perfectly solid. The various forces acting on the Earth (e.g., lunar and solar gravity, but also loading due to ice, oceans and even the atmosphere) result in periodic deformations and thus periodic motion of individual stations. These are mostly highly correlated over large areas and can therefore be neglected in relative positioning over up to a few hundred km. However, the periodic motions have been removed through relevant models in the realization of the ITRF and its reference station coordinates. In accord with current IERS conventions [25.13], the same models of the periodic site displacements must be accounted in all PPP applications to obtain ITRF-compatible site positions.

Dominant effects such as solid Earth and pole tides or ocean loading cause site displacements at the few cm to dm level and are discussed below in further detail. Effects with a magnitude of less than 1 cm, such as surface loading from atmospheric pressure, ground water and/or snow buildup, are neglected and not considered in the following. These small effects can be applied a posteriori or even monitored with PPP solutions (e.g., local ground water/snow buildup variations). For these reasons, no IGS solutions currently include the abovementioned environmental loading effects. Furthermore, diurnal and semidiurnal atmospheric tides $S_1$ and $S_2$, included in the IERS2010 conventions and applied by some IGS analysis centers have also been neglected here. The vertical amplitudes of $S_1$ and $S_2$ can reach up to about 2 mm, mainly in the equatorial regions, and they will largely average out over the standard 24 h solution periods used by IGS. The horizontal $S_1/S_2$ effects are about one order of magnitude smaller, so for all kinematic and most static PPP solutions, the horizontal and even vertical atmospheric tides can be neglected.

#### Solid Earth Tides

Similar to ocean tides, the gravitational attraction of the Sun and Moon causes a subtle deformation of the (presumably solid) Earth and its crust. It results in horizontal and vertical displacements that can be modeled by a spherical harmonics expansion and associated physical parameters (known as Love and Shida numbers), which describe the susceptibility of the Earth's body to the tide-generating potential. At an accuracy level of about 5 mm, it is sufficient to only consider the dominant, second-degree tides of the Sun and Moon along with a supplementary height correction term [25.57]. Within this approximation, the site displacement of a station at position $\boldsymbol{r}$ can conveniently be described by the geocentric unit vectors $\boldsymbol{e}_\odot = \boldsymbol{r}_\odot/r_\odot$, $\boldsymbol{e}_\leftmoon = \boldsymbol{r}_\leftmoon/r_\leftmoon$, and $\boldsymbol{e} = \boldsymbol{r}/r$ in Sun, Moon, and station direction

$$\begin{aligned}\Delta\boldsymbol{r} = \sum_{j=\odot,\leftmoon} \frac{GM_j}{GM_\oplus}\frac{r^4}{R_j^3}\Bigg\{&\left[3\mathrm{l}_2\left(\boldsymbol{e}_j\cdot\boldsymbol{e}\right)\right]\boldsymbol{e}_j \\ &+\left[3\left(\frac{\mathrm{h}_2}{2}-\mathrm{l}_2\right)\left(\boldsymbol{e}_j\cdot\boldsymbol{e}\right)^2-\frac{\mathrm{h}_2}{2}\right]\boldsymbol{e}\Bigg\} \\ &+\left[-0.025\,\mathrm{m}\sin\varphi\cos\varphi\sin\left(\theta_\mathrm{g}+\lambda\right)\right]\boldsymbol{e}\,.\end{aligned} \tag{25.9}$$

Here, $GM_\oplus$, $GM_\odot$, $GM_\leftmoon$ are the gravitational coefficients of the Earth, Sun, and Moon, while $\mathrm{l}_2 = 0.6090$ and $\mathrm{h}_2 = 0.850$ are the nominal second-degree Love and Shida numbers. The height correction term in (25.9) is described in terms of the station latitude $\varphi$ and longitude $\lambda$ as well as the Greenwich mean sidereal time $\theta_\mathrm{g}$.

For an accuracy of 1 mm or better further harmonics and the dependence of Love and Shida numbers on the station location and the frequency of each tidal constituent need to be considered [25.13, 58]. To facilitate a consistent application of the respective corrections, suitable computer implementations are made available along with the IERS conventions [25.13].

Overall, the solid Earth tides induce vertical station displacements of about 0.3 m and horizontal displacements of about 5 cm. Aside from periodic contributions with a dominating half-daily and daily periodicity, the tidal correction (25.9) also comprises a permanent displacement at the 1 dm level. Even though the periodic terms are largely averaged out in the processing of daily

arcs for static sites, the same does not apply for the permanent tidal displacement. Irrespective of the data arc and type of site, consideration of the full solid Earth tide correction is therefore essential in all PPP applications to comply with the *tide-free* ITRF realization.

#### Rotational Deformation due to Polar Motion (Pole Tide)

Aside from luni-solar tidal forces, small periodic changes in the deformation of the Earth are also caused by polar motion, that is, by changes in the location of the Earth's rotation axis relative to its crust. Following [25.13], the associated site displacements in east, north and up direction are given by

$$\begin{aligned}\Delta r_{\mathrm{E}} &= +9\,\mathrm{mm}\cos\theta\,[m_1\sin\lambda - m_2\cos\lambda]\,,\\ \Delta r_{\mathrm{N}} &= +9\,\mathrm{mm}\cos 2\theta\,[m_1\cos\lambda + m_2\sin\lambda]\,,\\ \Delta r_{\mathrm{U}} &= -33\,\mathrm{mm}\sin 2\theta\,[m_1\cos\lambda + m_2\sin\lambda]\,,\end{aligned} \tag{25.10}$$

for a station at longitude $\lambda$ and colatitude $\theta = \pi/2 - \varphi$. Here $m_1 = (x_{\mathrm{p}} - \bar{x}_{\mathrm{p}})$ and $m_2 = -(y_{\mathrm{p}} - \bar{y}_{\mathrm{p}})$ (expressed in [″]) are the coordinates of the Earth's rotation pole in the terrestrial reference frame, which are obtained as the difference of the polar motion variables $(x_{\mathrm{p}}, y_{\mathrm{p}})$ and the IERS model [25.13, Table 7.7] of the mean pole $(\bar{x}_{\mathrm{p}}, -\bar{y}_{\mathrm{p}})$.

Polar motion is not predictable, but exhibits dominating variations with periodicities of about 430 d (Chandler period) and 365 d (annual period). At amplitudes of up to 0.8″, the site displacements due to the pole tide may amount to roughly 25 mm in the vertical direction and about one quarter of this value in horizontal direction.

Polar motion centrifugal effects on the oceans cause an analogous ocean pole tide loading, also considered in the IERS2010 conventions. It also has seasonal and Chandler period variation, but it is rather small, nearly an order magnitude smaller than the above polar tides, so it can be safely neglected in most PPP applications.

#### Ocean Loading

Ocean tides result in a varying load of sea water and associated deformations of the Earth's crust. The induced site displacement is most pronounced in the vertical direction and typically at the cm level. However, in coastal regions, ocean loading can result in coordinate changes of up to 10 cm [25.20]. The response of the Earth's surface to the load changes depends largely on the topography and is typically not aligned with the body tides [25.59]. As with solid Earth tides, ocean loading effects show predominant semidiurnal and diurnal periodicities but, by convention, do not exhibit a permanent part.

Given these characteristics, ocean loading may be neglected for static positioning over daily periods, stations far off (typically > 1000 km) the coast or moderate accuracy requirements. However, it clearly needs to be considered for kinematic positioning, cm-level accuracy and coastal regions. As pointed out by [25.60], unmodeled ocean loading effects may also contaminate tropospheric ZTD or station clock estimates, which are highly correlated with the vertical position.

In its most basic form, coordinate shifts $\Delta c$ due to ocean loadings are described as a harmonic series

$$\Delta c = \sum_{j=1}^{11} A_{\mathrm{c}j}\cos(\chi_j(t) - \phi_{\mathrm{c}j}) \tag{25.11}$$

for each of three coordinate axes [25.13]. The individual terms considered in these series correspond to one of 11 semidiurnal ($M_2$, $S_2$, $N_2$, $K_2$), diurnal ($K_1$, $O_1$, $P_1$, $Q_1$), and long-period ($M_{\mathrm{f}}$, $M_{\mathrm{m}}$ and $S_{\mathrm{sa}}$) tide waves. The time-dependent angles $\chi_j$ are linear combinations of fundamental astronomical arguments such as the mean longitudes of the Sun and Moon and can consistently be computed using reference software implementations provided by the IERS [25.13]. The amplitudes $A_{\mathrm{c}j}$ and phases $\phi_{\mathrm{c}j}$, on the other hand, are station-specific quantities computed from global ocean tide models [25.61]. For a specific site and ocean tide model, these values can be conveniently obtained from an ocean loading provider service [25.62].

The ocean loading also induces periodic tidal variations of the Earth's center of mass (CoM) relative to a crust-fixed system aligned with the mean center of the Earth. These CoM offsets may be evaluated using an expression similar to (25.11) [25.13], but are not normally required for PPP users, since GNSS orbits products as provided by the IGS are, by convention, referred to a crust-fixed frame such as the ITRF.

### 25.2.4 Differential Code Biases

The observation model discussed in Sect. 25.1.1 is based on the simplifying assumption that all measurements are free of any biases. While this assumption is not necessarily true, it offers a proper model in practice, provided that GNSS clock products are generated with the same type of observations as used for the precise point positioning. For GPS, published clock offsets (in both the broadcast ephemerides and the precise products) are conventionally referred to an ionosphere-free combination of P(Y)-code observations on the L1 and L2 frequencies. Similarly, GLONASS precise clock products are based on L1/L2 P-code observations. When using the same signals for PPP, no further code

biases need to be considered and the observation model (25.1) can be used as is.

The situation is different, though, when working with other types of dual-frequency signals (e.g., the civil L1 C/A or L2C codes). In this case satellite-specific differential code biases (DCB) have to be applied to account for group delay differences between the signals tracked by the receiver and those of the clock reference signal [25.63]. A common application case is dual-frequency GPS PPP using commercial receivers that do not provide distinct P(Y)-code observations on L1, but deliver only C/A-code pseudoranges. Here, a supplementary bias

$$\frac{f_{L1}^2}{f_{L1}^2 - f_{L2}^2} \mathrm{DCB}^{s}_{\mathrm{C1C\text{-}C1W}} \tag{25.12}$$

needs to be added in the observation model (25.1) for the ionopshere-free pseudorange to translate the satellite clock offset and make it compatible with the employed observations. In the above equation

$$\mathrm{DCB}^{s}_{\mathrm{C1C\text{-}C1W}} = d^{s}_{\mathrm{C1C}} - d^{s}_{\mathrm{C1W}} \tag{25.13}$$

denotes the differential code bias of L1 C/A and L1 P(Y) pseudorange observations (indicated here by the corresponding RINEX observation codes C1C and C1W [25.50]). It may be noted that no receiver biases need to be considered in single-constellation processing, since those can readily be absorbed in the receiver-clock bias estimate. As an exception, such biases need to be calibrated and taken into account in PPP-based time transfer as further discussed in Chap. 41.

In multi-GNSS processing, satellite-specific DCBs need to be individually considered for a constellation whenever the tracked signals are different from the clock reference signals. In addition, an intersystem bias needs to be adjusted to compensate for time system differences between constellations and receiver-specific differential code biases (Chap. 21 and [25.63]).

DCBs of GPS and GLONASS satellites are routinely determined by various IGS analysis centers as part of their ionospheric analysis [25.16] for the legacy signals on L1 and L2. DCBs for the multitude of new signals and constellations are, furthermore, determined by the IGS from observed code differences and global ionosphere maps [25.10]. Use of these biases assists a more rigorous modeling of pseudorange observations. Even though PPP performance is generally driven by the high precision of carrier-phase observations, and partly *tolerant* to pseudorange errors, the proper consideration of DCBs is known to improve the convergence time in filter-based implementations and to enable a faster and more reliable ambiguity fixing.

### 25.2.5 Compatibility and Conventions

Precise point positioning fixes (or tightly constrains) external data such as the GNSS orbits and clock offset values. To ensure the desired cm- or mm-level accuracy, the PPP models and algorithms must be highly consistent with those used in the generation of the auxiliary products. Since PPP is in fact equivalent to a station position solution within a global network solution (but conveniently condensed within the precise orbit/clock products), it must adhere to the same conventions used in extracting orbit and clock data from the network. Among others, this may affect the choice of reference frames, Earth orientation parameters, antenna offset and phase pattern or the application of specific model corrections.

Within the IGS, which serves as a primary source of freely available high-accuracy GNSS data and products for scientific users, orbit and clock products are generated by various analysis centers (ACs). These adhere to common standards such as the IERS conventions (currently [25.13]), reference frames (currently ITRF2008/IGS08), and antenna phase center calibration models (currently *igs08.atx*, [25.48]). Clock products for GPS and GLONASS are based on ionosphere-free combinations of P(Y)-or P-code observations on the L1 and L2 frequencies and have been corrected for the eccentricity-dependent periodic relativistic clock variation. For other constellations, initial products provided within the IGS multi-GNSS experiment (MGEX) [25.64] are based on ionosphere-free E1/E5b (Galileo) or B1/B2 (BeiDou) combinations, but no formal standard has been established yet.

An overview of past and current conventions for the use of IGS products in PPP applications is provided in [25.65]. For specific and detailed information in a standardized format on each IGS AC global solution strategy, modeling and departures from the conventions, refer to the IGS central bureau archives [25.66].

## 25.3 Specific Processing Aspects

The concept of precise point positioning was originally developed for use with dual-frequency GPS observations, but is highly generic and can be applied to a variety of signals and constellations. Even though the basic modeling techniques discussed before are valid for all forms of PPP, some variants deserve specific consideration. Within the present section, single-frequency PPP is first discussed (Sect. 25.3.1), which is of particular interest for use with low-cost GNSS receivers. The use of GLONASS observations brings the added complexity of channel-dependent biases and is addressed in Sect. 25.3.2, while the use of new signals and other constellations is discussed in Sect. 25.3.3. Finally, PPP ambiguity fixing concepts are presented in Sect. 25.3.4, which offer a substantial increase in accuracy as well as a notably improved convergence time in sequential processing.

### 25.3.1 Single-Frequency Positioning

Traditional single-frequency point positioning (PP) utilizes pseudoranges only. If carrier-phase observations are available, they are commonly used for smoothing of pseudoranges, often internally within the receiver, in order to reduce pseudorange measurement noise [25.67]. The phase-smoothed pseudoranges are then used, along with ionospheric models (e.g., the broadcast Klobuchar model or global ionosphere maps [25.16]) to account for significant ionospheric delays [25.68–70]. Single frequency PP can use either the broadcast or more precise post-mission orbit/clock solutions. The broadcast and precise orbit/clocks are typically determined from dual-frequency data, so the satellite clocks reflect the corresponding differential code biases (e.g., the $\mathrm{DCB}_{\mathrm{C1W-C2W}}$ of GPS P(Y)-code pseudoranges on the L1 and L2 frequencies), which change from satellite to satellite and can reach several meters. Since single-frequency GPS receivers most commonly track the civil C/A-code signal rather than the encrypted P(Y)-code, an additional $\mathrm{DCB}_{\mathrm{C1C-C1W}}$ must be considered as well. For real-time use, equivalent timing group delay (TGD) and intersignal correction (ISC) parameters are transmitted as part of the modernized GPS navigation message [25.63, 71]. Neglecting these biases can cause positioning errors larger than when ionospheric delays are neglected [25.72]. The traditional, single-frequency PP is typically used for m-level navigation solutions only with four unknowns (three position coordinates and one clock). In such PP solutions, except for antenna offsets and a nominal tropospheric delay, practically all the effects discussed in Sect. 25.2 can be safely neglected.

A more precise alternative to single-frequency pseudorange PP is single-frequency PPP utilizing the code-plus-carrier (CPC) or GRAPHIC (group and phase ionospheric calibration [25.73]) combination $o_{\mathrm{GPH}} = (p+\varphi)/2$ of pseudorange and phase observations on the same frequency. It is ionosphere-free (to first order), since the ionospheric code and phase delays are the same, but of opposite signs. Namely, the carrier phases are advanced (shortened) and pseudoranges are delayed (lengthened) by the ionosphere (Chap. 19). Consequently, the new observable has a significantly lower observation noise (by a factor of two) than the original pseudorange and requires no external ionospheric information or corrections. However, due to the use of carrier phases, is subject to an ambiguity. This necessitates the use of pseudoranges and solving for ambiguities, much like in case of the standard dual-frequency PPP. This also results in a fairly long solution convergence (15 min or longer).

Many of the models and effects discussed above (Sect. 25.2) also need to be considered here, since the GRAPHIC-based PPP precision is at a few dm (Fig. 25.1). This applies specifically to tidal site displacement effects but also to carrier-phase wind-up when working with rotating and tumbling platforms [25.26]. As with the dual-frequency carrier-phase combination, the code-plus-carrier combination is not rigorously ionosphere-free but likewise includes some second- (and third-) order contributions. These are typically buried in the observation noise and multipath but may be taken into account in case of high ionospheric activity and when working with high-performance ranging signals.

The observation model for the single-frequency GRAPHIC combination is given by

$$\frac{1}{2}\left(p_{\mathrm{r}}^{\mathrm{s}}+\varphi_{\mathrm{r}}^{\mathrm{s}}\right)=\rho_{\mathrm{r}}^{\mathrm{s}}+c\left(dt_{\mathrm{r}}-dt^{\mathrm{s}}\right)+T_{\mathrm{r}}^{\mathrm{s}} +\lambda A_{\mathrm{GPH}}+\frac{1}{2}\lambda\omega+e_{\mathrm{GPH}}\,, \qquad (25.14)$$

where $\omega$ denotes the phase wind-up effect and $A_{\mathrm{GPH}} \approx -N/2$ is the (float valued) GRAPHIC ambiguity. It lumps minus one half of the carrier phase ambiguity as well as differential code biases between the employed single-frequency pseudorange observation and the (dual-frequency) code observations used for the satellite clock product. These DCBs need also be considered when combining the GRAPHIC observations with (single-frequency) pseudoranges to enable estimation of both the receiver clock offset and the GRAPHIC ambiguities. Depending on the accuracy

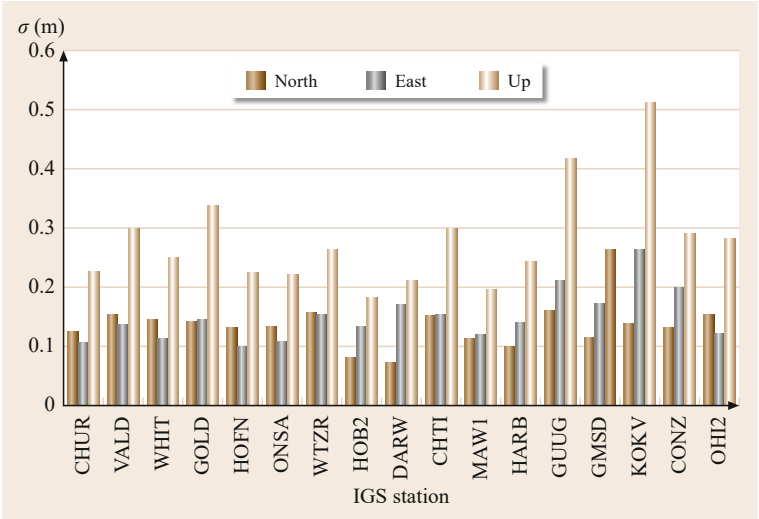

**Fig. 25.1** Repeatability of single-frequency kinematic PPP solutions at 17 globally distributed IGS stations obtained with IGS final orbits/clocks over a one-year period (Jan. 1, 2012–Feb. 9, 2013). The employed GRAPHIC observations are based on GPS L1 P(Y)-code and phase measurements. Individual *bars* for each station indicate the precision of the north, east, and up (height) components

requirements, tropospheric delays in (25.14) may be considered through models or estimated as in the case of dual-frequency PPP [25.74].

Except for very short data arcs that do not enable proper estimation of the ambiguities, the GRAPHIC-based PPP solution usually offers better positioning results than single-frequency pseudorange processing with a priori corrections from global ionosphere maps [25.75]. As discussed in [25.76], sub-decimeter accuracy (3-D RMS) can be achieved for least-squares solutions using batches of at least 6 h duration solutions. The ionosphere-free code-plus-carrier combination appears particularly attractive for use with advanced ranging signals such as the Galileo E5 alternative BOC (AltBOC) signal. Even though the GRAPHIC processing is not fully competitive to dual-frequency PPP, a three- to four-fold performance increase has been demonstrated in [25.77] when using AltBOC in comparison with legacy GPS L1 C/A observations. Due to the very low noise and high multipath resistance of this signal, 3-D RMS positioning accuracies of 20 cm down to 3 cm can be achieved with data arcs of 1–24 h.

As an alternative to the ionosphere-free code-plus-carrier processing, the direct processing of pseudorange and carrier-phase estimation has been proposed in [25.78] along with the estimation of the vertical total electron content (VTEC) and a common mapping function. Due to different pierce points a common VTEC for all observations is not appropriate though, and horizontal ionospheric gradients have to be estimated as well in this approach.

Irrespective of the specific formulation of the single-frequency PPP algorithms, a reliable detection and handling of cycle slips is vital for achieving a high overall performance. Since GRAPHIC observations may exhibit a noise level above the (half) carrier-phase wavelength, single-cycle slips may be hard to identify on this combination alone. Cycle-slip detection (and repair) techniques based on time-differenced carrier-phase observations and a geometry-based approach that overcome these difficulties are discussed in [25.79].

### 25.3.2 GLONASS PPP Considerations

Next to GPS, the Russian GLONASS was the second global navigation satellites system considered for precise point positioning [25.80, 81]. A joint use of both constellations promises notably improved convergence times and robustness, even if the accuracy of the estimated positions remains similar to that of GPS-only solutions [25.82–84].

However, the processing of GLONASS observations is complicated by the frequency division multiple access (FDMA) modulation scheme (Chap. 8), which makes use of slightly different signal frequencies on about 15 distinct channels. The individual channels are separated by 562.5 kHz and 437.5 kHz for L1 and L2, respectively (Chap. 8) and may result in interfrequency-channel biases (IFCB) for both code and phase observations. These biases affect the generation of precise orbit and clock products as well as the use of GLONASS observations for precise point positioning.

Depending on the receiver design, notable group delay variations across the different frequency channels may be encountered. Receiver-specific pseudorange IFCBs can exceed $\pm 10$ m and usually tend to have a linear behavior with rates up to about $\pm 2$ ns per channel index. The biases tend to be similar for the same receiver type, though antenna model and receiver model, or even a different receiver firmware version may

cause atypical behavior (Fig. 25.2). When GLONASS pseudoranges are weighted with sufficiently large uncertainty (e.g., 10 m), the pseudorange IFCBs have no significant effect (i. e., sub-mm) on PPP position and ZTD solutions but affect the receiver clock solutions. So in principle, pseudorange IFCBs need not cause significant problems in PPP solutions, unless ambiguity fixing is attempted (Sect. 25.3.4).

Aside from pseudorange IFCBs, GLONASS observations are also affected by carrier-phase IFCBs. These may differ by up to 5 cm per channel index between different receiver brands [25.85] and notably affect the ambiguity resolution in both differential and undifferenced (PPP) processing schemes. However, those small frequency-dependent phase biases are largely deterministic and can be attributed to group delays and digital delays in the signal processing that differ between receivers. They can essentially be eliminated when pseudorange and phase observations are made at the same sampling epoch [25.86].

To cope with these issues and to facilitate a consistent processing of GNSS observations from different receivers, current versions of the RINEX standard [25.50] specify a mandatory phase alignment of the GNSS measurements prior to generating the RINEX observations file. Consequently, for properly generated RINEX GLONASS data there should not be any phase IFCBs.

Provided that all the GNSS processes are using consistent and sufficiently precise observations and modeling, apart from distinct clocks solutions, each GNSS-specific PPP solution should then yield statistically equivalent position and ZTD solutions. This is confirmed, for example, in a performance assessment of [25.84] and independently illustrated in Fig. 25.3. The figure provides a comparison of GPS and GLONASS PPP solutions for selected IGS reference stations over a 13-month period. Differences between the GPS-only solution and the GLONASS-only solutions as well as deviations from the known IGS08 positions of the stations are generally at the few-mm level and most mean offsets are statistically insignificant when the real accuracy of PPP is considered (Sect. 25.5).

It is interesting, though, to note that GNSS-specific PPP solutions are fairly independent despite the fact that the measurements are observed by the same instrumentation (receiver/antenna). This is due to different observation sets, different satellite modeling and even local environmental effects (such as multipath and subdaily station movements), which may be somewhat different due to different constellation-specific satellite geometry, signal strength and/or frequencies. For example, GLONASS-GPS daily static PPP position solution differences at coastal stations may exhibit significant fortnight periodical signals (exceeding the repeatability sigmas) when ocean loading is neglected or wrongly applied. Satellite geometry and its repeatability likely cause this, since they are different for GPS and GLONASS. In this regard, different GNSSs may facilitate an important verification of individual PPP solutions.

### 25.3.3 New Signals and Constellations

The ongoing modernization of the GPS and GLONASS constellations as well as the buildup of new global and regional navigation satellite systems (BeiDou, Galileo, QZSS, IRNSS/NavIC) offers new prospects for improved PPP performance but poses also a variety of challenges to their users.

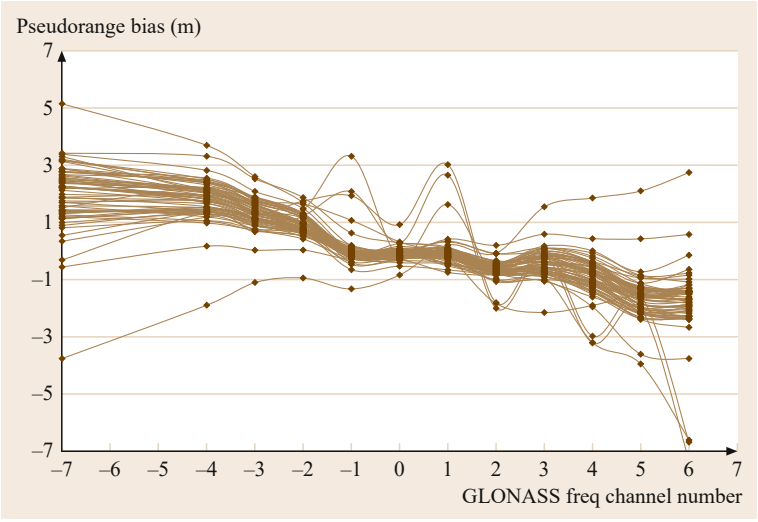

**Fig. 25.2** GLONASS interchannel pseudorange biases for a group of Leica receivers as determined on March 1, 2013. Most atypical biases seen here are due to different antennae or old receiver firmware

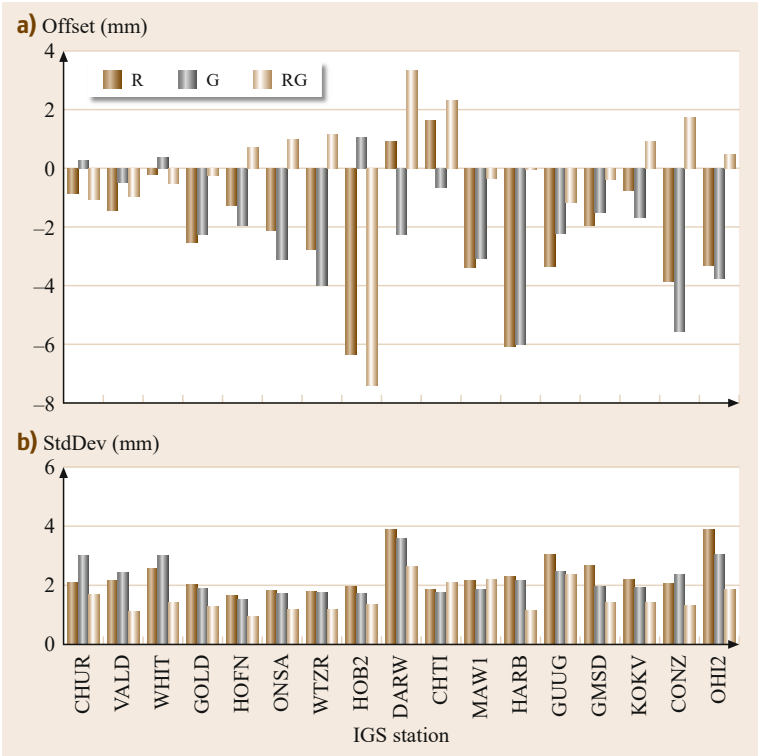

**Fig. 25.3a,b** Performance of static daily PPP solutions using GLONASS and GPS observations for 17 globally distributed IGS stations between 1 Jan. 2012 and 9 Feb. 2013 using European Space Agency (ESA) final GPS/GLONASS orbit/clock products. The graphs show the mean offset **(a)** and standard deviation **(b)** of the north position component for GLONASS-only processing (R) and GPS-only processing (G) relative to the IGS08 reference position as well as the difference of the two solutions (RG). Similar but slightly larger values apply for the scatter of the east and height components but no significant biases are obtained (not shown)

As discussed before, PPP depends critically on the consistency of auxiliary products (specifically the GNSS orbits and clocks) and the user processing. While relevant standards and conventions have evolved for GPS and GLONASS legacy signals over many years, they still need to be established for new signals and constellations. Along with that comes a need to thoroughly characterize the space segment (satellites, attitude laws, transmit antennas, biases) and the user segment (receivers, antennas, biases) in order to fully exploit the performance offered by the multitude of new signals in space.

While consistency of processing schemes, algorithms and even equipment can readily be ensured by commercial PPP service providers taking care of both the orbit/clock product generation and their usage, a larger effort is required for public services such as the IGS, which need to deal with a variety of different end-user equipment and possible processing tools. Such work has been initiated by the IGS within its Multi-GNSS experiment (MGEX; [25.64]) and resulted in the evolution of standards for the real-time and offline exchange of observation and navigation data (RINEX, RTCM; Annex A), conventional attitude models for all GNSS satellites [25.6], multifrequency receiver antenna calibrations [25.87], differential code biases for open signals of the various constellations [25.10] as well as early orbit and clock products for Galileo [25.88], BeiDou [25.89], and QZSS [25.90] or several of these new constellations [25.91, 92]. Even though the precision and accuracy of multi-GNSS products and system characterizations still lags behind GPS and GLONASS, continued efforts are made to improve their performance and to make them fully competitive.

As a straightforward extension of the GPS-only or GPS-GLONASS PPP concept discussed before, ionosphere-free combinations of pseudorange and phase observations of dual-frequency signals may be processed for any individual constellation or any combination of two or more constellations. When combining signals from multiple constellations, an intersystem bias (assumed to be constant over the processing arc) needs to be estimated for all but one constellation to compensate for possible system time offsets and constellation-specific receiver biases ([25.63, 93–96] and Chap. 21). Furthermore, satellite-specific DCBs will need to be applied, if the employed signals differ from those used in the generation of the respective clock product. The choice of signals used for the individual constellations will depend on availability (all satellites in the constellation should transmit the selected signal to avoid the presence of additional biases), signal characteristics ($C/N_0$, multipath resistance, etc.), and the employed clock product. Obviously, the two frequencies should be

widely spaced to minimize the noise of the ionosphere-free combination (allowing, e.g., GPS L1/L2 or L1/L5, but ruling out GPS L2/L5 as a meaningful option).

Initial results of multi-GNSS PPP processing involving BeiDou and/or Galileo next to GPS and GLONASS have, for example, been reported in [25.92, 97–99]. They confirm the benefit of an increased number of signals in space for the robustness and convergence time of PPP solutions and demonstrate an improved accuracy when applying state-of-the art models. The combination of signals from multiple constellations is of particular interest in constrained environments, which inhibit the use of low-elevation signals. Here, the minimum number of satellites required for kinematic point positioning (four to seven depending on the number of constellations and constellation-specific intersystem biases) can be ensured for cutoff angles as high as 40° in the combined GPS, GLONASS, BeiDou and Galileo service area [25.100]. Even though other constellations than GPS and GLONASS do not yet offer a fully global availability, multi-GNSS PPP is an emerging trend that will help to further improve PPP performance but also enables a better understanding of possible systematic errors that may go undetected in single-system solutions.

Along with the integration of the new constellations into the traditional, dual-frequency PPP concept, efforts are made to allow a seamless use of signals on more than just two frequencies into the PPP processing. This is of interest, since civil (or at least publicly accessible) signals are made available on three or even more frequencies by various new or modernized navigation satellite systems (including, so far, GPS L1/L2/L5, Galileo E1/E5a/E5b/E6, QZSS L1/L2/L5/E6, and BeiDou B1/B2/B3). A possible approach consists of the joint processing of multiple ionosphere-free dual-frequency combinations (e.g., GPS L1/L2 as well as GPS L1/L5). However, special care needs to be taken in this case to account for the correlation introduced by the repeated use of the same measurements (here L1) in the combined observations [25.101].

For a unified treatment of multiple signals, an uncombined, or *raw*, processing approach is followed in [25.102–104], which uses uncombined code and phase measurements on each of the available frequencies and introduces ionospheric slant delays as additional (epoch-wise) estimation parameters. With an undifferenced formulation one has the advantages of being able to use the simplest observational variance matrix and having all the parameters remain available for a possible further model strengthening. This latter aspect allows one to take advantage for instance of the time stability of biases or next-generation satellite clocks. Parameters that are not considered of interest can then easily be eliminated through the reduction of the normal equations, instead of performing an a priori elimination at the observational level that usually comes at the expense of a more complicated structure of the observational variance matrix. So far, experience with the *raw* PPP approach is limited due to the small number of satellites transmitting triple-frequency signals as well as time-varying biases between the L1, L2, and L5 signals of the GPS Block IIF satellites [25.105], which inhibit a proper exploitation of this method. This experience will grow with the advent of more signals and satellites, thus allowing a proper assessment of the different approaches.

### 25.3.4 Phase Ambiguity Fixing in PPP

Two principal benefits arise from fixing ambiguities to integers in the PPP context: improved positioning accuracy, specifically in the east component, and for filter-based PPP implementations, a reduction or possible elimination of the initial PPP solution convergence period. The latter benefit is particularly sought for the delivery of real-time PPP services, increasing their efficiency in achieving optimal solution accuracy.

DD phase ambiguity fixing has matured and is now routinely applied (Chap. 23) in either global or local positioning solutions. However, this is not directly applicable to PPP, due to the presence of pseudorange biases $d$ and carrier-phase biases $\delta$, which are eliminated in DD processing. This can be seen through a reparameterization of the basic observation model (25.1) explicitly exposing the different biases as follows

$$
\begin{aligned}
p^{\mathrm{s}}_{\mathrm{r,A}} &= \rho^{\mathrm{s}}_{\mathrm{r}} + c\,(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + c\left(d_{\mathrm{r,A}} - d^{\mathrm{s}}_{\mathrm{A}}\right) \\
&\quad + T^{\mathrm{s}}_{\mathrm{r}} + I^{\mathrm{s}}_{\mathrm{r}} + e_{\mathrm{A}}\,, \\
p^{\mathrm{s}}_{\mathrm{r,B}} &= \rho^{\mathrm{s}}_{\mathrm{r}} + c\,(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + c\left(d_{\mathrm{r,B}} - d^{\mathrm{s}}_{\mathrm{B}}\right) \\
&\quad + T^{\mathrm{s}}_{\mathrm{r}} + \mu I^{\mathrm{s}}_{\mathrm{r}} + e_{\mathrm{B}}\,, \\
\phi^{\mathrm{s}}_{\mathrm{r,A}} &= \rho^{\mathrm{s}}_{\mathrm{r}} + c\,(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + c\left(\delta_{\mathrm{r,A}} - \delta^{\mathrm{s}}_{\mathrm{A}}\right) \\
&\quad + T^{\mathrm{s}}_{\mathrm{r}} - I^{\mathrm{s}}_{\mathrm{r}} + N_{\mathrm{A}}\lambda_{\mathrm{A}} + \epsilon_{\mathrm{A}}\,, \\
\phi^{\mathrm{s}}_{\mathrm{r,B}} &= \rho^{\mathrm{s}}_{\mathrm{r}} + c\,(dt_{\mathrm{r}} - dt^{\mathrm{s}}) + c\left(\delta_{\mathrm{r,B}} - \delta^{\mathrm{s}}_{\mathrm{B}}\right) \\
&\quad + T^{\mathrm{s}}_{\mathrm{r}} - \mu I^{\mathrm{s}}_{\mathrm{r}} + N_{\mathrm{B}}\lambda_{\mathrm{B}} + \epsilon_{\mathrm{B}}\,.
\end{aligned}
\tag{25.15}
$$

The measurement biases affecting undifferenced observations are functionally indistinguishable from the clock and ambiguity parameters. Disregarding them in PPP solutions, whether they originate from pseudorange or carrier phases, contaminates clocks and ambiguities. In recent years, much attention has been given by different research groups to resolve this issue [25.102, 106–113]. The proposed solutions require external information, in addition to the usual satellite

orbit/clock products, to break the link between biases and ambiguities and to restore the integer nature of the ambiguities. The proposed methods are largely equivalent as their differences lie primarily in the chosen parameterizations, in the way the rank deficiencies are eliminated and whether or not they make use of the ionosphere-free combined observations [25.11].

The decoupled clock model (DCM) described in [25.109, 114] combines the four observations of (25.15) into three combinations: the two ionosphere-free (IF) combined pseudoranges and carrier phases and the Melbourne–Wübenna combination (Chap. 20). The IF combined observations each have specific satellite and station clock parameters ($dt_{\mathrm{r},p_{\mathrm{IF}}}$, $dt^{\mathrm{s}}_{p_{\mathrm{IF}}}$, $dt_{\mathrm{r},\varphi_{\mathrm{IF}}}$, $dt^{\mathrm{s}}_{\varphi_{\mathrm{IF}}}$), which include the respective combined biases ($d_{\mathrm{r,IF}}$, $d^{\mathrm{s}}_{\mathrm{IF}}$, $\delta_{\mathrm{r,IF}}$, $\delta^{\mathrm{s}}_{\mathrm{IF}}$). The Melbourne–Wübenna combination is parameterized with the usual widelane-narrowlane (WL/NL) ambiguities and station and satellite WL biases ($d_{\mathrm{r,WL}}$; $d^{\mathrm{s}}_{\mathrm{WL}}$). All IF and WL biases are combinations of the original observation biases. In the DCM implementation, the integer nature of ambiguities is assured by fixing a minimum set of ambiguities to arbitrary integers (the ambiguity datum), while estimating the clock and bias parameters at discrete epochs. The $N_{\mathrm{WL}}$ and $N_{\mathrm{NL}}$ can then be resolved using common integer search schemes (Chap. 23). The additional satellite parameters required for PPP under DCM are, apart from the clock corrections, which now are pseudorange-specific and carrier-phase-specific, also satellite specific WL biases. The PPP algorithm must estimate two station clocks, one for each observation type, and a station WL bias. Finally, an ambiguity datum must be maintained within the PPP through a minimum set of ambiguities fixed to arbitrary integers.

The integer recovery clock (IRC) approach described in [25.115] uses the same base observation combinations (two IF and one WL), however the parameterization is slightly different: in addition to the satellite and station WL biases and ambiguous phase clocks, code-phase biases are defined, which can be likened to the difference of the DCM pseudorange specific and carrier-phase-specific clocks. In its implementation, the satellite WL biases are estimated as daily constants, while the station WL biases are estimated epoch per epoch, with a constraint on the overall mean. Similar to the DCM, the full system is defined by a subset of arbitrary integer ambiguities and the remaining WL-NL ambiguities are fixed in bootstrapping integer search algorithms. In practice, for both formulations found above, these arbitrary ambiguity data are constrained using the IF pseudoranges, so the ambiguous satellite and station carrier-phase clocks are somewhat consistent with the pseudorange-specific clocks.

Still other parameterizations than the above given ones are possible as well, like, for example, the common or distinct clock formulations of [25.102, 116]. As all methods provide intrinsically the same external information, one can establish their one-to-one transformations thus showing how the different methods can be mixed between networks and users [25.11]. Instead of the two IF clocks and one WL phase bias, for instance, as used by the DCM and IRC approaches, one can also base the required satellite parameters on the pseudorange-specific IF clock and two between satellite differenced NL-WL network ambiguities or two NL-WL uncalibrated carrier-phase delays [25.110–112].

In the uncalibrated phase delay (UPD) approach of [25.111] and [25.117], the station biases are eliminated through single differencing and the single-differenced UPDs are estimated modulo 1 (WL-NL) cycle. Similar to [25.115], the WL single-difference (SD)-UPDs are estimated as daily constants while the NL SD-UPDs are estimated as piecewise linear polynomials over specified intervals. These network-level products are computed for all satellite combinations, an appropriate selection of which must be matched in the PPP algorithms to provide SD constraints to undifferenced ambiguities.

Another PPP phase ambiguity fixing method, introduced by [25.118], uses DD carrier-phase ambiguities from network DD processing, which are reintroduced into the PPP algorithms as the condition equations of the new undifferenced observations. As it uses information from the global network solution, this method does not require a reparameterization of the observation equations and is very well suited for efficient back-substitution of global results into single station solutions.

In all the above models, PPP solutions require additional network-level products, such as decoupled clocks, pseudorange or carrier-phase biases or UPD/SD-UPDs, to isolate the integer value of ambiguities. However, further development is required to accelerate integer ambiguity resolution and reduce the period of initial convergence, the main operational issue in PPP. From pseudorange initialization at the half-meter to meter level, to the centimeter accuracy attained once all parameters have reached their optimal state, convergence may take 15 min and even longer, depending on receiver-specific pseudorange noise and on the local tracking environment (multipath, ionosphere, antenna dynamics, etc.).

Significant improvements (or even elimination) of PPP convergence is possible when external a priori ionospheric information can be provided. However, this requires precise knowledge of ionospheric delay variations, typically interpolated from local or regional

networks. Furthermore, one has to abandon the ionosphere-free combination approach and instead work with observables that are still sensitive to the ionospheric delays. This can be done, as demonstrated in [25.116, 119–122], by working with the four original measurement types of (25.15) without creating any linear combinations explicitly, or alternatively, as shown in [25.123], by replacing the ionosphere-free Melbourne–Wübbena combination by its carrier phase and pseudorange constituent parts. Note that such PPP algorithms with fixed atmospheric delays become equivalent to real-time kinematic (RTK), provided that a proper weighting of the observables (undifferenced, DD, or combined) is used [25.11].

Improved results were also shown when using observations made on more frequencies and/or when using more GNSS satellites [25.82, 124–127]. For more details on ambiguity resolution, see Chap. 23.

## 25.4 Implementations

The availability of global GNSS precise orbits and clocks from various sources has provided the opportunity to develop and implement PPP-based services for positioning and navigation. Post-processed PPP services for both static and kinematic positioning are proving to be particularly useful and efficient for reference frame densification. They have been adopted by several countries as an efficient way to supplement and reduce the expensive infrastructure of dense networks of geodetic monuments traditionally used to provide access to national geodetic reference frames. Internet-based post-processed PPP services are now offered by several institutions to fulfill that function (Chaps. 35 and 36). Many real-time (RT) PPP based positioning and navigation services have also emerged in recent years. RT PPP services are usually more costly to operate and tend to be offered commercially to specialized market segments such as agriculture or land and marine natural resources exploration and exploitation.

It may be useful here to distinguish between online positioning (and navigation) services based on PPP and those based on the differential approach. Although they may appear the same to users who need only to submit GNSS data from one station, they differ fundamentally in their implementation. Differential-based services such as the US National Geodetic Survey Opus and the GeoScience Australia AUSPOS need data from several stations to form the double differences required by their DD processing algorithm. This additional data is normally obtained from their national continuous operating reference stations (CORS) networks as well as from the IGS global network.

Reliance on data from one or more base stations in addition to the one provided by the users has both advantages and disadvantages. On the plus side, the differential services offer more robust cycle-slip detection and repair as well as simpler carrier-phase ambiguity fixing as long as a sufficient number of nearby stations are available. Failure to meet that condition quickly reduces the area of applicability of the differential technique. While the PPP method can be used globally with almost uniform performance, the differential approach is better suited to regional or continental applications. The remainder of this section will only cover PPP-based services. Irrespective of the specific method, positioning and their users benefit from the continuing standardization for exchange formats for GNSS observation data, the derived products and, to some extent, the resulting solutions (Annex A).

### 25.4.1 Post-Processed Solutions

Post-processed PPP services are usually more precise than their real-time counterparts and tend to be used for applications requiring accuracy and stability. Although not quite as precise as differential positioning over medium or short baselines (e.g., $< 1000$ km), post-processed PPP is rapidly being adopted in several regions to establish geodetic control (Chap. 36). This is especially true in remote areas where geodetic control monuments are sparsely distributed or nonexistent. Because of the stability of some of the GNSS orbits and clock products used, post-processed PPP is now providing long-term station velocity estimates for geodynamic applications that compare favorably with those obtained with the differential technique.

Typically for post-processed PPP applications, users submit GNSS data from a single station to the service via the Internet and receive, normally by e-mail and within minutes, an estimated position along with ancillary information. Depending on the service, various formats, such as RINEX, can be used for the GNSS data submission. Very little standardization currently exists for the dissemination of post-processed PPP results. Once received on the host server, GNSS data is processed according to the PPP method using GNSS orbits and clock corrections computed by the service provider or obtained from a third party such as the IGS. In addition to the orbits and clock corrections, PPP services may also call upon other specialized web services for additional corrections such as the ocean tide loading

corrections, troposphere delay parameters and receiver and satellite antenna PCVs.

In addition to the online services, PPP processing is now offered by several GNSS equipment manufacturers within their suite of post-processing software. The computations may be performed within a specialized PPP module or the GNSS data sent to an existing online service. In either case, results are seamlessly integrated into reports and other functions offered by those packages.

### 25.4.2 Real-Time Solutions

In contrast to the post-processed PPP services that rely on users sending GNSS observation data to a central server, most real-time applications require that GNSS orbit and clock corrections be sent in real time to the point of data collection. PPP position estimation is then performed according to PPP algorithms inside the GNSS receivers or on a colocated computer. Transmission of real-time corrections for PPP is usually done over the Internet using transport protocols developed for that purpose, such as NTRIP (networked transport of Radio Technical Commission for Maritime Services (RTCM) via Internet protocol [25.128]). To ensure that RT PPP services are available even in regions without access to high-speed Internet, some providers are also distributing corrections using geostationary communication satellites, which greatly increase service costs. Most real-time PPP services are currently offered for a cost by commercial enterprises. Costs of those services usually vary with the region as well as with the accuracy required.

Like post-processed PPP services, little standardization currently exists for RT PPP services as most are based on proprietary data formats and customized GNSS end-user equipment. Normally offered by providers of high-precision navigation services in niche markets, GNSS user equipment manufacturers or joint partnerships, RT PPP services tend to be closed-access and fully integrated services, where providers support end-to-end solutions, from computing real-time orbits and clock correction to embedding specialized software in end-user GNSS equipment. This could change in the coming years with the advent of new standardized formats applicable to RT PPP (Annex A) and Internet-based, free RT PPP corrections such as those of the IGS real-time service (Chap. 33). Open, real-time correction services, although useful for many applications, will require that algorithms in end-user applications be consistent with the models and conventions used to compute the correction streams.

### 25.4.3 PPP Positioning Services

Listing existing PPP based positioning services is problematic, since such a list can rapidly become outdated or incomplete. Nonetheless, a few examples of post-processed services often referenced in the literature are described in Table 25.3. The listed services all provide static or kinematic processing, use the RINEX observation format and output ITRF estimated coordinates. They, however, provide their results in nonstandard, service-specific output. Many of those services can be accessed and compared at Internet portals such as the University of New Brunswick's Precise Point Positioning Software Centre [25.129]. Other PPP services may exist that are specific to a given country, region or application.

Although each service has its own user interface, they should all provide comparable position estimates for a specific data set. A thorough assessment of the various services is, however, beyond the scope of this publication. For the interested reader, several papers comparing various post-processed and RT PPP services are available. Having several PPP services that provide independent position estimates also creates some redundancy and increases confidence that a PPP solution can be obtained whenever a particular service is unavailable or suspected of not providing reliable position estimates. However, caution is advised whenever comparing or integrating results from different services to ensure that estimated positions are for the same location, at the same epoch and in the same reference frame. Many services extract information directly from the observation file that is critical to identify the reference point of the position estimates, such as the receiver antenna type and antenna height. Processing reports should be closely examined to ensure that position estimates provided by the various services are indeed compatible.

## 25.5 Examples

To illustrate the performance offered by the precise point positioning concept, example results of GPS/GLONASS-based PPP solutions are presented in this section. The PPP software of Natural Resources Canada (NRCan; [25.130] and Table 25.3) has been used, along with 24 h data sets from 17 globally distributed IGS stations observed during the period of Jan. 1, 2012–Feb. 9, 2013. About half of the 17 stations are IGS reference frame stations, that is, a subset of those stations used to align IGS daily solutions to the current ITRF. To reduce computation time and also decrease possible correlation, 24 h PPP solutions using 5 min observation sampling were estimated at five-day intervals.

The NRCan PPP incorporates all the modeling effects described in Sect. 25.2, including ocean loading, higher-order ionospheric corrections, polar tides and a proper handling of eclipsing satellites for both GPS and GLONASS. However, the atmospheric and hydrological loading effects have not been applied here. Furthermore, only GMF and GPT have been used for tropospheric mapping and a priori $ZTD_h$, respectively, since GMF/GPT should give slightly better repeatability than the more rigorous VMF1 ones, when no atmospheric loading is applied (Sect. 25.2.1). Also, no ambiguity fixing (Sect. 25.3.4) has been employed. Although only the NRCan PPP software has been used here, other recent PPP implementations should give similar results.

### 25.5.1 Static PPP Solutions

Table 25.4 shows the comparison of static PPP positioning solutions with respect to IGS08 reference coordinates using final IGS GPS orbits/clock products as well as European Space Agency (ESA) GPS/GLONASS products. Note that Table 25.4 includes both mean offsets and repeatability of the daily static PPP solutions (one position solution for each 24 h interval), which are affected by real or apparent nonlinear station displacements during this 13-month period. Consequently, the RMS values (the last three columns of Table 25.4) are believed to be a good estimate of the accuracy of static PPP. Here one can notice that the addition of GLONASS has only slightly improved the RMS of the ESA GPS-only PPP solutions. This is likely due to small (real or apparent) systematic effects, common to both GPS and GLONASS PPP solutions. Nevertheless, even the accuracy of the ESA GLONASS-only PPP is quite impressive, considering that it is based on only 24 satellites and that the GLONASS orbit/clock modeling is still being improved.

As expected, the IGS final orbit/clock combinations yielded the smallest RMS of the mean offsets in Table 25.4, though the ESA GLONASS-only PPP RMSs were only slightly larger than the rest. The repeatability of IGS (GPS-only) and ESA GLONASS+GPS PPP solutions are the best. The GLONASS addition improved the longitude repeatability in particular, namely from 3.0 mm down to 2.7 mm.

Ambiguity fixing (Chap. 23), which was not been applied here, would also improve longitude repeatability to a level comparable to what is seen in latitude. The mean offset RMSs, on the other hand, are not expected to be improved by fixing ambiguities, as they are mainly due to station and orbit/clock systematic effects, which are not affected or reduced by ambiguity fixing. However, the initial PPP solution convergence, typically of about 15 min or longer for GPS-only PPP, may be significantly shortened when ambiguities are fixed (Sect. 25.3.4). This is not applicable here, since the 24 h PPP solutions are already fully converged, albeit to nonintegers.

Note that Table 25.4 includes some remote stations with suboptimal performance (e.g., OHI2, or the GLONASS HOB2 and DARW data), which have degraded repeatability and mean offset RMS. For most stations the repeatability and RMS are significantly better than those shown in Table 25.4 as can be seen from results previously shown in Fig. 25.3.

### 25.5.2 Kinematic PPP Solutions

In kinematic mode, independent PPP positions are estimated at each observation epoch, typically every 1–30 s, depending on application and user dynamics. When observation intervals are shorter than the satellite clock sampling, clock interpolation is necessary. Due to satellite clock instability, only clocks at 30 s or lower sampling interval can be reliably interpolated at the cm precision level. IGS and most IGS AC clock solutions currently use 30 s sampling but higher-rate clock products may be offered by individual analysis centers for specific applications [25.131].

To demonstrate kinematic PPP performance, even though under rather ideal conditions, the 17-station static dataset discussed before has also been reprocessed in kinematic mode, where an independent position is solved at each observation (and satellite clock) epoch. Since backward smoothing (substitution) was used for all kinematic PPP solutions, the statistics reflect the solution quality after ambiguity convergence. The resulting kinematic PPP epoch repeatability for each of the 17 stations with the final IGS (GPS-only)

**Table 25.4** Repeatability and root mean square (RMS) of the static daily PPP mean offsets (in mm) with respect the IGS08 positions at 17 globally distributed IGS stations, between Jan. 1, 2012 and Feb. 9, 2013, obtained with the final IGS GPS and ESA AC GLONASS/GPS orbits/clocks. Columns dN, dE, and dH refer to the north (latitude), east (longitude) and height (up) component of the position

| Static PPP | $\sigma$ | | | RMS of means | | | RMS | | |
|---|---|---|---|---|---|---|---|---|---|
| AC orbits/clocks | dN (mm) | dE (mm) | dH (mm) | dN (mm) | dE (mm) | dH (mm) | dN (mm) | dE (mm) | dH (mm) |
| igs (GPS) | 2.2 | 3.2 | 6.6 | 1.7 | 2.2 | 3.6 | 2.8 | 3.9 | 7.5 |
| esa (GPS) | 2.3 | 3.0 | 6.6 | 2.9 | 2.3 | 3.7 | 3.7 | 3.8 | 7.6 |
| esa (GLONASS) | 2.4 | 3.3 | 7.7 | 3.0 | 3.0 | 4.2 | 3.8 | 4.5 | 8.8 |
| esa (GLONASS+GPS) | 2.2 | 2.7 | 6.6 | 2.8 | 2.5 | 3.7 | 3.6 | 3.7 | 7.6 |

and ESA (both GPS and GLONASS) orbits/clocks are shown in Table 25.5.

As expected, the ESA GLONASS+GPS kinematic PPP performed the best, better than GPS-only PPP using the IGS or ESA orbits/clocks. The latitude and longitude of the GLONASS+GPS PPP solutions have sub-cm repeatability at most stations, while the height repeatability is about twice as large (i. e., 2 cm or less at most stations). Note that the RMS differences with respect to IGS08 (not shown here) are about the same as the static PPP RMS, which are much smaller than the kinematic PPP repeatability. Consequently, kinematic PPP repeatability can be seen to represent post-processed kinematic PPP accuracy, achievable under ideal observing conditions (static).

The GLONASS-only kinematic PPP solutions in Table 25.5 performed much worse than the GPS-only ones, with repeatability often exceeding 5 cm. This should be expected, as there are only 24 GLONASS satellites, yielding weaker geometry and less robust epoch solutions than the 32 GPS satellites. Furthermore, GLONASS orbits/clocks are still less precise and less robust than the GPS ones. Nevertheless, adding GLONASS data already improves kinematic PPP precision or accuracy, sometimes quite significantly. Even for several remote stations (e.g., DARW and HOB2), which had rather large sigmas for GLONASS-only PPP repeatability (Table 25.5), the addition of GLONASS data improved in most cases the GPS-only PPP, sometimes quite significantly. In a real dynamic environment, users are cautioned that kinematic PPP precision can be considerably worse, in particular when operating in real time, which cannot take the advantage of post processing and backward smoothing and is impacted by additional errors due to latencies of real-time clock solutions.

**Table 25.5** Repeatability ($\sigma$ [cm]) of kinematic PPP solutions at 17 IGS stations with IGS and ESA orbit clock products using GPS-only (G), GLONASS-only (R) and GPS+GLONASS (GR) observations (Jan. 1, 2012–Feb. 9, 2013)

### 25.5.3 Tropospheric Zenith Path Delay

Another parameter estimate available in a PPP solution is the wet tropospheric zenith path delay $ZTD_w$, which when added to the a priori hydrostatic $ZTD_h$, yields the total ZTD. When the wet and dry ZTD and the corresponding mapping functions are properly separated (Sect. 25.2.1), $ZTD_w$ can be used to infer the atmospheric precipitable water content (Chap. 38), which can be assimilated into a NWM, although the total ZTD is usually preferred.

Figure 25.4 gives an example of total ZTD PPP solutions at the former IGS station CHAT obtained in 2009 (with an earlier version of the NRCan PPP software), utilizing the IGS Final GPS orbits/clocks. The PPP also estimated stochastic ZTD gradient solutions (Sect. 25.2.1), which are rather small and for brevity are not shown here. The PPP solutions (at 5 min sampling) are compared to the IGS total ZTD products, which are also using 5 min sampling and IGS orbit/clock PPP, but are generated with a different software (GIPSY/OASIS [25.132]). Figure 25.4 also compares the ZTD of the CODE AC, GFZ AC and JPL AC global solutions with the IGS ZTD products. One can see a fairly good agreement for all ZTD solutions, which use the 5 min sampling (IGS, JPL, PPP). The 0.5 h and 2 h samplings, used respectively by GFZ and CODE, are not as responsive to the rapid changes of the total ZTD in the second half of the week (see the ZTD scale on the right). They have likely caused the fairly large (COD-IGS) and (GFZ-IGS) ZTD differences.

The same comparisons seen in Fig. 25.4 have also been done at 33 globally distributed IGS reference stations resulting in a RMS of 2.8 mm for the (PPP-IGS) ZTD differences. ZTD solutions based on the current PPP software version and the latest IGS orbit/clock and ZTD solutions should give an even better agreement. It is important to realize that the ZTD and height PPP parameters are weakly correlated, namely up to 20% of height errors (either real or apparent) may be mapped into ZTD estimates [25.133]. This is why it is essential that for precise ZTD solutions all the models of Sect. 25.2 be properly taken into account.

### 25.5.4 Station Clock Solutions

Time and frequency transfer applications of GNSS will be addressed specifically in Chap. 41. This section shows the level of precision at which station clock parameters are recovered using PPP. For this purpose, eight IGS stations (AMC2, BRUX, IENG, NRC1, PTBB, SPT0, USN3, WAB2) located at time and frequency laboratories were processed in three successive 24 h PPP solutions using the NRCan-PPP software in static mode and applying backward smoothing (substitution) to eliminate the initial convergence period. IGS final satellite orbit and clock products were used. The IGS clock products also include stations clock estimates that are consistent with those of satellites, all clocks being referenced to the IGS timescale [25.134].

Figure 25.5 shows the difference of PPP station clock estimates with respect to the IGS Final solutions, where the level of agreement is a few 100 ps (equivalent to 3 cm) or less for the best performing stations, and the solution boundary discontinuities are typical of the systematic effect of pseudorange errors averaged over the 24 h solution interval.

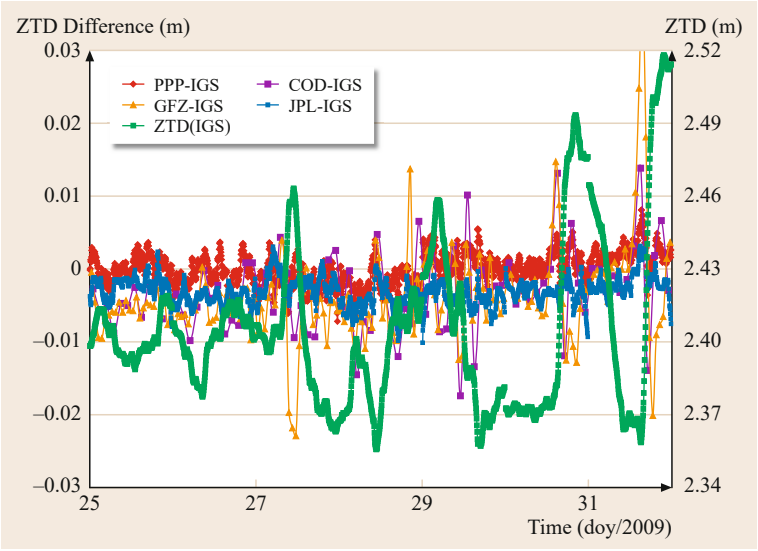

**Fig. 25.4** Total ZTD differences from PPP with IGS final orbits/clocks (PPP-IGS) along with Center for Orbit Determination in Europe (CODE), Deutsches GeoForschungsZentrum Potsdam (GFZ) and JPL analysis center solutions with respect to IGS total ZTD at the former IGS station CHAT. The RMS of PPP-IGS ZTD differences are 2.3 mm for station CHAT during this week-long period and 2.8 mm for 33 globally distributed IGS reference stations (IGS, PPP and JPL used 5 min ZTD solution sampling; GFZ and CODE AC used 0.5 h and 2 h ZTD solution intervals, respectively) (after [25.65])

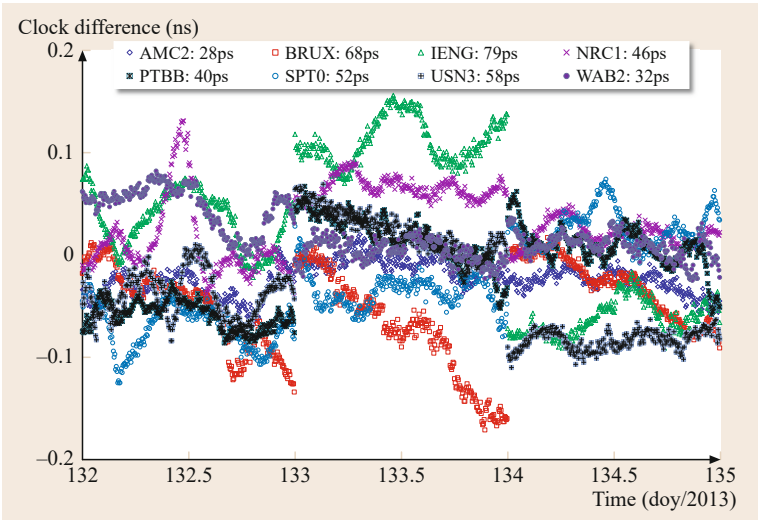

**Fig. 25.5** Daily PPP clock solution differences with respect to IGS final solutions for eight IGS stations located at time and frequency laboratories for three consecutive days. RMS differences for each station are below 200 ps

## 25.6 Discussion

The dual-frequency PPP concept, with related methodology and modeling for static and kinematic PPP solutions with respective precisions of a few mm and one cm, has been reviewed and discussed. Such PPP solutions include position estimates that are directly in the reference frame of the input orbits/clocks, but also facilitate consistent recovery of ZTD solutions at a few-mm level and station clock solutions at the subnanosecond level. Even in single-frequency mode, using ionosphere-free code-plus-phase combinations enables a fairly precise kinematic PPP (navigation) at a few-dm level. This single-frequency PPP can also facilitate ionospheric total electron content (TEC) solutions and monitoring, which compare favorably with the ones based on dual-frequency pseudorange observations.

The PPP solutions can be viewed as an efficient means of realizing the reference frame implied by the fixed orbits/clocks. In fact, they are a station-based back substitution of the global network solutions applied to generate the orbits/clocks products. Consequently, dual-frequency PPP position, ZTD and clock solutions should be as precise as the ones obtained in the corresponding global solutions, provided that the PPP uses consistent models and ambiguity fixing. Ambiguity fixing can improve the PPP positioning precision, particularly the longitude solutions using data spans significantly shorter than 24 h, and it can possibly reduce the time period to initial PPP solution convergence, or even eliminate it, if external, precise ionospheric delays are available.

Even though the above discussions and review pertained mainly to the dual-frequency (L1, L2) PPP with GPS and GLONASS orbits/clocks, extension to a different frequency pair (e.g., L1, E5) and emerging GNSS constellations, such as BeiDou ad Galileo, are straightforward, once all intersystem biases are resolved. Addition of new GNSS signals and satellites will be quite beneficial to PPP solutions, making them more precise and robust, particularly so for kinematic applications. In fact, independent PPP processing of observations from different GNSS systems may provide the redundancy required to facilitate the evaluation of geodetic quantities, as new observation combinations and orbital geometries are exploited to analyze local and long-term systematic effects.

The above discussions have relied heavily on IGS developed conventions (modeling and formats) and IGS orbit/clock products. It is likely that developers and users of PPP will use the IGS orbit/clock solutions, in particular when long time series are to be analyzed with the highest accuracy for consistency with the current IERS standards. It is encouraging to know that the IGS mandate also calls for the provision of orbit/clock solutions for all available GNSSs, as they emerge. Despite their IGS focus, the above discussions should also benefit PPP users of other, for example commercial orbit/clock services, since most of these services benefit from and largely follow the IGS modeling, conventions and developments.

Without IERS conventions and readily available IGS products [25.135] resulting from the significant efforts sustained to develop precise orbit models by many participating organizations, efficient and precise PPP solutions such as those discussed here would not have

been possible. PPP solutions can only be as accurate as implied by the adopted GNSS orbits and clocks!

*Acknowledgments.* Data and solution products from the International GNSS Service (IGS) have been used in the preparation of this chapter. Also, the significant help and contributions of the Editors, Oliver Montenbruck and Peter Teunissen, are acknowledged, in particular in regards to the emerging GNSS signals and undifferenced ambiguity resolutions.

# 26. Differential Positioning

Dennis Odijk, Lambert Wanninger

This chapter describes the concepts of differential global navigation satellite system (DGNSS) positioning focusing on practical details given that the fundamental concepts have been covered in prior chapters. The chapter starts with a review of the general concepts of DGNSS, including a quantitative discussion on the biases in DGNSS measurements. The next section focusses on code-based DGNSS positioning, presenting an overview of DGNSS services as well as a brief discussion on the format and latency of DGNSS corrections. A significant part of this chapter is devoted to carrier-phase dominated DGNSS, or real-time kinematic (RTK) positioning. Besides a theoretical consideration that includes the Russian Global Navigation Satellite System (GLONASS) and multi-GNSS RTK, the section provides examples of RTK positioning performance that are obtained in practice. The last section details on network RTK, which is an extension of the standard RTK technique to cover longer distances.

## 26.1 Differential GNSS: Concepts

This section describes and compares the concepts of differential GNSS (DGNSS) positioning. We will address the code (pseudorange)-based DGNSS positioning techniques as well as the more precise carrier-phase-dominated DGNSS positioning techniques. Pseudorange DGNSS remains an important method for obtaining meter level positions, whereas real-time kinematic (RTK) carrier-phase DGNSS receiver systems and correction services are essential tools in surveying and many other fields. Furthermore, network-based approaches to deliver RTK carrier-phase DGNSS services have more recently gained importance.

Before discussing the differential positioning techniques, Sect. 26.1.1 reviews the global navigation satellite system (GNSS) code and phase observation equations, as they form the basis of the positioning models.

### 26.1.1 Differential GNSS Observation Equations

Reference is made to the basic (linearized) observation equations as presented in Chapts. 19 and 21, but now with the satellite position vector still assumed as unknown in the observation equations (in Chap. 21 it was assumed that the satellite positions are known, such that they disappear from the linearized positioning model). If, similar to Chap. 21, it is assumed that there are two receivers, a rover (or remote) receiver denoted by $r$ and a reference (pivot or base) receiver denoted

by 1, that both track data of satellite $s$ that corresponds to GNSS constellation S at the same frequency $j$, the between-receiver differenced (linearized) observation equations for pseudorange (code) and carrier-phase read

$$\begin{aligned}\triangle p^s_{1r,j} &= -\boldsymbol{e}_r^{s\top}\triangle\boldsymbol{r}_{1r} + \boldsymbol{e}_{1r}^{s\top}(\triangle\boldsymbol{r}^s - \triangle\boldsymbol{r}_1) \\ &\quad + T^s_{1r} + \mu^{\mathrm{S}}_j I^s_{1r} + c\left[dt_{1r} + d^{\mathrm{S}}_{1r,j}\right. \\ &\quad \left. + \Delta d^s_{1r,j}\right] + e^s_{1r,j}\,, \\ \triangle\varphi^s_{1r,j} &= -\boldsymbol{e}_r^{s\top}\triangle\boldsymbol{r}_{1r} + \boldsymbol{e}_{1r}^{s\top}(\triangle\boldsymbol{r}^s - \triangle\boldsymbol{r}_1) \\ &\quad + T^s_{1r} - \mu^{\mathrm{S}}_j I^s_{1r} + c\left[dt_{1r} + \delta^{\mathrm{S}}_{1r,j}\right. \\ &\quad \left. + \Delta\delta^s_{1r,j}\right] + \lambda^{\mathrm{S}}_j N^s_{1r,j} + \varepsilon^s_{1r,j}\,. \end{aligned} \tag{26.1}$$

The following notation is used:

| | |
|---|---|
| $\triangle p^s_{r,j}$ | Observed-minus-computed code |
| $\triangle\varphi^s_{r,j}$ | Observed-minus-computed phase |
| $\boldsymbol{e}^s_r$ | Line-of-sight vector of unit length |
| $\triangle\boldsymbol{r}_1$ | Incremental pivot receiver position |
| $\triangle\boldsymbol{r}_{1r}$ | Incremental relative receiver position |
| $\triangle\boldsymbol{r}^s$ | Incremental satellite position |
| $T^s_{1r}$ | Differential tropospheric delay |
| $\mu^{\mathrm{S}}_j$ | Ionospheric coefficient for $j$-th freq. |
| $I^s_{1r}$ | Differential ionospheric delay |
| $c$ | Velocity of light |
| $dt_{1r}$ | Differential receiver clock |
| $d^{\mathrm{S}}_{1r,j}$ | Differential receiver code bias |
| $\delta^{\mathrm{S}}_{1r,j}$ | Differential receiver phase bias |
| $\Delta d^s_{1r,j}$ | Differential code interchannel bias |
| $\Delta\delta^s_{1r,j}$ | Differential phase interchannel bias |
| $\lambda^{\mathrm{S}}_j$ | Wavelength for frequency $j$ |
| $N^s_{1r,j}$ | Differential carrier-phase ambiguity |
| $e^s_{1r,j}$ | Differential code noise |
| $\varepsilon^s_{1r,j}$ | Differential phase noise. |

Note that $(\cdot)^\top$ denotes the transpose of a matrix or vector. The between-receiver differencing has eliminated the satellite clock as well as satellite hardware biases from the observation equations. Compared to the undifferenced observation equations, all other parameters are changed to their between-receiver differential counterparts. Similar to Chap. 21, the between-receiver differenced observables and parameters are denoted by $(\cdot)_{1r} = (\cdot)_r - (\cdot)_1$. Note that besides the (incremental) satellite position vector (i. e., $\triangle\boldsymbol{r}^s$), also the (incremental) position vector of the reference receiver 1 (i. e., $\triangle\boldsymbol{r}_1$) is maintained in the differential observation equations (instead of assuming it as known). The reason for this is as to evaluate the impact of errors in either one of them on the differential observation equations (Knowing the satellite positions as well as the pivot receiver position implies that $\triangle\boldsymbol{r}^s = 0$, as well as $\triangle\boldsymbol{r}_1 = 0$ (Sect. 26.1.2). If the position of the reference receiver is only approximately known, using DGNSS precise *position differences* between reference and rover (also referred to as *baseline coordinates*), denoted by $\boldsymbol{r}_{1r}$, are estimated.

An alternative approach for DGNSS is that instead of forming differences of observations between rover and pivot receivers, *pseudorange corrections* and/or *phase-range corrections* (Chap. 21) are formed based on the data of the pivot receiver. These *differential corrections* are then transmitted to the rover receiver to correct its observations.

Finally, we remark that the differential *interchannel (or interfrequency) biases* in (26.1), that is, $\Delta d^s_{1r,j}$ and $\Delta\delta^s_{1r,j}$, only appear in case of GLONASS (frequency division multiple access (FDMA)) observations. These interchannel biases (ICBs) exist as each GLONASS signal transmits on its own frequency channel (Chap. 8). In case of code division multiple access (CDMA) signals these interchannel biases are absent.

### 26.1.2 Differential GNSS Biases

The main motivation for the development of differential positioning techniques was the presence of *Selective Availability* (SA) on Global Positioning System (GPS) signals. SA was implemented to deliberately degrade the GPS positioning performance after it was discovered that single point positioning (SPP) based on the civil C/A-code performed better than originally expected [26.1]. SA implied that the GPS broadcast ephemerides were manipulated and the satellite clock stability was degraded (*dithering*) by the U.S. government [26.2]. This had as consequence that the accuracy of C/A-code-based SPP (i. e., the GPS standard positioning service) was only about 100 m. SA has been turned off since 2 May 2000, resulting in a SPP accuracy of about 10 m, an improvement of a factor 10. As an illustration, Fig. 26.1 shows the position errors obtained using SPP for an Australian international GNSS service (IGS) station (YAR1) during the first 8.3 h of 2 May 2000. From the graphs it can be directly seen that after SA was turned off at about 04:07 UTC, the position accuracy improved tremendously.

Although the main motivation for the development of differential techniques was to eliminate the effects of SA, DGNSS has remained a very important positioning method after SA was turned off, because of its elimination and reduction of biases. Besides the elimination of the satellite clock and hardware biases, biases due to orbit and atmospheric are significantly reduced, based on their spatial correlation. The remainder of this section provides a quantitative assessment of the different types of DGNSS biases.

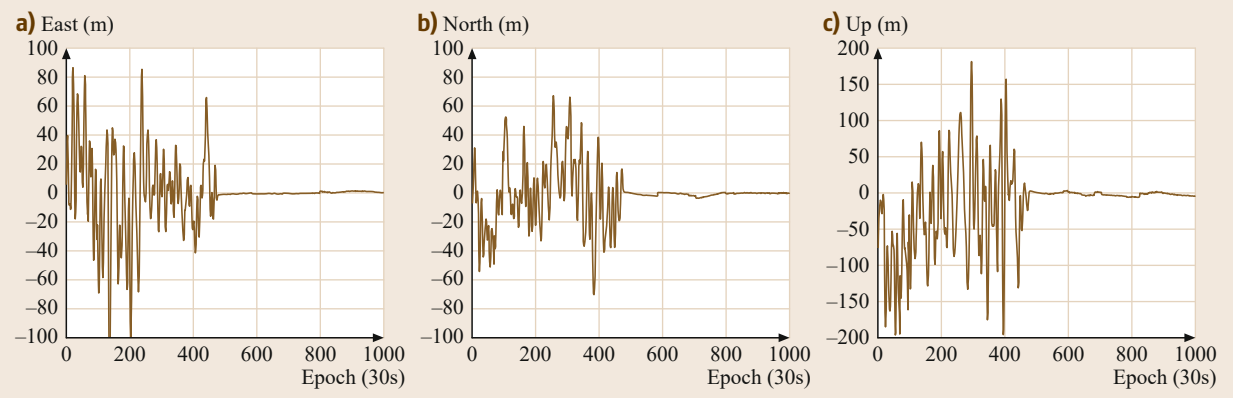

**Fig. 26.1a–c** East (a), north (b), and up (c) position errors of station YAR1 (Western Australia) obtained with single point positioning during the first 8.3 h Coordinated Universal Time (UTC) of 2 May 2000. The effect of turning off *Selective Availability* at about 04:07 UTC (epoch 480 in the graphs) is clearly visible

### Satellite and Pivot Receiver Position Biases

The satellite position as well as the position of the pivot receiver are multiplied by the differential line-of-sight vector $\boldsymbol{e}^s_{1r}$ in the observation equations (26.1). The effect of a bias in either the satellite position or pivot receiver position can be evaluated as follows. Recall (21.84) in Chap. 21, which gives a rule-of-thumb for the impact of a bias in the satellite position on the relative baseline

$$\left|\boldsymbol{e}^{s\,\top}_{1r}\,\triangle\boldsymbol{r}^s\right| \le \frac{\|\boldsymbol{r}_{1r}\|}{\|\boldsymbol{r}^s-\boldsymbol{r}_r\|}\|\triangle\boldsymbol{r}^s\| \,. \tag{26.2}$$

Here $\|\boldsymbol{r}_{1r}\|$ denotes the baseline length between reference and rover receivers, $\|\boldsymbol{r}^s-\boldsymbol{r}_r\|$ is the distance between receiver and satellite and $\|\triangle\boldsymbol{r}^s\|$ the size of the bias in the satellite position. The impact of a bias in the position of the pivot receiver, denoted by $\|\triangle\boldsymbol{r}_1\|$, is upper bounded in a similar manner

$$\left|\boldsymbol{e}^{s\,\top}_{1r}\,\triangle\boldsymbol{r}_1\right| \le \frac{\|\boldsymbol{r}_{1r}\|}{\|\boldsymbol{r}^s-\boldsymbol{r}_r\|}\|\triangle\boldsymbol{r}_1\| \,. \tag{26.3}$$

The accuracy of broadcast GPS ephemerides is about 1 m. Using the above rule-of-thumb, this has an effect of $1000\,\text{mm}/20\,000\,\text{km} = 0.05\,\text{ppm}$ of the baseline length. For a baseline of 1000 km, the bias is then 5 cm. The accuracy of precise GPS ephemerides is better than 5 cm (Chap. 33), resulting in a bias of $50\,\text{mm}/20\,000\,\text{km} = 0.0025\,\text{ppm}$ of the baseline length. This 5 cm bias only has an effect of 2.5 mm for a 1000 km baseline. Figure 26.2a shows the bias in the baseline as a function of the bias in either satellite position or pivot receiver position for four baseline lengths. From this figure, it can be inferred that biases in satellite position and/or pivot receiver position get drastically reduced in the between-receiver differenced observation equations.

The fact that the coordinates of the pivot or reference receiver need not be accurate for the differential solution to be precise means that DGNSS can be accomplished by setting the pivot receiver coordinates to any reasonably valid position solution. This fact allows for *moving reference station DGNSS* which has applications in navigation, specifically in vehicle-to-vehicle relative navigation and also in terrestrial or space formation flying. In such applications, the absolute location of the rover is not required, rather the relative location of two moving vehicles is of interest.

### Differential Ionospheric Biases

As the ionospheric delays are spatially correlated, the between-receiver differenced ionospheric bias is much less than its absolute counterparts. To get insight into the size of this differential ionospheric bias, we make use of a simple mapping of the (slant) ionospheric delays to the vertical ionospheric delays at a representative height of the ionosphere above the Earth's surface (Chap. 19)

$$\begin{aligned} I^s_r &= \frac{1}{\cos z^{s\prime}_r} I_\text{v} \,, \\ z^{s\prime}_r &= \arcsin\left(\frac{R_\oplus}{R_\oplus + h_\text{ion}} \sin z^s_r\right) . \end{aligned} \tag{26.4}$$

Here $I_\text{v}$ denotes the vertical ionospheric delay at height $h_\text{ion}$ of the ionospheric layer, $z^s_r$ the zenith angle at the receiver, $z^{s\prime}_r$ the zenith angle at the ionospheric layer, and $R_\oplus$ the Earth's radius. Figure 26.2b depicts the geometry of this single-layer ionosphere in relation to the between-receiver difference.

The vertical ionospheric delay at the ionospheric point of receiver $r$ is, in principle, different from the vertical delay of receiver 1, due to the existence of hor-

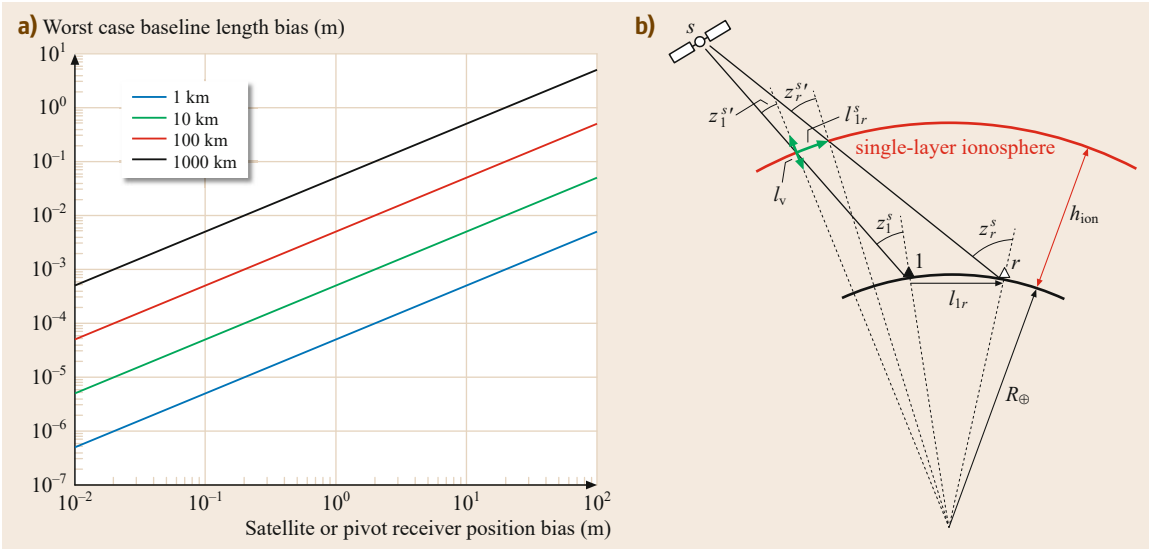

**Fig. 26.2** **(a)** Baseline length bias as a function of a bias in satellite position or pivot receiver position for four baseline lengths. **(b)** Geometry of a single-layer ionosphere model in relation to the between-receiver difference for stations 1 and $r$

izontal gradients in the ionosphere. If it is assumed that the vertical delay of receiver $r$ is equal to

$$I_\mathrm{v} + \frac{\partial I_\mathrm{v}}{\partial l} l^s_{1r} \,,$$

where $\partial I_\mathrm{v}/\partial l$ denotes the horizontal gradient and $l^s_{1r}$ the baseline length at the ionospheric single layer (Fig. 26.2b), the between-receiver ionospheric bias can be decomposed as follows

$$I^s_{1r} = -\left(\frac{1}{\cos z^{s\prime}_1} - \frac{1}{\cos z^{s\prime}_r}\right) I_\mathrm{v} + \frac{l^s_{1r}}{\cos z^{s\prime}_r} \frac{\partial I_\mathrm{v}}{\partial l} \,. \qquad (26.5)$$

Figure 26.3 now plots for different baselines, varying from 10 to 400 km, the functions $(1/\cos z^{s\prime}_1 - 1/\cos z^{s\prime}_r)$ as well as $l^s_{1r}/\cos z^{s\prime}_r$ as a function of the zenith angle at receiver 1 ($z^s_1$). For these graphs, the height of the ionospheric layer was set to $h_\mathrm{ion} = 350$ km. Besides that the graphs show that these functions become larger with increasing baseline length, it can be seen that for all baselines they reach a maximum around a zenith angle of $z^s_1 \approx 75°$. This also means that their combination in (26.5) and thus the differential ionospheric bias is maximized at this zenith angle. Furthermore, from Fig. 26.3 follows that at this zenith angle $(1/\cos z^{s\prime}_1 - 1/\cos z^{s\prime}_r)$ is about 0.6 ppm of the baseline length $l_{1r}$, whereas $l^s_{1r}/\cos z_r{}^{s\prime}$ is about 1.5 ppm of the baseline length $l_{1r}$.

Using these values for a zenith angle of 75° (this corresponds to an elevation of 15°), the size of the differential ionospheric bias is assessed based on worst-case choices for the vertical delay $I_\mathrm{v}$ and the horizontal gradient $\partial I_\mathrm{v}/\partial l$. These choices, which are given in Table 26.1, apply to levels for the vertical total electron content (VTEC) that can be reached during the daytime in either solar minimum or solar maximum years, as the ionospheric activity is clearly correlated with the progression of the 11-yearly solar cycle. These VTEC values have been converted from total electron content (TEC) unit to the ionospheric delay at the GPS L1 frequency in meters. Difference is made in levels that apply to mid-latitude regions and equatorial regions, as the levels around the equator are normally much higher than at mid-latitudes. Levels for polar regions are not included in the table, as they vary more or less in between the mid-latitude and equatorial levels. The equatorial vertical delay levels in Table 26.1

**Table 26.1** Typical worst-case values for vertical ionospheric delay $I_\mathrm{v}$ and horizontal ionospheric gradient $\partial I_\mathrm{v}/\partial l$ during solar minimum and maximum years for mid-latitude and equatorial regions

| | Mid-latitudes | Equatorial region |
|---|---|---|
| Solar minimum | $I_\mathrm{v} = 3$ m<br>$\frac{\partial I_\mathrm{v}}{\partial l} = 2$ ppm | $I_\mathrm{v} = 12$ m<br>$\frac{\partial I_\mathrm{v}}{\partial l} = 2$ ppm |
| Solar maximum | $I_\mathrm{v} = 6$ m<br>$\frac{\partial I_\mathrm{v}}{\partial l} = 10$ ppm | $I_\mathrm{v} = 22$ m<br>$\frac{\partial I_\mathrm{v}}{\partial l} = 50$ ppm |

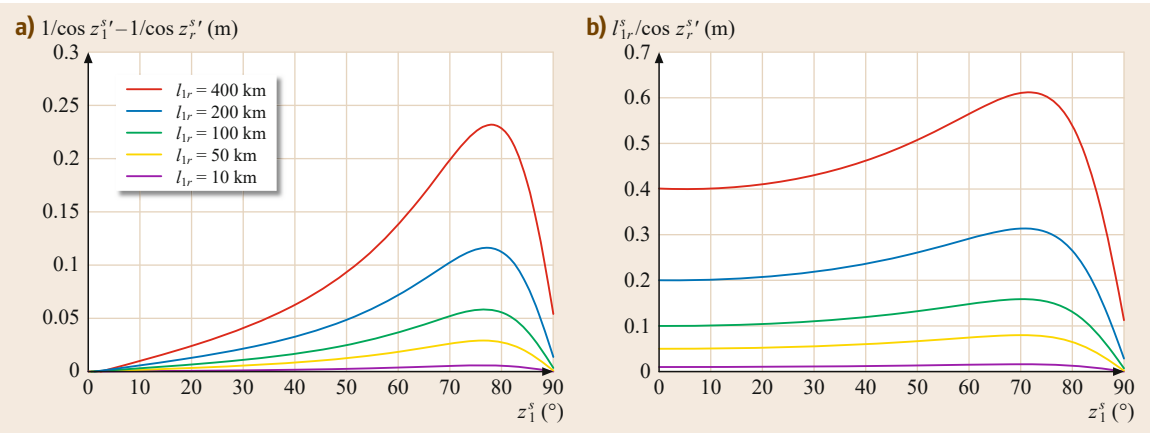

**Fig. 26.3** **(a)** Amplification of $I_v = 1$ m into $I_{1r}^s$; **(b)** amplification of $\frac{\partial I_v}{\partial l} = 1$ ppm into $I_{1r}^s$, for different baseline lengths

are confirmed by [26.3, 4], whereas the mid-latitude levels are confirmed by, among others, [26.5, 6]. Concerning the horizontal gradients, the normal east–west gradient due to the diurnal cycle of the ionosphere is about 1 ppm. So, during solar minimum years they are not much larger than this; in Table 26.1 we have assumed 2 ppm for both mid-latitude and equatorial regions. Much larger gradients are usually observed close to solar maximum: whereas horizontal gradients at mid-latitudes can range up to 10 ppm [26.7], very large (north–south) gradients of almost 50 ppm have been reported by [26.8, 9] for the equatorial anomaly regions, occurring post sunset.

Using the values of Table 26.1, the differential ionospheric bias is calculated using (26.5) for a zenith angle at the reference receiver of 75°. Table 26.2 presents the absolute value of this differential ionospheric bias, in ppm of the baseline length. From this table, it follows that the size of the differential ionospheric bias varies significantly, in the sense of depending on the location on Earth as well as in what stage of the solar cycle the GNSS measurements are collected. The lowest values are obtained during solar minimum at mid-latitudes (1 ppm), whereas the highest values (62 ppm) apply to solar maximum at equatorial regions.

Depending on the positioning application at hand, these differential ionospheric bias levels put restrictions to the maximum baseline length for which they can be neglected. For *carrier-phase-based DGNSS positioning*, requiring the highest positioning accuracy (Sect. 26.3), the differential ionospheric biases are allowed to be only a few centimeters in order to neglect them. For example, if it is required that $|I_{1r}^s| \leq 2.5$ cm; based on Table 26.2 the baseline length may be up to 25 km during solar minimum at mid-latitudes. However, this is only about 0.5 km during solar maximum for baselines that are measured in equatorial regions. For *code-based DGNSS applications* that require a much lower positioning accuracy (Sect. 26.2), the differential ionospheric biases can be ignored for much longer baselines.

**Table 26.2** Worst-case (absolute) differential ionospheric bias $|I_{1r}^s|$ in ppm of the baseline length for mid-latitude and equatorial regions during solar minimum and maximum years

| | Mid-latitudes | Equatorial region |
|---|---|---|
| Solar minimum | 1 ppm | 4 ppm |
| Solar maximum | 11 ppm | 62 ppm |

### Differential Tropospheric Biases

The tropospheric bias is normally decomposed into a *hydrostatic* plus a *wet* component (Chap. 6). The hydrostatic delay, which equals about 90% of the tropospheric bias, can be predicted very well based on the surface's air pressure. The wet component (accounting for about 10%) is caused by atmospheric water vapor and is more variable and therefore harder to predict. Usually the hydrostatic component is corrected using an a priori model, whereas the wet component is estimated as unknown parameter in the processing after having it *mapped* to local zenith.

We may get an impression of the size of the zenith tropospheric bias by using *Saastamoinen*'s troposphere model [26.10]. Mapping both hydrostatic and wet delays to local zenith, the zenith hydrostatic delay, denoted by $T_h^z$ and zenith wet delay, denoted by $T_w^z$, can be calculated as

$$T_h^z = Bp$$
$$T_w^z = B\left(\frac{1255}{T} + 0.05\right)e \qquad (26.6)$$

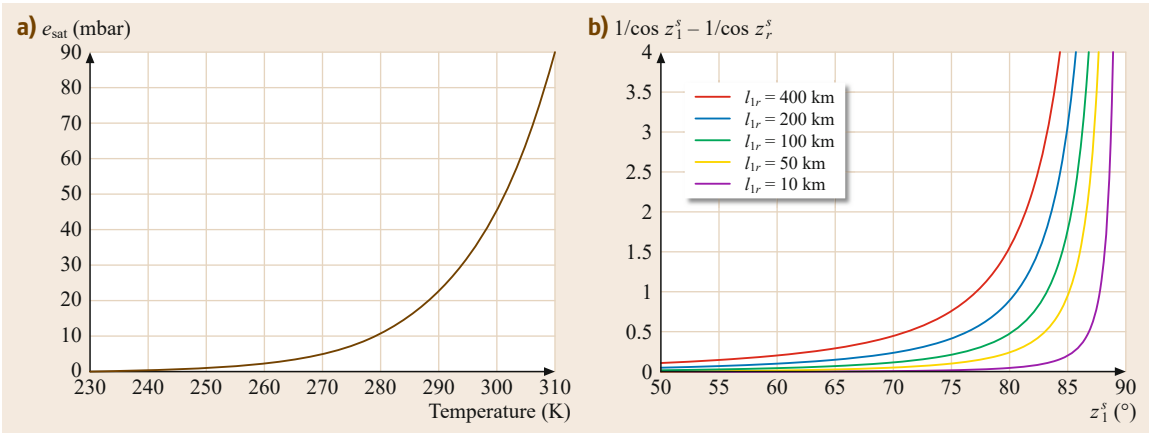

**Fig. 26.4** **(a)** Partial pressure of saturated air as a function of temperature; **(b)** differential tropospheric mapping function as a function of baseline lengths ranging from 10–400 km

with the constant $B = 0.002277\,\mathrm{m/mbar}$. Here $p$ denotes the air pressure (mbar), $T$ the temperature (K) and $e$ the partial pressure of water vapor (mbar) at the Earth's surface. This partial pressure can be computed as follows [26.11]

$$e = \mathrm{rh}\, e_{\mathrm{sat}}$$
$$e_{\mathrm{sat}} = \exp\left(a - \frac{b}{T}\right). \qquad (26.7)$$

Here rh denotes the relative humidity ($0 \le \mathrm{rh} \le 1$) and $e_{\mathrm{sat}}$ the partial pressure of *saturated* air, which can be modeled as an exponential function of the (inverse) temperature. This function, for which its constants $a$ and $b$ are taken from [26.12], is plotted in Fig. 26.4a for the temperature ranging between 230 and 310 K.

According to the above functions, Table 26.3 presents the calculated values for the hydrostatic, wet, and total delay in zenith for two types of tropospheric conditions, that is, *cold and dry* as well as *hot and humid*. Under these two extreme atmospheric conditions, from Table 26.3 it follows that the difference in (total) zenith delay can be almost 1 m. Note that the *hot and humid* values of about 2.4 m for the zenith hydrostatic delay and about 0.8m for the zenith wet delay are maximum values that can be reached [26.13].

To assess the size of the differential tropospheric bias, the reference receiver is assumed to experience the tropospheric conditions as in Table 26.3. For the troposphere at the rover receiver, it is first assumed that it is at another *height*, as it is well known that both temperature and pressure in the lower part of the atmosphere decreases with altitude. The temperature and pressure at height $H$ (km) can be assessed as follows, based on a constant temperature lapse rate of 6.5 K/km [26.11]

$$T_H = T_0 - 6.5H\,,$$
$$p_H = p_0 \left(\frac{T_H}{T_0}\right)^{\mu+1} \quad \text{with } \mu \approx 4\,, \qquad (26.8)$$

where $T_0$ and $p_0$ denote the temperature and pressure at $H = 0$, respectively. For a (rover) receiver that is 1000 m higher than the receiver in Table 26.3, Table 26.4 presents the tropospheric zenith delays under the two *extreme* conditions, where it is assumed that relative humidities are same. Besides a difference in height, tropospheric biases between receivers may also experience differences due to *horizontal gradients*, which may occur as a result of (cold) weather fronts. Therefore, we also consider a rover receiver that is at the same height as the reference receiver, but experiences a temperature and pressure that are 10 K and 10 mbar, respectively, lower than at the reference receiver. Table 26.5 presents the calculated zenith tropospheric

**Table 26.3** Examples of extreme atmospheric conditions and zenith hydrostatic, wet and total delays for reference receiver 1

| | $p$ (mbar) | $T$ (K) | rh (%) | $T^z_{1,h}$ (m) | $T^z_{1,w}$ (m) | $T^z_1$ (m) |
|---|---|---|---|---|---|---|
| Cold+dry | 950 | 230 | 10 | 2.16 | 0.00 | 2.16 |
| Hot+humid | 1050 | 310 | 90 | 2.39 | 0.75 | 3.14 |

**Table 26.4** Examples of extreme atmospheric conditions and zenith hydrostatic, wet and total delays, for receiver $r$ with a height difference of +1000 m with respect to the receiver in Table 26.3

| | $p$ (mbar) | $T$ (K) | rh (%) | $T^z_{r,h}$ (m) | $T^z_{r,w}$ (m) | $T^z_r$ (m) |
|---|---|---|---|---|---|---|
| Cold+dry | 823.1 | 223.5 | 10 | 1.87 | 0.00 | 1.87 |
| Hot+humid | 944.1 | 303.5 | 90 | 2.15 | 0.50 | 2.65 |

**Table 26.5** Examples of extreme atmospheric conditions and zenith hydrostatic, wet and total delays, for receiver $r$ at the same height as the receiver in Table 26.3, but temperature and pressure are, respectively, 10 K and 10 mbar lower due to a horizontal gradient in the troposphere (cold weather front)

| | $p$ (mbar) | $T$ (K) | rh (%) | $T^z_{r,h}$ (m) | $T^z_{r,w}$ (m) | $T^z_r$ (m) |
|---|---|---|---|---|---|---|
| Cold+dry | 940 | 220 | 10 | 2.14 | 0.00 | 2.14 |
| Hot+humid | 1040 | 300 | 90 | 2.37 | 0.40 | 2.77 |

delays for this rover receiver (again assuming the same relative humidities).

Based on these examples, we can now assess the size of the differential (slant) tropospheric bias between reference and rover receivers. For this purpose, the wet delay is mapped to zenith using a simple $1/\cos z$ mapping function, such that it is possible to decompose the between-receiver tropospheric bias as follows

$$T^s_{1r} = -\left(\frac{1}{\cos z^s_1} - \frac{1}{\cos z^s_r}\right) T^z_1 + \frac{1}{\cos z^s_r}(T^z_r - T^z_1). \tag{26.9}$$

Here $T^z_1$ and $T^z_r$ denote the zenith tropospheric delay at receivers 1 and $r$, respectively. Similar to the differential ionospheric bias, the differential tropospheric bias shows a dependence on the length of the baseline through factor $(1/\cos z^s_1 - 1/\cos z^s_r)$. This factor is plotted for several baseline lengths in Fig. 26.4b. In contrast to the ionospheric factor (Fig. 26.3a), this tropospheric factor does not have a maximum for a certain zenith angle; it is rapidly increasing for high zenith angles or low elevations. For the assessment of the differential tropospheric biases, we therefore assume that there is a cut-off zenith angle of 75°, above which the data are not used. For this cut-off angle, Table 26.6 shows the magnitude of the differential tropospheric biases that can be expected for the examples. It is assumed that the baseline length is 100 km. Besides the results for the baseline for which the rover is 1000 m higher than the reference and the baseline that experiences a cold front, results are included for a baseline for which the atmospheric conditions at both receivers are the same. For such a baseline, the differential tropospheric biases are only a result of the fact that both receivers see the satellite at different elevations.

In addition to the total differential tropospheric bias, Table 26.6 also gives the differential zenith wet delays, which give an impression of the amount of remaining bias after application of an a priori troposphere model. From the table follows that the size of the total differential tropospheric biases varies between 0.54 m (identical cold and dry conditions for both receivers)

**Table 26.6** Worst-case differential tropospheric bias $|T^s_{1r}|$ in meter for a 100 km baseline and the atmospheric conditions in Tables 26.3–26.5. Between brackets are the differential zenith wet delays $|T^z_{1r,w}|$. The satellite cut-off elevation is 15°

| | Identical atmospheric conditions | Height difference of 1000 m | Cold weather front |
|---|---|---|---|
| Cold+dry | 0.54 (0.00) | 1.67 (0.00) | 0.62 (0.00) |
| Hot+humid | 0.79 (0.19) | 2.70 (1.16) | 2.23 (1.55) |

and 2.70 m (hot and humid conditions and a height difference of 1 km between both receivers). This corresponds to 5–27 ppm of the baseline length. After a priori correction, the remaining differential biases are much smaller, although for the *hot and humid* conditions they cannot be neglected for this 100 km baseline and need to be estimated. For the *cold and dry* conditions as well as sufficiently short baselines they can be ignored.

### Receiver Noise, Multipath, and Other Biases

Biases that are *not* reduced or cancelled in between-receiver differential GNSS, as they are not spatially correlated, are first of all differential receiver clocks and differential receiver hardware biases. For the carrier-phase observations, this also includes the differential ambiguities. Hence, these biases need to be estimated as unknown parameters.

Biases that remain are *unmodeled* biases, due to for example, ionospheric scintillations, radio interferences, multipath, signal scattering, signal attenuation, and diffraction [26.14]. Of these additional biases, *multipath* biases (Chap. 15) are most likely to dominate. Multipath affects both code and phase measurements, but for phase data the multipath bias is generally 100 times smaller (centimeter level) than for code data (meter level) [26.15]. Multipath is a highly localized phenomenon and cannot be removed by the differential positioning approach; any multipath experienced by the reference receiver will be directly passed to the rover receiver. To mitigate this, the reference station location must be carefully chosen and a multipath mitigating receiver and antenna should be used. The use of multiple reference stations at different locations to average out multipath contributed to the development of *wide-area DGPS services* (WADGPS) [26.16], (Sect. 26.2).

Finally, random *receiver noise* is not cancelled when forming differential GNSS measurements. Although receiver noise depends on the type of make of receiver and antenna [26.17], we find some theoretical lower bounds on the precision of high-end geodetic GPS receivers in [26.14]: 1 dm for code observations

and 0.1 mm for phase observations. In practice, these values are however larger, as unmodeled biases cannot be separated from receiver noise. For GPS phase data, the precision is at the level of a few millimeters, whereas for GPS code data this is a few decimeters (for high-end receivers, [26.18]). It has been initially demonstrated that the receiver noise of newer signals (e.g., GPS L5) or of new constellations (Galileo, BeiDou navigation satellite system (BDS)) is lower than of the GPS L1 and L2 signals [26.19–22].

## 26.2 Differential Navigation Services

In this section, code-based DGNSS is discussed. First, Sect. 26.2.1 describes the DGNSS implementations that exist in practice, followed by an overview of DGNSS services in Sect. 26.2.2. Section 26.2.3 focusses on the message format that is used for transmitting the DGNSS corrections to users, whereas Sect. 26.2.4 discusses the issues due to the difference in time between the generation of the DGNSS corrections and the time they are applied by users (i. e., latency).

### 26.2.1 DGNSS Implementations

The principle of DGNSS is visualized in Fig. 26.5. A GNSS reference receiver that is stationed at a known location tracks data of all satellites in view and determines differential (DGNSS) corrections that are transmitted (in real time) to users (rover receivers) that track GNSS data at a certain distance of the reference station. These users correct their data allowing them to improve their positioning accuracy compared to a SPP solution.

If the corrections are determined based on the data of a single reference station (Fig. 26.5a), the technique is referred to as *local DGNSS* [26.23]. The rover receiver is usually of the single-frequency type (GPS: L1). The maximum distance the rover receiver is allowed to be is about 1000 km, as to have sufficient satellites in common between rover and reference. Because of the distance-dependent biases (atmosphere, orbit), the position accuracy of local *DGPS* is restricted to 1–10 ppm [26.24]. For a distance of 1000 km, the position accuracy is then about 10 m, which corresponds to the accuracy of SPP, so it does not make sense to cover larger distances. The position accuracy can be improved if DGNSS is based on a whole *network* of reference stations, instead a single reference station (Fig. 26.5b). All reference stations, equipped with dual-frequency or multifrequency receivers at known locations, send their data to a central processing facility which generates DGNSS corrections that are valid for the region the network covers. This is the *wide-area DGNSS* (WADGNSS) technique. WADGNSS has the following advantages over local DGNSS [26.25]:

- A network covers an effective area that is *larger* than based on a single reference station.
- Differential corrections are *consistent* within the area covered by the network, whilst based on different single reference stations discrepancies may show up.
- A network is able to calculate *models for distance-dependent biases* (atmospheric errors, orbits) that are valid over the coverage area, while this is not possible based on a single reference station.

Note that the above advantages also apply to network RTK as compared to single reference RTK (Sect. 26.4). By using a network of reference stations, the coverage area of DGNSS can span the size of the United States or Europe, or even the world. The positioning accuracy

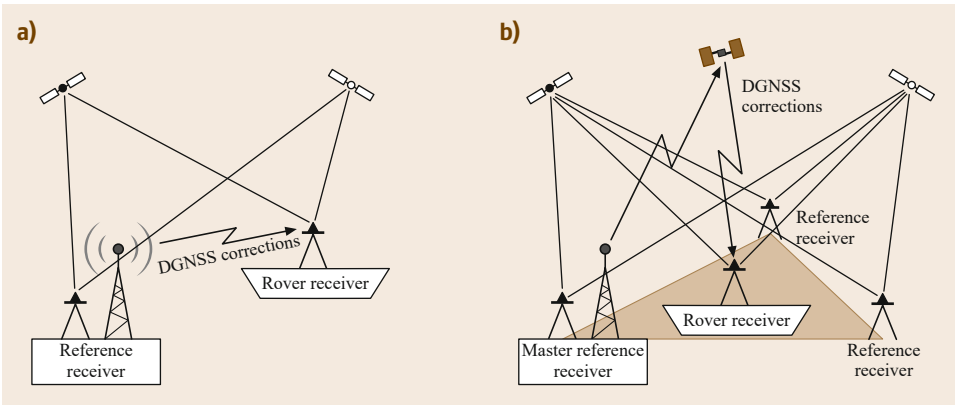

**Fig. 26.5** **(a)** Local DGNSS, based on a single reference station, where the corrections to the rover are sent by a ground-based antenna, vs. **(b)** Wide-area DGNSS, based on a network of reference stations, with the corrections transmitted via a satellite

of (code-only) *WADGPS* has been reported to be within 5 m [26.26]. Higher, even submeter accuracies are feasible for WADGPS, when the code data are *smoothed* with carrier-phase data [26.27]. The combined use of code with carrier-phase then makes WADGNSS conceptually equivalent to *precise point positioning* (PPP) (Chap. 25).

The positioning accuracy of local (single-frequency) DGNSS can be improved by a priori reducing the differential ionospheric biases by means of an ionosphere model of which its coefficients are broadcast in the navigation message. In case of GPS or BDS this is the Klobuchar model [26.28, 29], whereas for Galileo this is the semiempirical NeQuick model, which is based on the algorithm proposed by [26.30]. These models correct for some part of the differential ionospheric biases, but not completely. The *Klobuchar* model claims to remove 50–80% of the magnitude of the ionospheric bias [26.31], while it has been initially demonstrated that the *NeQuick* model performs better than Klobuchar [26.32]. Differential tropospheric biases should be a priori corrected for using standard models, for example, the Saastamoinen model [26.10] or the empirical global pressure and temperature (GPT) model [26.33].

## 26.2.2 DGNSS Services

### DGNSS: Marine and Terrestrial Applications

By far the largest present application of DGNSS is in the *marine transport* sector. This is primarily because during the 1990s, the coast guards and lighthouse authorities of several maritime nations deployed extensive networks of reference stations providing differential corrections to mitigate the effects of SA on GPS. Almost immediately after the implementation of SA by the U.S. Air Force, the U.S. Federal Aviation Administration, and the U.S. Coast Guard began to make plans to correct for SA using differential techniques. This resulted in the *U.S. nationwide DGPS* (NDGPS) system that is jointly operated by the U.S. Coast Guard and the U.S. Department of Transportation [26.34]. The NDGPS network (operational since 1999) initially made use of existing marine radio beacons as a method for transmitting differential corrections to users and originally only covered coastal areas. Later on also reference stations were deployed at inland locations, such that the whole U.S. is covered by the NDGPS network. In 2016 it was decided to maintain coverage in maritime and coastal regions only [26.35], due to the growth of other Continuously Operating Reference Station (CORS) networks inland.

### DGNSS Service Providers: GBAS or SBAS

On the transmission of the DGNSS corrections, one can distinguish between DGNSS services that broadcast the differential corrections through terrestrial messages, such as the U.S. NDGPS, or systems that broadcast these messages using (geostationary or geosynchronous) satellites. The first type of systems are referred to as *ground-based augmentation systems* (GBAS) (Chap. 31), whereas those of the second type are *satellite-based augmentation systems* (SBAS) (Chap. 12). The transmission through satellites has the advantage that a larger area can be covered compared to the transmission by means of terrestrial links.

Examples of governmental GBAS- and SBAS-based DGNSS services can be found in Table 26.7, which provides an overview of some (but not all) DGNSS service providers. Although this table only mentions a few countries that provide a nationwide DGNSS service, many countries actually have their governmental DGNSS services, covering both coastal (offshore) and/or inland (onshore).

**Table 26.7** Examples of governmental and commercial real-time WADGPS service providers (code-only services)

| Provider name | Governmmental/Commercial | Coverage area | GBAS/SBAS |
|---|---|---|---|
| NDGPS | Governmental | United States | GBAS |
| SAPOS EPS | Governmental | Germany | GBAS |
| AMSA | Governmental | Australia | GBAS |
| LAAS | Governmental | United States | GBAS |
| WAAS | Governmental | United States | SBAS |
| EGNOS | Governmental | Europe | SBAS |
| MSAS | Governmental | Japan | SBAS |
| GAGAN | Governmental | India | SBAS |
| QZSS | Governmental | Japan | SBAS |
| OmniSTAR VBS (Trimble) | Commercial | Global | SBAS |
| StarFire (NavCom/J. Deere) | Commercial | Global | SBAS |
| Starfix.L1 (Fugro) | Commercial | Global | SBAS |
| Veripos Standard (Veripos) | Commercial | Global | SBAS |
| Thales DGPS DGRS 610/615 | Commercial | Flexible | GBAS |

Note that the governmental Wide Area Augmentation System (WAAS), European Geostationary Navigation Overlay Service (EGNOS), Multi-Function Satellite Augmentation System (MSAS), and GPS Aided Geo Augmented Navigation (GAGAN) systems are all of the SBAS type which are discussed in Chap. 12. Although the MSAS and Quasi-Zenith Satellite System (QZSS) are both Japanese systems, they differ in the types of services they offer: whereas MSAS is a WAAS or EGNOS compatible system that provides corrections to augment single-frequency code-based positioning, QZSS provides corrections to augment positioning (including high-accuracy carrier-phase-based positioning) in the densely built Japanese urban regions (Chap. 11). The local area augmentation system (LAAS), which is used for the precision approach and landing of aircraft (Chap. 31), is of the GBAS type as it uses a very high frequency (VHF) radio link for the transmission of DGPS corrections.

In addition to these governmental services, commercial service providers exist that operate on a global scale (Table 26.7). Commercial DGNSS systems are either of the GBAS or the SBAS type. Nowadays, these commercial providers offer not only code-based DGPS services, but also multi-GNSS (GPS+GLONASS+BDS+Galileo+QZSS) code and carrier-based PPP and PPP-RTK as well as network-RTK services, yielding higher positioning accuracies. These services are not included in Table 26.7, as the table is restricted to DGPS based on code data only. The positioning accuracies that are claimed by the DGNSS code-based service providers are all in the same range: about 1–3 m, although some (commercial) providers claim submeter positioning accuracy.

Next to the correction message, many governmental/commercial DGNSS systems provide a form of *integrity* message to alert the users of a potential fault in either the corrections or the GNSS signals themselves. More details on the integrity monitoring of GNSS signals can be found in Chap. 24.

### 26.2.3 Data Communication: RTCM Message

The data communication link is essential for the (real-time) transmission of the DGNSS corrections to users. Most DGNSS service providers use a *standardized* format that is defined and published by the Radio Technical Commission for Maritime Services Special Committee 104 (RTCM SC-104) (Annex ). Initially, RTCM corrections were defined only for pseudorange differential GPS (version 2.0) as this is all that is required to provide a marine DGPS service. Support for carrier-phase GPS measurements was added in version 2.1, GLONASS support was included in version 2.2, and modernized data structures, increased bandwidth efficiency and support network RTK was implemented with version 3.0. Versions 2.3 and 3.2 are current though the standards continue to evolve to meet user needs. Both versions 2.3 and 3.2 define message formats for transmitting station information, pseudorange and range-rate corrections (Sect. 26.2.4) as well as carrier-phase raw data and carrier-phase corrections for GPS and GLONASS. Version 3.2 provides additional support, through multiple signals messages, for most of the emerging GNSSs as well as support for various formats of network RTK and PPP corrections [26.36].

While SBAS systems deploy (communication) satellites as link for the communication of the RTCM corrections, for GBAS systems there are several communication links in use:

- Radio communication (VHF/High frequency (HF); Frequency Modulation (FM) Radio Data Service (RDS))
- Mobile communication (Global System for Mobile Communication (GSM), General Packet Radio Service (GPRS), Universal Mobile Telecommunication System (UMTS))
- Internet communication (NTRIP).

Note that GPRS makes use of a combination of Internet and mobile telephone (GSM), whereas UMTS is the successor of GPRS. Of specific interest is the *networked transport of RTCM via Internet protocol* (NTRIP) for the streaming of DGNSS data which was developed by the German Federal Agency for Cartography and Geodesy (BKG) in 2004 [26.37]. The standard has been adopted by most receiver manufacturers allowing RTCM corrections to be broadcast over the Internet.

### 26.2.4 Latency of DGNSS Corrections

Users of DGNSS would like to have their corrections corresponding to the same time as the time at which they collect their measurements, in order to compute a differential solution with the best possible accuracy. In practice, however, there may be some delay or *latency* before the corrections arrive at the user. In addition, the reference station (or the network) may only transmit corrections at a certain time interval (i. e., the *update rate*), which may not correspond with the data sampling rate of the user.

To deal with this latency problem and to provide corrections that can be applied during the time before a new set of corrections arrives, the RTCM protocol uses a first-order polynomial to *predict* the DGNSS cor-

rections, based on the rate of these DGNSS corrections, the so-called *range-rate* corrections

$$\mathrm{PRC}(t) = \mathrm{PRC}(t_0) + (t - t_0)\mathrm{RRC}(t_0)\ . \tag{26.10}$$

Here $t_0$ denotes the time instant the pseudorange corrections (PRC) are determined at the reference station and $t$ the time instant corresponding to the measurements of the user, such that their difference $t - t_0$ is the latency. The range-rate corrections are denoted by range-rate correction (RRC) and these are also part of the RTCM correction message, next to the pseudorange corrections. It will be clear that the acceptable latency depends on the application at hand and the DGNSS position accuracy that is required.

Before SA was turned off, the DGPS pseudorange corrections varied much more in time than after it was removed. With SA on, the RRCs were useful in reducing the update rate of the DGPS corrections. However, with SA turned off, the temporal variations in the pseudorange corrections are predominantly governed by the temporal variations in the atmospheric and orbit errors. Hence, as the RRCs vary very slowly and are almost zero, some authors propose not to use it anymore as it may deteriorate the DGPS position accuracy [26.38].

Even if the update rate of the DGNSS corrections is high, there is always some latency due to the communication link that is used to transmit them to the users. For example, a DGPS RTCM data stream as broadcast by the EUREF station in Brussels to a user in Frankfurt via the NTRIP caster, resulted in latencies of up to one second for transmission through the Internet. Using GPRS, that is, a combination of mobile phone and the Internet, the latencies were at most two seconds [26.39].

## 26.3 Real-Time Kinematic Positioning

This section discusses the aspects of carrier-phase-dominated DGNSS positioning and in particular the RTK positioning technique that relies on resolving the carrier-phase ambiguities to estimate the receiver position with a high precision. Before RTK is discussed, Sect. 26.3.1 reviews the double-differenced observation equations underlying the carrier-phase and code-based positioning model. As the receiver-satellite geometry has a drastic impact on the precision of the estimated carrier-phase ambiguities and position coordinates, Sect. 26.3.2 is devoted to this and relates it to the development of carrier-phase-based positioning techniques from a historical point of view, starting from conventional static GNSS to RTK positioning. The last three subsections are all devoted to RTK. Section 26.3.3 discusses intricacies that occur when GLONASS data are used for RTK, whereas Sect. 26.3.4 addresses aspects that are relevant to multi-GNSS RTK positioning, including intersystem biases and inter-satellite-type biases. Finally, Sect. 26.3.5 presents examples of the performance of RTK ambiguity resolution and positioning.

### 26.3.1 Double-Differenced Positioning Model

When carrier-phase observations are included in the positioning model, the system of between-receiver differenced observation equations (26.1) cannot be used directly. As with DGNSS based on the code data, it is first assumed that the satellite positions are known ($\triangle \boldsymbol{r}^s = 0$). Also the position of the receiver position is usually assumed to be known ($\triangle \boldsymbol{r}_1 = 0$), although this is strictly not required.

Having done so, the system can still not be solved in a unique way, as it is *rank-deficient* (Chap. 22), because the columns of the design matrix between the differential receiver phase biases and differential ambiguities are linear dependent. To overcome this rank deficiency, one of the satellites has to be selected as *pivot satellite*. Alternatively, the rank deficiency between receiver phase biases and ambiguities can be eliminated by differencing the between-receiver differenced observations with respect to those of this pivot satellite. As discussed in Chap. 21, this then leads to the *double-differenced* (linearized) observation equations for pseudorange and carrier-phase

$$\begin{aligned}
\triangle p^{1s}_{1r,j} &= -\boldsymbol{e}_r^{1s\top} \triangle \boldsymbol{r}_{1r} + T^{1s}_{1r} + \mu^{\mathrm{S}}_j I^{1s}_{1r} \\
&\quad + c\Delta d^{1s}_{1r,j} + e^{1s}_{1r,j}\ , \\
\triangle \varphi^{1s}_{1r,j} &= -\boldsymbol{e}_r^{1s\top} \triangle \boldsymbol{r}_{1r} + T^{1s}_{1r} - \mu^{\mathrm{S}}_j I^{1s}_{1r} \\
&\quad + c\Delta \delta^{1s}_{1r,j} + \lambda^{\mathrm{S}}_j N^{1s}_{1r,j} + \varepsilon^{1s}_{1r,j}\ .
\end{aligned} \tag{26.11}$$

The double-differenced observables and parameters are denoted by $(\cdot)^{1s} = (\cdot)^s - (\cdot)^1$, with satellite 1 selected as pivot. For sufficiently short baselines, it is usually allowed to ignore the double-differenced tropospheric and ionospheric delays (Sect. 26.1.2). If they cannot be neglected, a common procedure for the tropospheric delays is to correct the observations using an a-priori troposphere model and map the residual delays to local zenith, and this zenith troposphere delay (ZTD)

is estimated as an unknown parameter. If the double-differenced ionospheric delays cannot be ignored as well, they are estimated as unknown parameters, together with the other parameters (Chap. 21).

### 26.3.2 Carrier-Phase-Based Positioning Methods

The carrier-phase observations have millimeter precision. However, high (millimeter to centimeter) precision for the position parameters can unfortunately not be attained directly, which is due the presence of the unknown carrier-phase ambiguities, even when the differential atmospheric parameters can be ignored. In order to solve both position and ambiguities with high precision, one needs a *long* observation time (can be more than half an hour), which is due to the *receiver-satellite geometry* that changes only slowly, as GNSS satellites are in a very high altitude orbit with respect to an Earth-bound receiver.

Using a short-time span, the position and ambiguity precision is predominantly governed by the precision of the *pseudorange* data, which is at the level of a few decimeters for geodetic receivers. In the limiting case, with a *single epoch* of data, the position solution is fully determined by the pseudorange data, as the phase data are all needed to solve the ambiguity parameters. In the presence of multiple epochs of data, the phase data start to contribute to the position/ambiguity solution. However within a short-time span this contribution is only marginal, which can be understood as follows, following the reasoning provided in [26.25].

#### Conventional Static Positioning

Consider the following system of linearized observation equations for double-differenced *phase data only* of $m$ satellites collected by a stationary receiver during $k$ observation epochs

$$E\left(\begin{bmatrix}\boldsymbol{y}(t_1)\\ \boldsymbol{y}(t_2)\\ \vdots\\ \boldsymbol{y}(t_k)\end{bmatrix}\right)=\begin{bmatrix}\mathbf{A}(t_1) & \mathbf{I}\\ \mathbf{A}(t_2) & \mathbf{I}\\ \vdots & \vdots\\ \mathbf{A}(t_k) & \mathbf{I}\end{bmatrix}\begin{bmatrix}\boldsymbol{x}\\ \boldsymbol{\nabla}\end{bmatrix}. \qquad (26.12)$$

In the above system, $\boldsymbol{y}(t_i)$ denotes a $f(m-1)$ vector that contains the $m-1$ double-differenced phase observations for each of the $f$ frequencies at epoch $i$, $\boldsymbol{x}$ denotes the vector of relative coordinate components and $\boldsymbol{\nabla}$ the vector of $f(m-1)$ carrier-phase ambiguities. The receiver-satellite geometry, as contained in the line-of-sight vectors at epoch $i$, is captured by $f(m-1)\times 3$ matrix $\mathbf{A}(t_i)$. Thus, for one frequency

$$\mathbf{A}(t_i)=\left[-\boldsymbol{e}_r^{12}(t_i),\ldots,-\boldsymbol{e}_r^{1m}(t_i)\right]^{\top}.$$

Matrix $\mathbf{I}$ denotes the identity matrix of dimension $f(m-1)$.

Note that the carrier-phase ambiguities are parameterized as multiplied by their wavelengths (so they are expressed in meters rather than cycles). These ambiguities do not have a time index, as they are constant in time, as long as no *cycle slips* occur. A cycle slip causes a jump of the ambiguity, but this jump (which equals an integer multiple of wavelengths) can be detected by application of the standard hypothesis testing theory ([26.40, 41] and Chap. 24). Having detected a cycle slip, the corresponding ambiguity parameter is adapted for it, such that the time-constancy of the ambiguity is not violated.

If the time that is spanned by the epochs 1 to $k$ is short (e.g., a few minutes), the receiver-satellite geometry will only change slowly, as the line-of-sight vectors will not be very different from one epoch to another. In this case, $\mathbf{A}(t_1)\approx\mathbf{A}(t_2)\approx\cdots\approx\mathbf{A}(t_k)$. In the limiting case, if the receiver-satellite geometry is assumed to be *stationary*, that is, $\mathbf{A}(t_1)=\mathbf{A}(t_2)=\cdots=\mathbf{A}(t_k)$, the system of observation equations (26.12) is rank deficient, as the columns of the design matrix between position and ambiguities are linear dependent. Although, in practice, the receiver-satellite geometry is not stationary (except for geostationary satellites from e.g., BDS), the slow change of it has as consequence that both position and ambiguities are only poorly estimable. Hence, in order to be able to estimate $\boldsymbol{x}$ and $\boldsymbol{\nabla}$ with sufficient precision, one will have to make sure that the receiver-satellite geometry has changed significantly, such that $\mathbf{A}(t_1)\neq\mathbf{A}(t_k)$. Using the conventional static GPS surveying technique [26.42, 43] it takes typically 20–30 min for short baselines (ignoring differential ionospheric delays), but it could take several (1–3) hours for long baselines (parameterizing the differential ionospheric delays as unknown parameters) [26.25].

#### Semikinematic Positioning

As the conventional static positioning technique is not very attractive in terms of productivity due to its long observation times, several positioning techniques have been proposed in the past to reduce the observation time that is needed to solve the position (and ambiguities) with sufficient precision [26.44, 45].

Three variants of these *semikinematic* positioning techniques are discussed here (Fig. 26.6):

1. With revisiting of stations [26.46]
2. Starting from a known baseline
3. With antenna swap.

All the three methods are based on the assumption that the rover receiver is allowed to collect data for a short

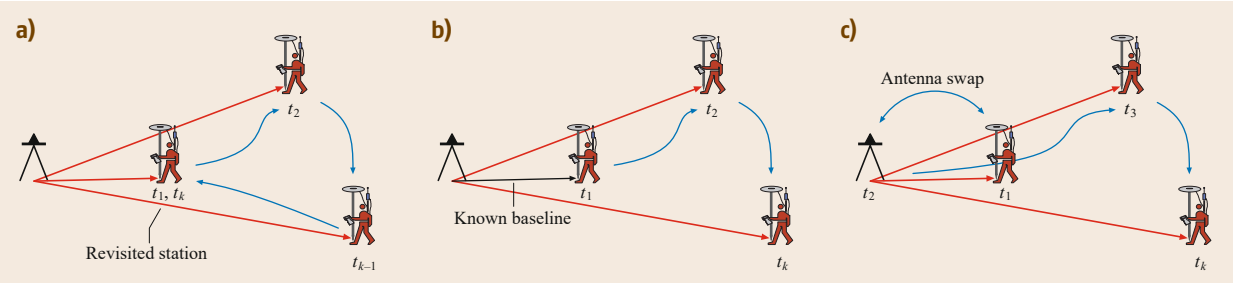

**Fig. 26.6a–c** Semikinematic relative positioning strategies: **(a)** with revisiting of stations; **(b)** starting from a known baseline; **(c)** with antenna swap

time (e.g., a few minutes) at one point and then visits another point to collect data for only a short time as well. In this way, the productivity can be increased compared to static positioning. Instead of model (26.12), these semikinematic methods are based on the following model

$$E\left(\begin{bmatrix}\boldsymbol{y}(t_1)\\ \vdots \\ \boldsymbol{y}(t_k)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{A}(t_1) & & & \mathbf{I}\\ & \ddots & & \vdots \\ & & \mathbf{A}(t_k) & \mathbf{I}\end{bmatrix}\begin{bmatrix}\boldsymbol{x}(t_1)\\ \vdots \\ \boldsymbol{x}(t_k)\\ \nabla\end{bmatrix}. \tag{26.13}$$

Here $\boldsymbol{x}(t_i)$ denotes the relative position vector at epoch $i$. Thus, provided that the area that is covered is of small scale, the rover receiver collects data during a short time at each point, continuously tracking the satellites when moving between the points.

*With Revisiting of Stations.* With conventional static positioning, it is not so much the number of epochs but the *change of geometry* that contributes to the determination of the phase ambiguities. Hence, one can suffice with two periods of data collection at the same point in static mode, where these two periods are separated by a sufficient long time interval (e.g., 30 min if the distance between reference and rover is short). During this time interval, the rover receiver can visit other points. In Table 26.8, the model corresponding to this *revisiting stations* semikinematic positioning technique is presented, where it is assumed that the first point is observed for a short time at both the start and end of the session, such that the geometry has changed considerably, that is, $\mathbf{A}(t_1) \neq \mathbf{A}(t_k)$.

*Starting from a Known Baseline.* Another variant of semikinematic positioning requires two points with *precisely known coordinates*, at which the reference and rover receivers are placed at the first epoch. As the relative position is known, the ambiguities can be quickly determined with very high precision. After this initialization, the rover receiver is moved to a next point for quick position determination, thereby continuously

**Table 26.8** System of observation equations corresponding to the semikinematic relative positioning strategies

| Variant | Model |
|---|---|
| With revisiting of stations | $E\left(\begin{bmatrix}\boldsymbol{y}(t_1)\\ \vdots \\ \boldsymbol{y}(t_{k-1})\\ \boldsymbol{y}(t_k)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{A}(t_1) & & & \mathbf{I}\\ & \ddots & & \vdots \\ & & \mathbf{A}(t_{k-1}) & \mathbf{I}\\ \mathbf{A}(t_k) & & & \mathbf{I}\end{bmatrix}\begin{bmatrix}\boldsymbol{x}(t_1)\\ \vdots \\ \boldsymbol{x}(t_{k-1})\\ \nabla\end{bmatrix}$ |
| Starting from a known baseline | $E\left(\begin{bmatrix}\boldsymbol{y}(t_1)-\mathbf{A}(t_1)\boldsymbol{x}(t_1)\\ \boldsymbol{y}(t_2)\\ \vdots \\ \boldsymbol{y}(t_k)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{0} & & & \mathbf{I}\\ \mathbf{A}(t_2) & & & \mathbf{I}\\ & \ddots & & \vdots \\ & & \mathbf{A}(t_k) & \mathbf{I}\end{bmatrix}\begin{bmatrix}\boldsymbol{x}(t_2)\\ \vdots \\ \boldsymbol{x}(t_k)\\ \nabla\end{bmatrix}$ |
| With antenna swap | $E\left(\begin{bmatrix}\boldsymbol{y}(t_1)\\ \boldsymbol{y}(t_2)\\ \boldsymbol{y}(t_3)\\ \vdots \\ \boldsymbol{y}(t_k)\end{bmatrix}\right) = \begin{bmatrix}\mathbf{A}(t_1) & & & & \mathbf{I}\\ -\mathbf{A}(t_2) & & & & \mathbf{I}\\ & \mathbf{A}(t_3) & & & \mathbf{I}\\ & & \ddots & & \vdots \\ & & & \mathbf{A}(t_k) & \mathbf{I}\end{bmatrix}\begin{bmatrix}\boldsymbol{x}(t_1)\\ \boldsymbol{x}(t_3)\\ \vdots \\ \boldsymbol{x}(t_k)\\ \nabla\end{bmatrix}$ |

tracking the signals. The model corresponding to this technique is given in Table 26.8, where the relative position at the first epoch is known, such that the observations at the first epoch are corrected for this. Note that the design matrix is now of full rank, even in the case $\mathbf{A}(t_1) = \cdots = \mathbf{A}(t_k)$.

*With Antenna Swap.* In this variant, the idea is to determine the ambiguities with high precision by moving the antenna of the reference receiver to the initial location of the rover receiver, while, at the same time, the antenna of the rover receiver is moved to the location of the reference receiver. This implies that after the antennas have been swapped, the carrier-phase ambiguities are not changed (as the satellites are continuously tracked), but the relative position after the swap is of *opposite sign* as before the swap. Making use of this property, that is, $\boldsymbol{x}(t_2) = -\boldsymbol{x}(t_1)$, results in the *antenna swap* model as given in Table 26.8. Also this model is of full rank, even in case $\mathbf{A}(t_1) = \cdots = \mathbf{A}(t_k)$.

### (Real-Time) Kinematic Positioning

Instead of waiting until the (float) ambiguities are precise enough such that the position can be estimated with high precision, one can make use of the *integerness* of the double-differenced carrier-phase ambiguities. Once the ambiguities can be resolved to their integer values, they can be removed from the system of observation equations, such that the position can be solved with a very high precision.

The procedure to solve for the precise position is as follows (Chap. 23). One starts to estimate the ambiguities using model (26.13) using standard least-squares or Kalman filtering. This solution is referred to as *float solution*. Although for short-time spans the float ambiguities have a poor precision and high correlation, it is possible to *decorrelate* them resulting in ambiguities that have a better precision and less correlation. By means of a special *search technique* it is then possible to find the integer values of the double-differenced ambiguities. Both decorrelation and integer search are efficiently implemented in the least-squares ambiguity decorrelation adjustment (LAMBDA) method, which is the standard for *integer ambiguity resolution* (Chap. 23). Having resolved the integer ambiguities, a second standard least-squares estimation is carried out keeping these ambiguities fixed in the model

$$E\left(\begin{bmatrix}\boldsymbol{y}(t_1)-\nabla\\ \vdots\\ \boldsymbol{y}(t_k)-\nabla\end{bmatrix}\right) = \begin{bmatrix}\mathbf{A}(t_1) & & \\ & \ddots & \\ & & \mathbf{A}(t_k)\end{bmatrix}\begin{bmatrix}\boldsymbol{x}(t_1)\\ \vdots\\ \boldsymbol{x}(t_k)\end{bmatrix}. \tag{26.14}$$

The solution if this model is referred to as *fixed solution*. The fixed solution has high precision as the carrier-phase data with the integer ambiguities subtracted now act as *very precise pseudorange* data.

The success of integer ambiguity resolution depends on the *strength* of the underlying positioning model. *Instantaneous ambiguity resolution*, where the integer ambiguities can be resolved already after a single epoch of data, is only feasible for very strong models, such as the short-baseline GPS model based on dual-frequency phase and code data [26.47]. Weaker models, such as the short-baseline single-frequency model or the long-baseline model parameterizing ionospheric delays [26.48], require more time before the ambiguities can be reliably fixed. These weaker models can however be strengthened by incorporating dynamic models (in a Kalman filter) on some of the parameters (i. e., position, ZTD, ionospheric delays, hardware biases), or, alternatively, by combining data of multiple GNSS constellations (Sect. 26.3.4).

Because of its high productivity provided that the distance between reference and rover is short, RTK is commonly used in cadastral and engineering surveying.

## 26.3.3 GLONASS RTK Positioning

The double-differenced observation equations (26.11) form the basis of the model underlying RTK positioning. It is remarked that a formulation in terms of the *undifferenced* observation equations may however be used as well (see Chap. 21 as well as [26.49, 50]). In this section, we will address the issues that arise when the double-differenced observation equations are used for RTK based on GLONASS observations.

For GLONASS signals that are based on the FDMA technology (Chap. 8), we have to deal with interchannel code and phase biases, denoted by $\Delta d^s_{1r,j}$ and $\Delta\delta^s_{1r,j}$ in (26.1), which are not automatically eliminated in the double-differenced positioning model (26.11). A usual assumption for the GLONASS interchannel phase biases is that they can be modeled as a *linear* function of the frequency or channel [26.51], that is, $\Delta\delta^s_{1r,j} = \kappa^s \Delta\delta_{1r,j}$, with $\kappa^s$ denoting the *integer channel number*. Based on this, for a short baseline (neglecting the differential atmospheric biases), the double-differenced observation equations for GLONASS read

$$\begin{aligned}\triangle p^{1s}_{1r,j} &= -\boldsymbol{e}^{1s\top}_r \triangle \boldsymbol{r}_{1r} + c\Delta d^{1s}_{1r,j} + e^{1s}_{1r,j}\,,\\ \triangle \varphi^{1s}_{1r,j} &= -\boldsymbol{e}^{1s\top}_r \triangle \boldsymbol{r}_{1r} + \kappa^{1s} c\Delta\delta_{1r,j}\\ &\quad + \lambda^s_j\left(N^s_{1r,j} - \frac{\lambda^1_j}{\lambda^s_j}N^1_{1r,j}\right) + \varepsilon^{1s}_{1r,j}\,.\end{aligned} \tag{26.15}$$

In contrast to the phase interchannel biases, the interchannel biases for code can however not be modeled as a linear function [26.52]. Besides the presence of the differential interchannel biases, there is another difference with the phase observation equations for CDMA signals: the carrier-phase ambiguity is due to the satellite or channel-dependent wavelengths *not directly estimable as a double-differenced ambiguity*, which would imply that we cannot make use of its integer property, which is the key to high-precision RTK positioning.

The presence of phase interchannel biases poses a first problem for the estimation of the ambiguities, as they cannot be estimated separately from each other (as their columns in the design matrix of the model would show a rank deficiency). However, in case the RTK baseline is formed by pairs of receivers that are of the *same manufacturer*, it turns out that they can be ignored, that is, $\Delta d^{1s}_{1r,j} = 0$ and $\Delta\delta_{1r,j} = 0$, removing them from the differential GLONASS observation equations [26.53]. In the case that the baseline is observed by receivers of *different manufacturers* (i. e., mixed receiver pairs), it is possible to calibrate these interchannel biases, based on their stability [26.54]. A-priori correction values for $\Delta\delta_{1r,j}$ are provided in [26.54, 55], from which follows that they can range up to 5 cm for adjacent channels (i. e., for $\kappa^{1s} = 0$) for a certain mixed receiver pair. The size of the interchannel biases for code may range up to 5 m [26.56].

Unfortunately, ignoring or correcting the interchannel biases does not automatically mean that the GLONASS ambiguities can be estimated as double-differences and thus as integers. In the literature, some authors [26.53, 57] try to overcome this by rewriting the ambiguity term as its equivalent

$$\lambda^s_j\left(N^s_{1r,j} - \frac{\lambda^1_j}{\lambda^s_j}N^1_{1r,j}\right) = \lambda^s_j N^{1s}_{1r,j} + \lambda^{1s}_j N^1_{1r,j}\,. \qquad (26.16)$$

Thus, the GLONASS ambiguity combination is rewritten as a double-differenced ambiguity $N^{1s}_{1r,j}$, plus the between-receiver differenced ambiguity that corresponds to the pivot satellite $N^1_{1r,j}$. Unfortunately the two ambiguity terms cannot be estimated as separate parameters. *Takac* [26.53] proposes to get an approximation of $N^1_{1r,j}$ by estimating it from the difference of the between-receiver differenced code and phase observations

$$\begin{aligned}\triangle p^1_{1r,j} - \triangle\varphi^1_{1r,j} = {} & c\left[d^r_{1r,j} - \delta^r_{1r,j}\right] - \lambda^1_j N^1_{1r,j} \\ & + e^1_{1r,j} - \varepsilon^1_{1r,j}\,. \qquad (26.17)\end{aligned}$$

The additional assumption to approximate $N^1_{1r,j}$ is that differential code-phase receiver bias $d^r_{1r,j} - \delta^r_{1r,j}$ is zero for identical receiver pairs, while it can be calibrated for mixed receiver pairs. However, since the precision of the approximate $N^1_{1r,j}$ is not very high, as it is driven by the noisy code data, it may result in unreliable resolution of the double-differenced ambiguities $N^{1s}_{1r,j}$ [26.58].

An alternative formulation to deal with the GLONASS pivot ambiguity is presented by [26.59]. Here the authors reparameterize the GLONASS ambiguity terms in (26.16) as

$$\lambda^s_j N^{1s}_{1r,j} + \lambda^1_j N^1_{1r,j} = \lambda^s_j \tilde{N}^{1s}_{1r,j} + \lambda^{1s}_j \tilde{N}^1_{1r,j}\,. \qquad (26.18)$$

Here the double-differenced and pivot satellite ambiguities are reparameterized as

$$\begin{aligned}\tilde{N}^{1s}_{1r,j} &= N^{1s}_{1r,j} - \frac{\kappa^{1s}}{\kappa^{12}}N^{12}_{1r,j}, \quad s \geq 3 \\ \tilde{N}^1_{1r,j} &= N^1_{1r,j} + \frac{\lambda^2_j}{\lambda^{12}_j}N^{12}_{1r,j}\,. \qquad (26.19)\end{aligned}$$

Use is made of the property that

$$\lambda^s_j\frac{\kappa^{1s}}{\kappa^{12}} = \lambda^2_j\frac{\lambda^{1s}_j}{\lambda^{12}_j}\,.$$

Note that the reparameterized double-differenced ambiguity $\tilde{N}^{1s}_{1r,j}$ is biased by a multiple of the integer ambiguity between satellite 2 and the pivot satellite, that is, $N^{12}_{1r,j}$. Because of this, satellite 2 can be considered as a *second pivot satellite*. Because the reparameterized double-differenced ambiguity $\tilde{N}^{1s}_{1r,j}$ is not an unknown parameter for this second pivot satellite (it only shows up from the third satellite onward), it is now possible to separate both reparameterized ambiguities, which means that *both* double-differenced ambiguities $\tilde{N}^{1s}_{1r,j}$ and the between-receiver differenced ambiguity of the first pivot satellite $\tilde{N}^1_{1r,j}$ can be estimated.

There seems however to be one problem: the double-differenced ambiguities $\tilde{N}^{1s}_{1r,j}$ are generally not integer, as they are biased by $(\kappa^{1s}/\kappa^{12})N^{12}_{1r,j}$. Although the GLONASS channel numbers $\kappa^s$ are integers (and thus $\kappa^{1s}$ as well), in general the fraction $\kappa^{1s}/\kappa^{12}$ destroys the integerness of $\tilde{N}^{1s}_{1r,j}$. However, there is an exception: in case the channel numbers of the two pivot satellites differ by one (i. e., $|\kappa^{12}| = 1$), the fraction $\kappa^{1s}/\kappa^{12}$ will actually be an integer and, consequently $\tilde{N}^{1s}_{1r,j}$ will be an integer as well. Thus, this implies that the two GLONASS pivot satellites cannot be arbitrarily chosen, but this should be two satellites with *adjacent channel numbers*. Only in that case integer resolution of GLONASS ambiguities becomes possible. However, it is stressed that this approach of GLONASS integer ambiguity resolution fully relies on the underlying assumption that the differential interchannel biases may

be ignored (i. e., $\Delta d^{1s}_{1r,j} = 0$ and $\Delta\delta_{1r,j} = 0$), which only holds for identical receiver pairs. For mixed receivers still external calibrations are needed, despite the claims made by [26.59].

### 26.3.4 Multi-GNSS RTK Positioning

The presence of more than one GNSS constellation benefits RTK positioning as code and phase data of multiple systems can be integrated in the positioning model. This was already demonstrated in Chap. 21 for the model underlying SPP, but it also applies to RTK positioning.

If we restrict ourselves to CDMA-based constellations, the interchannel biases are absent and for an arbitrary constellation S the between-receiver differenced code and phase observation equations read as in (26.1). Selecting a *pivot satellite for each constellation* then yields double-differenced observation equations, similar to (26.11), but then for each constellation. Common parameters between the constellations are the receiver position coordinates, plus ZTDs if these are parameterized; all other estimable parameters are constellation specific. It is possible to have a multi-GNSS model that is stronger than sketched as above, by making use of frequencies that are *identical* between different systems (e.g., GPS L1 and Galileo E1).

#### Differential Intersystem Biases (DISBs)

For frequencies that are identical between constellations, it is possible to difference the data of the second constellation using the data of the pivot satellite of the *first* constellation. Consider two receivers tracking data of two constellations, denoted by A and B (Fig. 26.7), then the double-differenced observation equations read (for a short baseline), for observations of constellation A

$$
\begin{aligned}
E(\Delta p^{1_\mathrm{A}s_\mathrm{A}}_{1r,j}) &= -\boldsymbol{e}_r{}^{1_\mathrm{A}s_\mathrm{A}\top}_{\mathrm{A}}\Delta\boldsymbol{r}_{1r}\,,\\
E(\Delta\varphi^{1_\mathrm{A}s_\mathrm{A}}_{1r,j}) &= -\boldsymbol{e}_r{}^{1_\mathrm{A}s_\mathrm{A}\top}_{\mathrm{A}}\Delta\boldsymbol{r}_{1r} + \lambda^{\mathrm{A}}_j N^{1_\mathrm{A}s_\mathrm{A}}_{1r,j}\,.
\end{aligned}
\qquad (26.20)
$$

Here $s_\mathrm{A} = 2_\mathrm{A}, \ldots, m_\mathrm{A}$, with $m_\mathrm{A}$ the number of satellites that are tracked of constellation A. The pivot satellite of A is denoted by $1_\mathrm{A}$. We may now difference the observations of constellation B that are tracked on the same frequency as observations of constellation A relative to the pivot satellite of A. This yields, assuming $\lambda^{\mathrm{B}}_j = \lambda^{\mathrm{A}}_j$

$$
\begin{aligned}
E(\Delta p^{1_\mathrm{A}s_\mathrm{B}}_{1r,j}) &= -\boldsymbol{e}_r{}^{1_\mathrm{A}s_\mathrm{B}\top}\Delta\boldsymbol{r}_{1r} + cd^{\mathrm{AB}}_{1r,j};\\
E(\Delta\varphi^{1_\mathrm{A}s_\mathrm{B}}_{1r,j}) &= -\boldsymbol{e}_r{}^{1_\mathrm{A}s^{\top}_\mathrm{B}}\Delta\boldsymbol{r}_{1r} + c\delta^{\mathrm{AB}}_{1r,j}\\
&\quad + \lambda^{\mathrm{A}}_j N^{1_\mathrm{A}s_\mathrm{B}}_{1r,j}\,.
\end{aligned}
\qquad (26.21)
$$

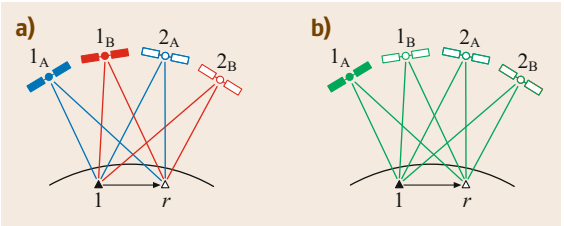

**Fig. 26.7** **(a)** Two constellations, A and B, each defining its own pivot satellite, denoted by $1_\mathrm{A}$ and $1_\mathrm{B}$; **(b)** two constellations, A and B, having the pivot satellite in common, in this case $1_\mathrm{A}$, based on the assumption that the DISBs are known or zero

Here $s_\mathrm{B} = 1_\mathrm{B}, \ldots, m_\mathrm{B}$, with $m_\mathrm{B}$ the number of satellites that are tracked of constellation B. Note that for constellation B, we have one double difference more for phase and code, which corresponds to the first satellite of B, denoted by $1_\mathrm{B}$. At the same time, there are additional parameters to be estimated for constellation B, which are

$$
d^{\mathrm{AB}}_{1r,j} = d^{\mathrm{B}}_{1r,j} - d^{\mathrm{A}}_{1r,j} \;\text{ and }\; \delta^{\mathrm{AB}}_{1r,j} = \delta^{\mathrm{B}}_{1r,j} - \delta^{\mathrm{A}}_{1r,j}\,. \qquad (26.22)
$$

These are the *differential intersystem biases* (DISBs) [26.60] for code and phase. We emphasize that the above definitions of the DISB parameters apply to the short-baseline model in the absence of differential atmospheric biases. The estimability and interpretation of the DISBs change for the ionosphere-float model, in which the ionospheric delays are estimated and which is used for longer baselines [26.61].

The performance of the model parameterized into DISBs is exactly the same as model with constellation-specific pivot satellites. Only in case we have information on these DISBs and include this in the model, the performance will be better. In the case we a priori *know* the DISBs, the observations can be corrected for them

$$
\begin{aligned}
E(\Delta p^{1_\mathrm{A}s_\mathrm{B}}_{1r,j} - cd^{\mathrm{AB}}_{1r,j}) &= -\boldsymbol{e}_r{}^{1_\mathrm{A}s^{\top}_\mathrm{B}}\Delta\boldsymbol{r}_{1r};\\
E(\Delta\varphi^{1_\mathrm{A}s_\mathrm{B}}_{1r,j} - c\delta^{\mathrm{AB}}_{1r,j}) &= -\boldsymbol{e}_r{}^{1_\mathrm{A}s^{\top}_\mathrm{B}}\Delta\boldsymbol{r}_{1r} + \lambda^{\mathrm{A}}_j N^{1_\mathrm{A}s_\mathrm{B}}_{1r,j}\,.
\end{aligned}
\qquad (26.23)
$$

for $s_\mathrm{B} = 1_\mathrm{B}, \ldots, m_\mathrm{B}$. Now, in the absence of DISB parameters, the observations of constellation B can be processed identically as those of constellation A, as they have a common pivot satellite and identical type of parameters. In other words, both constellations can be processed *as if* their signals correspond to one constellation (Fig. 26.7). This is referred to as *tightly* combined processing in [26.62]. Whereas in a combined model consisting of observation equations (26.11) for each constellation, there are $f(m_\mathrm{A} + m_\mathrm{B} - 2)$ estimable integer ambiguities (assuming $f$ frequencies for both constella-

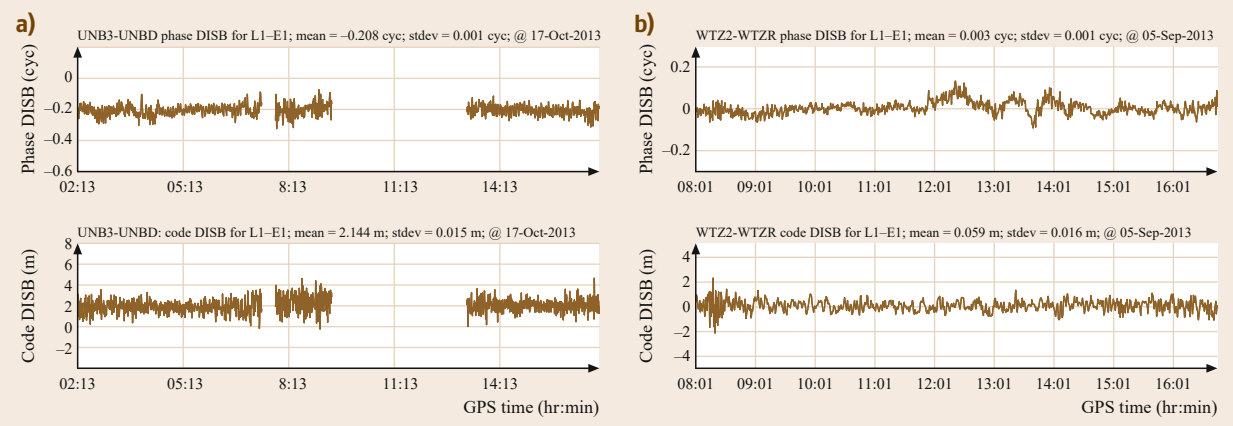

**Fig. 26.8a,b** Example of L1 (GPS) – E1 (Galileo) DISBs for phase (*top graphs*) and code (*bottom graphs*), estimated for the 20 m baseline between UNB3 (Trimble NetR9) and UNBD (Javad TRE-G2T) **(a)** and the zero baseline between WTZ2 (Leica GR25) and WTZR (Leica GRX1200+GNSS) **(b)**. Gaps in the time series mean that Galileo satellites were not tracked during that period

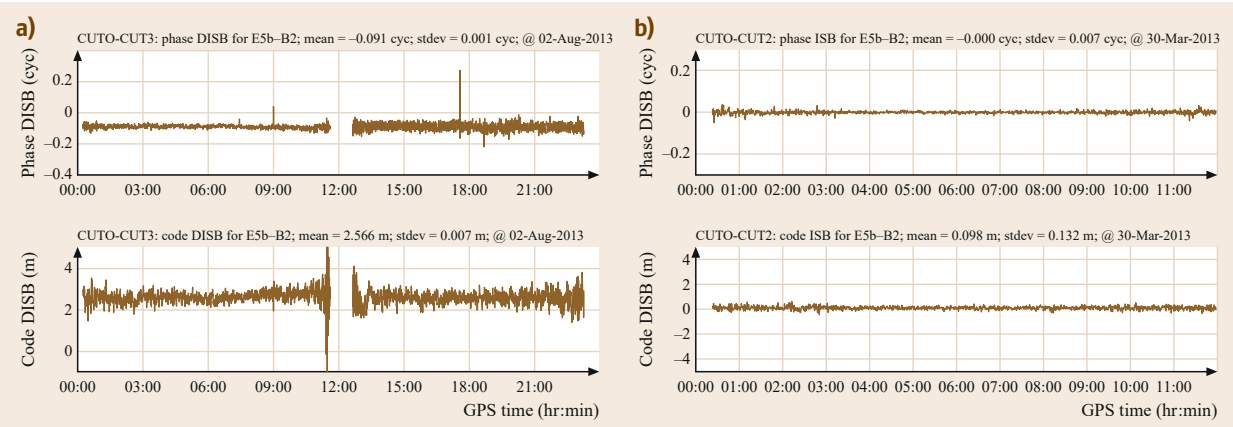

**Fig. 26.9a,b** Example of E5b (Galileo) – B2 (BDS) DISBs for phase (*top graphs*) and code (*bottom graphs*), estimated for the zero baseline between CUT0 (Trimble NetR9) and CUT3 (Javad TRE-G3TH) **(a)** and the zero baseline between CUT0 (Trimble NetR9) and CUT2 (Trimble NetR9) **(b)**. Gaps in the time series mean that Galileo satellites were not tracked during that period

tions), this is increased with $f$ integer ambiguities for the *tightly* combined or DISB-known model.

Concerning the size and variability of the DISBs, it was demonstrated that for pairs of *identical receivers*, that is, receivers of the same manufacturer, the DISBs are close to zero, that is, $\delta^{AB}_{1r,j} = 0$ and $d^{AB}_{1r,j} = 0$, whilst for *mixed receiver* combinations they are nonzero, but very stable in time [26.60, 63, 64].

As example, Fig. 26.8 depicts DISBs for phase and code that are estimated for the GPS L1 and Galileo E1 frequencies (both 1575.42 MHz). The figure shows that for the baseline at the University of New Brunswick, Canada, that consists of mixed receivers the mean of the estimated phase DISBs is about −0.2 cyc, while the estimated code DISB has a mean of about 2 m. For another baseline in Wetzell, Germany, which consists of receivers that are both of Leica, the DISBs for both phase and code are estimated with a mean that is close to zero.

Figure 26.9 shows the estimated DISBs for another frequency, that is, Galileo's E5b and BDS's B2 frequency (both 1207.14 MHz). The left graphs show that for a zero baseline at the campus of Curtin University (Australia) consisting of mixed receivers the mean of the estimated phase DISBs is about −0.1 cyc, while the estimated code DISB has a mean of about 2.6 m. On the other hand, the right graphs depict that the phase and code DISBs estimated for another zero baseline at Curtin University, this time consisting of two identical Trimble receivers, are close to zero.

#### Differential Inter-Satellite-Type Biases (DISTBs)

In case BDS data are used for RTK positioning, either standalone or combined with other GNSSs, another type of bias has shown up in case the baseline consists of mixed receivers. This is the so-called (differential) inter-satellite-type bias (ISTB), that is present between the signals at the *same frequency* of the BDS geostationary (GEO) satellites on one hand and the other BDS (IGSO, MEO) satellites on the other hand [26.65, 66].

Table 26.9 summarizes the phase DISTBs for two receiver manufacturers, relative to a Trimble receiver. Like the DISBs, the DISTBs turn out to be very stable, such that they can be calibrated. It follows from [26.65] that the GEO satellites have phase DISTBs of exactly *half cycles* with respect to IGSO/MEO satellites in the case of mixed receivers. However, it depends on the combination of mixed receiver types, which frequency is actually affected and which not. As follows from Table 26.9, the B1 frequency is not affected for the Trimble–Septentrio combination, but is affected for the Trimble–Javad combination. For the B2 frequency, the effect is vice versa.

After the discovery in [26.65], the GNSS receiver manufacturers updated their receivers firmware in order to eliminate the DISTBs when using mixed receivers for BDS RTK [26.66]. However, users who employ receivers with old firmware should still be aware of the presence of DISTBs when processing BDS data.

### 26.3.5 RTK Positioning Examples

To provide insight into the actual performance of RTK ambiguity resolution and positioning, in this subsection examples are presented that are obtained in Western Australia. This is done based on data for both *GPS standalone* as well as *multi-GNSS* RTK (GPS+BDS).

Results are shown for both a short (1 km) baseline, observed between stations CUT0 and CUTT, both at Curtin University campus, as well as a long baseline that was measured between Curtin's CUT0 and a receiver stationed in Muresk (MURK) at a distance of 80 km. *Short* and *long* here refer to whether the differential ionospheric biases can be neglected or not.

**Table 26.9** Differential inter-satellite-type biases (DISTBs) (cyc) for phase between BDS geostationary Earth orbit (GEO) and inclined geosynchronous orbit (IGSO)/medium earth orbit (MEO) satellites with Trimble as pivot receiver

| BDS frequency | Septentrio | Javad |
|---|---|---|
| B1 | 0 | 0.5 |
| B2 | 0.5 | 0 |

Table 26.10 summarizes some details concerning the types of receivers that have collected the data, as well as the time of measurements, data cut-off angles, and sampling intervals. For the short baseline, data are processed in both *single-frequency* and *dual-frequency* modes, whereas for the long-baseline data are only processed in dual-frequency mode, as the long-baseline single-frequency model is too weak.

Once the float ambiguities are precise enough, integer ambiguity resolution is performed at each epoch by means of the LAMBDA method in combination with the fixed failure-rate ratio-test (FFRT; Chap. 23).

#### Short-Baseline RTK Results

Figures 26.10–26.14 show the time series of the position solution for rover CUTT, estimated in kinematic mode (for each epoch; no dynamic model on the position), in east-north-up. These components are relative to the ground-truth position for CUTT. Each figure shows two curves, one with the *ambiguities float* and the other with the *ambiguities fixed*. Next to the graphs, tables with empirical standard deviations are given. The float solution is obtained by means of a Kalman filter, with only a dynamic model on the ambiguities (i. e., they are time constant). Note from the figures that the ambiguity-fixed solution does not always start at the beginning of the time span, but it is only computed as soon as the ambiguities can be reliably fixed to integers (which is after acceptance by the FFRT). The tables with empirical position standard deviations therefore only present the float solution for the time after the ambiguities can be fixed, as to directly compare them to their fixed counterparts. This implies that one has to be careful when the float standard deviations are compared that correspond to different processing strategies.

From Figs. 26.10–26.13, it can be seen that in all cases the float solution needs time before it has converged, where the time of convergence depends on the strength of the model. If we assume a convergence criterion of 1 cm in both horizontal components and of 2 cm in the vertical component, Table 26.11 gives the time that is needed for each scenario in order for the float solution to converge.

**Table 26.10** Characteristics of the short-baseline and long-baseline RTK examples

| Short-baseline RTK | Long-baseline RTK |
|---|---|
| CUT0-CUTT: 1 km | CUT0-MURK: 80 km |
| 2 Trimble NetR9 receivers | 2 Trimble NetR9 receivers |
| Date: 20 April 2013 | Date: 19 February 2014 |
| Cutoff elevation: 10° | Cutoff elevation: 10° |

| North | 0.040 | 0.003 |
| Up | 0.092 | 0.007 |

**Fig. 26.13** GPS L1+L2 RTK float (*light*) vs. fixed (*dark*) position errors, as well as standard deviations for 1 km baseline CUT0-CUTT

For single-frequency GPS, this convergence time is 0.5 h, but for single-frequency BDS this is much longer: as many as 4 h are required. This very slow convergence is probably due to the geostationary satellites of BDS for which the geometry hardly changes over time. Moreover, due to this almost stationary geometry multipath on the signals of these geostationary satellites gets barely averaged out in time [26.67]. With stronger models, the convergence time is reduced: for single-frequency GPS+BDS as well as dual-frequency GPS this is 20 min and 25 min, respectively (compared to 30 min for GPS L1). These relatively long convergence times can be avoided using *ambiguity resolution*.

**Table 26.11** Performance of ambiguity resolution and positioning for 1 km baseline CUT0-CUTT (ionosphere-fixed model). The float position is converged if the horizontal position error < 1 cm and the vertical position error < 2 cm

| Observables | Float position conv. after (min) | Fixed ambiguities/position after |
|---|---|---|
| GPS L1 | 30 | 4 min |
| BDS B1 | 240 | 25 min |
| GPS L1 & BDS B1 | 20 | Instantaneous |
| GPS L1+L2 | 25 | Instantaneous |

**Table 26.12** Performance of ambiguity resolution and kinematic positioning for 80 km baseline CUT0-MURK (ionosphere-float model). The float position is converged if the horizontal position error 2 cm and the vertical position error < 5 cm

| Observables | Float position conv. after (min) | Fixed ambiguities/position after (min) |
|---|---|---|
| GPS L1+L2 | 185 | 35 |
| BDS B1+B2 | 262 | 80 |
| GPS L1+L2 & BDS B1+B2 | 165 | 20 |

Table 26.11 also presents the time that is needed to fix the ambiguities to integer. For single-frequency GPS this is 4 min and this is considerably less time than the 30 min that are needed for the float solution to converge. After these 4 min, the fixed position solution has immediately an accuracy at the centimeter level (Fig. 26.10). Also the time-to-fix-ambiguities for single-frequency BDS is much shorter than the float convergence time. For the stronger multi-GNSS (GPS L1 & BDS B1) and dual-frequency GPS models, the times-to-fix-ambiguities are extremely fast; based on only a single epoch of data the ambiguities can be fixed (*instantaneous* ambiguity resolution).

Alternatively, Fig. 26.14 presents the position errors for the dual-frequency GPS case, but now based on an *epoch-by-epoch* processing instead of Kalman filtering. In this case, the model is so strong such that it is not necessary to keep the ambiguities constant in time. As there are no dynamic models for any of the parameters, the float position solution is fully governed by the code data; this explains the noisy (decimeter to meter level) float position errors in Fig. 26.14. The fixed solution is however very precise (millimeter to centimeter level).

Then in this example the demonstrated performance of single-frequency multi-GNSS RTK even allows for an increase of the *cut-off elevation*, other than the customary cut-off angle that is typically set to 10° as done in this example. In [26.68, 69], it is demonstrated that a high cut-off angle set to 35° still results in high ambiguity resolution success rates. This makes RTK more robust for applications in environments where GNSS signals at low elevations are obstructed or experience multipath, such as for example in urban canyons or open-pit mines.

### Long-Baseline RTK Results

In a similar way as for the short baseline, Figs. 26.15–26.17 show the float and fixed position errors but now for rover MURK corresponding to the long (80 km) baseline. Figure 26.15 gives the results for dual-frequency GPS, Fig. 26.16 for dual-frequency BDS and Fig. 26.17 for the combination of both constellations. For these three scenarios, Table 26.12 presents the time needed before the float solution is converged, as well as the time that is needed to reliably fix the integers and obtain a fixed solution.

The long-baseline model is weaker than the short-baseline model, because of the presence of differential ionospheric parameters, as well as a (residual) ZTD parameter. Because of this, the convergence criterion is slightly relaxed compared to the short-baseline model: 2 cm for the horizontal components and 5 cm for the vertical component. From Table 26.12, it follows that in case of GPS-only this criterion is met only after about 3 h. An even longer convergence time is required for BDS-only: almost 4.5 h. This longer time than GPS for BDS is, like in the short-baseline case, probably due to the stationary geometry of the geostationary satellites,

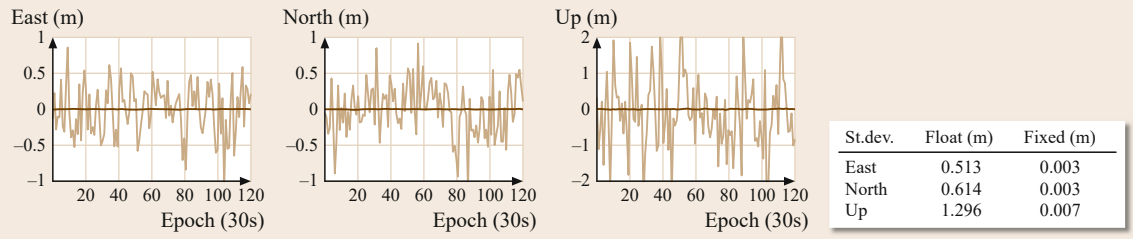

**Fig. 26.14** GPS L1+L2 RTK float (*light*) vs. fixed (*dark*) position errors, as well as standard deviations for 1 km baseline CUT0-CUTT, based on *epoch-by-epoch* processing

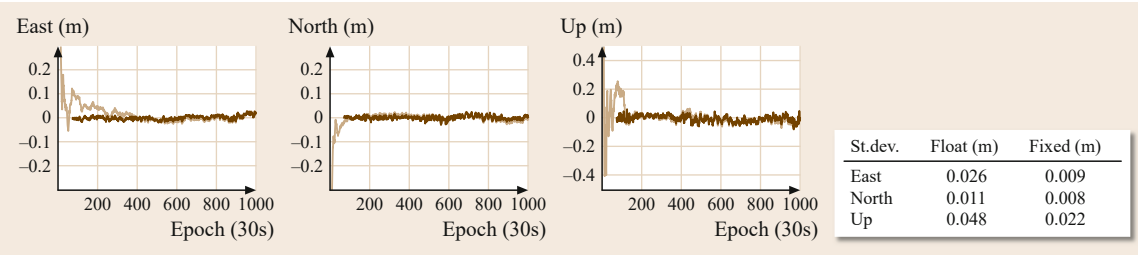

| St.dev. | Float (m) | Fixed (m) |
|---|---|---|

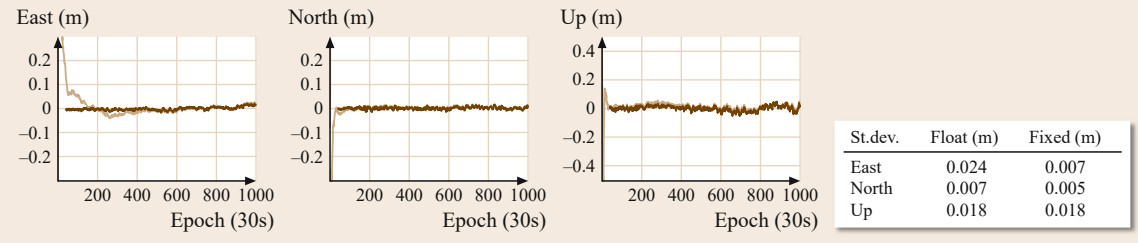
| North | 0.012 | 0.008 |
| Up | 0.038 | 0.027 |

**Fig. 26.16** BDS B1+B2 RTK float (*light*) vs. fixed (*dark*) position errors, as well as standard deviations for 80 km baseline CUT0-MURK



| St.dev. | Float (m) | Fixed (m) |
|---|---|---|
| East | 0.024 | 0.007 |
| North | 0.007 | 0.005 |
| Up | 0.018 | 0.018 |

**Fig. 26.17** GPS+BDS L1+L2&B1+B2 RTK float (*light*) vs. fixed (*dark*) position errors, as well as standard deviations for 80 km baseline CUT0-MURK

in combination with systematic multipath biases which have a larger impact on the convergence time than the presence of the additional atmospheric parameters in the model, as the convergence time of the short-baseline model is already 4 h. These types of long convergence times for BDS were also observed by [26.70, 71]. GPS combined with BDS has the shortest convergence time, but still almost 3 h. From Fig. 26.17, it follows that mainly for the east component it takes this long time before it has converged to a level below 2 cm.

Integer ambiguity resolution fortunately has a favorable effect. In the GPS-only case, the integers can be fixed after 35 min, while this is 80 min for BDS-only. Combining GPS and BDS has the shortest time-to-fix, which is just 20 min (Table 26.12). After these times, for all three scenarios the fixed position precision is at the subcentimeter level horizontally and below 3 cm vertically, see Figs. 26.15–26.17. One can see from the tables at the right side of the graphs that the gain due to ambiguity fixing is for the long-baseline cases less than for the short-baseline cases, see the tables corresponding to the short-baseline graphs in Figs. 26.10–26.14. This is because ambiguity resolution needs more time in the long-baseline cases and at the times the ambiguities are finally fixed, the float position precision has already been improved considerably due to the change in receiver-satellite geometry.

## 26.4 Network RTK

This section deals with the extension of the RTK technique to network RTK. It describes the required processing steps to be performed on the reference station observations, different forms of network RTK realizations, typical correction models, and it discusses PPP-RTK.

### 26.4.1 From RTK to Network RTK

One significant drawback of single base RTK, as described above, is that the maximum distance between reference station and rover receiver must not exceed 10–20 km in order to be able to rapidly and reliably resolve the carrier-phase ambiguities. This limitation is caused by distance-dependent biases, mainly ionospheric signal refraction but also orbit errors and tropospheric refraction (Sect. 26.1.2). These errors, however, can be accurately modeled using the measurements of an array of GNSS reference stations surrounding the rover site. Thus, the solution to the distance limitation of RTK lies in multibase techniques which became popular under the name network RTK, sometime abbreviated to NRTK. In fact, also network RTK has a distance limitation. This limitation refers to the distances between the reference stations. They should not exceed 100–200 km in order to be able to produce highly accurate real-time correction models of the distance-dependent errors.

Similar to the development of wide-area DGNSS as an extension of local single base DGNSS (Sect. 26.2.1), the network RTK technique enabled the establishment of positioning services which serve larger regions or whole countries by setting up and maintaining networks of reference stations, collecting and preprocessing their observations and distributing observation corrections in real time to RTK users. Only because of the development of network RTK such services became feasible. An area of 100 000 km$^2$ requires a network of about 20 reference stations spaced by 75 km if the network RTK technique is used. In comparison, a service using single base RTK with maximum distances to the closest reference station of 7.5 km would require about 900 equally spaced reference receivers for the same area.

### 26.4.2 Data Processing Methods for Network RTK

Network RTK requires the processing of the reference station observations in order to produce real-time correction models of the distance-dependent errors. Therefore, the reference station observations of a whole network (or a subnetwork) must be gathered at one data processing site, usually a central processing center. From there, the rover receivers are fed with those reference corrections and model coefficients that they are enabled to perform RTK positioning.

The main data processing steps between gathering the reference station observations and the RTK positioning result are the following (Fig. 26.18).

In the *first processing step* ([1] in Fig. 26.18) ambiguity fixing is performed in the reference station network. This also includes that the undifferenced carrier-phase observations are altered according to the determined double-difference ambiguity values so that afterward all observations are on the same ambiguity level. Only observations with fixed ambiguities can be used for the precise modeling of the distance-dependent errors. This processing step is the crucial part of network RTK because ambiguities of rather long baselines (50–100 km) have to be fixed and they must be fixed in real-time. This network ambiguity resolution differs considerably from common RTK ambiguity resolution since the station coordinates are precisely known. All existing difficulties are caused by observation errors and all a priori information which is able to reduce these errors should be used: IGS predicted satellite ephemerides, ionospheric, and tropospheric corrections based on recent results of the network processing, carrier-phase multipath corrections from the evaluation of the past network data, and antenna phase centre corrections from antenna calibrations.

In the *second processing step* correction model coefficients are estimated ([2] in Fig. 26.18). Several techniques have been developed to model (or interpolate) the distance-dependent biases between reference stations and user receivers. For an overview of potential algorithms, see [26.72] and [26.73]. Ionospheric and orbit biases must be modeled individually for each satellite. Tropospheric corrections, however, may be estimated station by station. It is advantageous to separate the dispersive (ionospheric) biases from the nondispersive biases (orbit and troposphere, sometimes referred to as *geometric*), since ionospheric errors show larger short-term variations as compared to the other distance-dependent biases. Thus, ionospheric corrections must be updated (transmitted to the user) more often, in practice e.g., every 10 s as compared to every 60 s for orbit and tropospheric corrections. Furthermore, in order to be able to correct for small-scale features of ionospheric refraction the modeling area should be kept small, that is, ionospheric correction models may be based on the observations of just three surrounding reference stations. On the other hand, the quality of the geometric

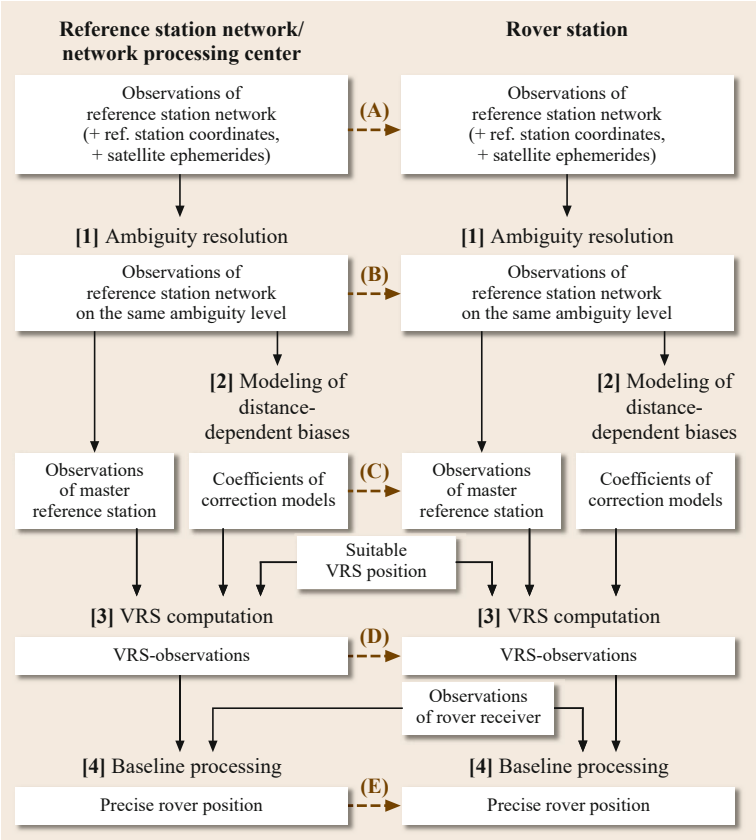


**Fig. 26.18** Network RTK processing steps and data transmission options

correction models may improve when a larger number of reference stations is used.

In the *third processing step* of network RTK ([3] in Fig. 26.18), a set of computed reference observations is produced from the real observations of a selected master reference station, often the one closest to the rover receiver, and the precise correction models for distance-dependent biases. Based on the correction models and horizontal coordinate differences between master reference position and approximate rover position, the reference observations are virtually shifted to the rover site. This results in virtual reference station (VRS) observations.

The *fourth and last step* ([4] in Fig. 26.18) consists of the RTK style baseline processing between VRS and rover.

Existing network RTK positioning services run one or more network processing centers where the reference station observations are gathered and where they are preprocessed. The data processing consists at least of real-time ambiguity resolution of the network carrier-phase observations. This goes along with a rigorous quality control of the data. Furthermore, the spatial stability of the reference station antennas is controlled based on the gathered observations. More processing steps may be performed in the processing center, depending on selected communication links and data formats for transmitting the network data to the user.

Figure 26.18 depicts five ways of how to transfer network information to the user. These approaches differ with respect to allocation of the processing steps either to the network processing center or to the rover. This affects the information content and the data formats of the messages to be transmitted to the rover, and also the selection of appropriate communication channels. Nowadays the most widely used methods are (B) and (D).

### Observations of Several Reference Stations

((A) in Fig. 26.18): The rover station receives the observation data streams of several reference stations surrounding his position. After ambiguity resolution of the network data, the rover is able to compute network corrections and even VRS observations to be used for his positioning. The major drawback of this method is related to the ambiguity resolution of the network observations which usually requires an initialization time of several minutes.

#### Network Observations on Common Ambiguity Level

((B) in Fig. 26.18): Broadcast of observations of a master reference station and observation differences between auxiliary reference stations and master reference station, all being on the same ambiguity level. The user performs the interpolation step on its own and thus obtains network corrections and valuable information on their quality. Then, he is able to compute VRS observations and his position in the baseline mode. This technique is known under the name of master-auxiliary concept (MAC) [26.74, 75].

#### Coefficients of Correction Model

((C) in Fig. 26.18): Broadcast of observations of a master reference station and coefficients of the correction models of distance-dependent biases. The user applies the correction models to the reference station observation data set according to the coordinate differences between his position and the position of the master reference station, and thus he obtains VRS observations for his site. This technique is often referred to as FKP, an abbrevation of the German term *Flächen–Korrektur-parameter* which stands for area correction parameters (Sect. 26.4.3, [26.24, 76]).

#### Virtual Reference Station (VRS) Observations

((D) in Fig. 26.18): The user sends his approximate position to the central computing facility and by return receives VRS observations to be used for baseline positioning [26.77, 78]. In the early days of network RTK, a major advantage of this technique was that no upgrade to the user equipment software was necessary. But, this method has the drawback that in general no information can be provided on the quality of the interpolation process and thus on the quality of the VRS reference observations.

#### Precise Rover Position

((E) in Fig. 26.18): The observations of the rover receiver are transmitted to a central processing facility where the baseline processing from VRS to rover is performed. The rover's precise position and quality information may be transmitted back to the user.

Data transfer of reference station observations and broadcast ephemerides to the central processing facility and also of data products from the central processing facility to the user requires adequate communication channels and data formats. The most widely used format for transmission of real-time GNSS observation data and intermediate products is RTCM Standard 10 403.2. Positioning results are transmitted using National Marine Electronics Association (NMEA) 1083. In the case of post-processing and transmission of data files, receiver independent exchange format (RINEX) is the most common open format. It can be used for GNSS observations ((A) and (D) in Fig. 26.18) and broadcast ephemerides, but not for observation differences between stations ((B) in Fig. 26.18) or coefficients of correction models ((C) in Fig. 26.18). More details on data formats are found in Annex .

### 26.4.3 Network RTK Correction Models

An often used, simple and robust model for network RTK corrections makes use of horizontal gradients of the distance-dependent errors. It is convenient to separate dispersive (ionosphere) from nondispersive (troposphere and orbit) errors. This separation requires dual-frequency carrier-phase observations at the reference stations. The minimum number of reference stations is usually three which surround the service area. The horizontal gradients define a plane correction surface (Fig. 26.19), thus a two-dimensional (2-D) linear interpolation is performed.

These horizontal gradients are usually referred to as FKP. Sets of FKP values are determined for each individual satellite. Such a set consists of four values: namely $\mathrm{FKP_{N0}}$, $\mathrm{FKP_{E0}}$ which are the distance-dependent gradients of the nondispersive errors in ppm for north-south and east-west direction, respectively, and $\mathrm{FKP_{NI}}$, $\mathrm{FKP_{EI}}$ which are the distance dependent gradients of the dispersive errors scaled to their effects on GPS L1 frequency $f_1$ in ppm for north–south and east–west direction, respectively. The distance-dependent errors in m for the nondispersive and dispersive components are calculated as

$$\begin{aligned} \delta e_0 &= \mathrm{FKP_{N0}}\Delta r_\mathrm{N} + \mathrm{FKP_{E0}}\Delta r_\mathrm{E}\,, \\ \delta e_\mathrm{I} &= \mathrm{FKP_{NI}}\Delta r_\mathrm{N} + \mathrm{FKP_{EI}}\Delta r_\mathrm{E}\,, \end{aligned} \tag{26.24}$$

where $\Delta r_\mathrm{N}$ and $\Delta r_\mathrm{E}$ are the horizontal coordinate differences in kilometer for the north–south and east–west directions, respectively, of a baseline, for example, between master reference station and rover station.

The distance-dependent errors $\delta e_\varphi$, $\delta e_p$ for a carrier-phase measurement and a code measurement on frequency $f$ are computed as

$$\begin{aligned} \delta e_\varphi(f) &= \delta e_0 + \frac{f_1^2}{f^2}\delta e_\mathrm{I}\,, \\ \delta e_p(f) &= \delta e_0 - \frac{f_1^2}{f^2}\delta e_\mathrm{I}\,, \end{aligned} \tag{26.25}$$

where $f_1$ is the GPS L1 frequency.

There are variations of (26.24) and (26.25) which are also in practical use. Differences exist with regard

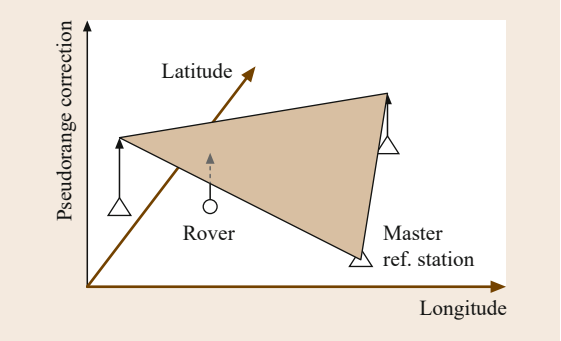

**Fig. 26.19** Correction by linear interpolation

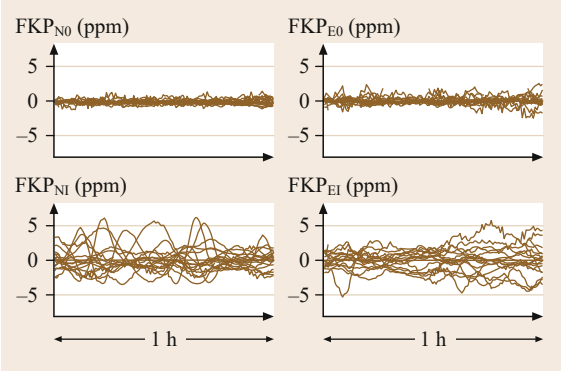

**Fig. 26.20** Examples of FKP values

to the selected reference frequency to which the dispersive effects are scaled and sometimes the dispersive effects are mapped to the zenith direction [26.36]. This, however, causes no or only negligible changes of the correction effects.

A typical time series of FKP values are shown in Fig. 26.20. Each line connects the model coefficients of a specific satellite. The FKP for the dispersive effects (lower panels) are often larger in size and show more short-term variations. This emphasizes that one should consider updating them more frequently as those values which correct nondispersive effects, for example, every 10 s as compared to every 60 s (*upper panels* of Fig. 26.20).

### 26.4.4 Refined Virtual Reference Stations

Computing VRS observations involves the shift of the master reference observations to the selected position of the VRS. This shift actually consist of two different processes: one performs the geometrical shift of the observations mainly considering the changing distances to the satellites, the other applies corrections for the distance-dependent biases according to the latitudinal and longitudinal differences between master reference station position and VRS position. In general, the same VRS position is used for both processes. Only then, the VRS is able to resemble real observation data collected at this site.

There are reasons to refine this concept and to distinguish between two different positions of a VRS: the geometric position and the position used to apply the correction models (Fig. 26.21). The latter position should be as close as possible to the actual rover position. The geometric position of the VRS may be a different one.

Experience shows that parts of the ionospheric errors can be of very small-scale size, so that they are not completely captured in a regional network of reference stations. Thus, the baseline from the VRS to the

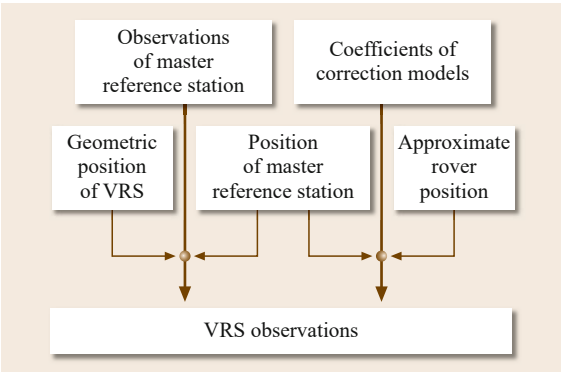

**Fig. 26.21** Modification to the generation of VRS observations

rover often contains more remaining ionospheric errors than a short baseline between a real reference station and the rover would do. As a consequence, the baseline processing between VRS and rover must not assume a complete elimination of ionospheric effects which would be correct for a very short baseline between two real receivers. It should assume that the residual ionospheric effects are as large as those of a baseline of a few or even more kilometers depending on the actual ionospheric conditions, on the distances between the real reference stations, and on the modeling approach.

In order to communicate this information to the user, a different form of virtual reference station is created, a so-called PRS or i-MAX [26.79]. The geometric position of the VRS is selected in such a way that the baseline length to the rover receiver is able to reflect the size of the remaining ionospheric errors which can then be handled by an appropriate stochastic modeling approach.

Another kind of refined VRS is suggested for larger scale kinematic applications. A moving rover requires changing positions of the virtual reference sta-

tion. Since baseline processing software do not accept a moving reference station, a so-called semikinematic VRS [26.80] is produced. The corrections of the distance-dependent errors are applied according to the changing positions of the moving rover. At the same time, a fixed position of the VRS is used to imitate best a reference station.

Such refined VRS are produced for individual rovers and they must only be used for baseline processing with those rover receiver.

### 26.4.5 From Network RTK to PPP-RTK

In recent years, precise point positioning (PPP, Chap. 25) without or with ambiguity fixing started to compete with the differential positioning technique RTK. One of the main drawbacks of PPP is the fairly long convergence time of several to many minutes which is needed to obtain accurate ambiguity estimates or a reliable ambiguity fixing. With RTK or network RTK the convergence times usually do not exceed 1 or 2 min and the obtainable positioning accuracies exceed those of PPP.

The main reason for these differences lies in the correction or elimination by differencing of ionospheric and tropospheric errors. Local (RTK) or regional (network RTK) reference stations can be considered as atmospheric sensors whose information is able to speed up ambiguity fixing. This leads to PPP-RTK where faster PPP ambiguity fixing and also higher accurate positioning results are obtained by including atmospheric corrections based the on observation data of local or regional GNSS reference stations. The overall performance of PPP-RTK is similar to the one of network RTK [26.81–83].

*Acknowledgments.* We would like to thank Dr Amir Khodabandeh of the GNSS Research Centre at Curtin University for his help with the writing of the GLONASS RTK section.

# 27. Attitude Determination

Gabriele Giorgi

Attitude estimation is the process of determining the spatial orientation of an object. A system formed by multiple Global Navigation Satellite System (GNSS) antennas placed at known relative positions acts as an attitude sensor. This chapter provides an overview of practical applications of GNSS-based attitude determination, gives the principles of attitude representation and estimation, and reviews a constrained ambiguity resolution method to reliably fix the carrier-phase integer ambiguities and obtain precise attitude estimations.

## 27.1 Six Degrees of Freedom

The pose of a rigid body in a three dimensional space can be described by six independent parameters, of which three refer to the absolute position of a body reference point and three describe the body orientation. Whereas positioning deals with the estimation of the absolute location, attitude estimation is the process of determining the orientation of the body with respect to a reference frame. The combination of absolute position and orientation enables a complete static characterization of a rigid body in space, as shown in Fig. 27.1.

Several attitude sensors are available to obtain the spatial orientation of a body. These can be classified in two distinct categories: relative and absolute sensors. Relative attitude sensors detect changes in the body dynamics by exploiting internal devices, and keep track of rotational accelerations induced by the body motion, generating an output proportional to the magnitude of the rotations. The absolute orientation of the body is then obtained by continuously propagating a known initial state. Due to the accumulation of measurement errors, the integration process causes estimation biases that tend to increase over time, thus requiring periodic recalibrations. An example of a relative attitude sensor is the gyroscope, which reacts to variations of the body orientation by opposing a measurable gyroscopic resistance force.

Absolute attitude sensors detect the body orientation by exploiting an external source, independent of the body whose attitude has to be determined. Examples of absolute sensors are star trackers, which relate the body orientation with respect to the direction pointing to a group of selected stars; magnetometers, which sense the direction of an external magnetic field; and

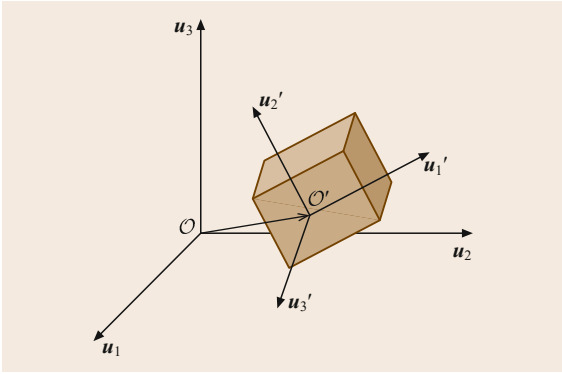

**Fig. 27.1** The pose of a rigid body in space is completely characterized by the position of a reference point O′ and the rotation of a frame integral with the body with respect to a reference frame

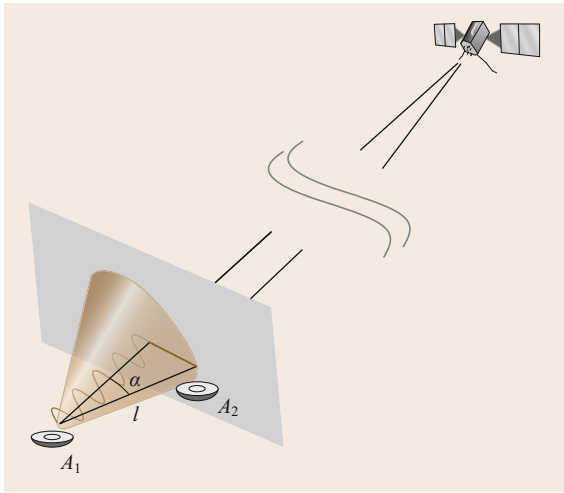

**Fig. 27.2** The differential range measurement at two antennas tracking the same satellite provides information about the potential direction of the baseline vector

horizon sensors, which track the angular direction(s) of the line(s) of sight to near-horizon regions.

Global Navigation Satellite System (GNSS) antennas can be employed as absolute attitude sensors. A coarse indication of the orientation of an antenna with respect to the line-of-sight vector to the tracked satellite can be obtained by comparing the received signal strength against the antenna radiation pattern. Multiple error sources may alter the received power levels, such as multipath and atmospheric disturbances, and rotations about the antenna boresight axis are not observable with symmetrical antenna gain patterns. Typical accuracies are in the order of ten degrees, with error peaks reaching several tens of degrees [27.1].

A system formed by two or more GNSS antennas is better suited to provide orientation estimates. The idea of using GNSS signals to obtain attitude information dates back to 1976, when the concept of supplying a spacecraft in a low Earth orbit with two Global Positioning System (GPS) antennas placed at known distance was first proposed [27.2]. The initial concept was then refined, principally by including carrier-phase measurements to improve the ranging capabilities of the GPS-based differential positioning [27.3, 4]. After initial successful tests on static platforms [27.5, 6], several tests on vessels [27.7] and aircrafts [27.8] demonstrated the viability of GPS single-baseline heading estimation, whereas the full capabilities of a GPS antenna array for three-axis attitude determination was first proven on a real-time flight test aboard a DC-3 aircraft in 1991 [27.9]. Over the course of the last two decades constant improvements in the areas of fast initialization procedures, reliable on-the-fly carrier-phase ambiguity estimation, and enhanced accuracy in real-time dynamic environments have been made, and GNSS-based

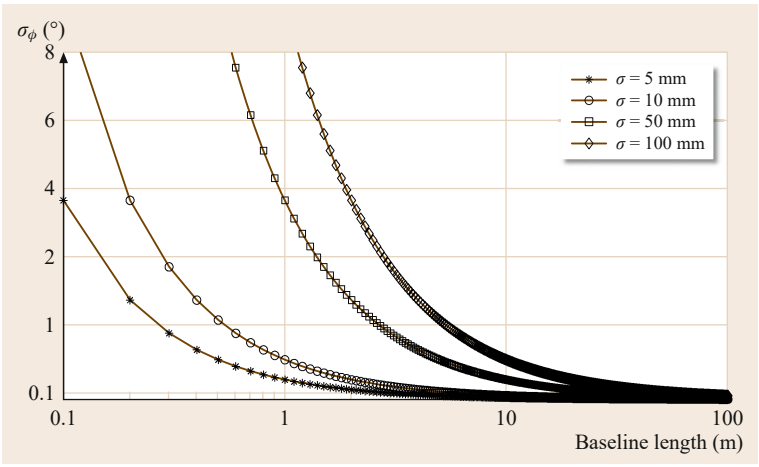

**Fig. 27.3** Coarse prediction of attitude estimation precision ($\sigma_\phi$) as function of the baseline length and differential range measurement precision $\sigma$

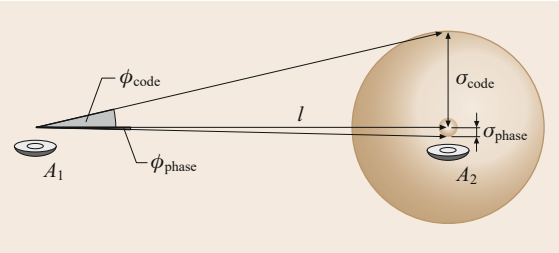

**Fig. 27.4** GNSS carrier-phase measurements provide much more precise differential positioning than pseudorange (code) measurements, thus enabling highly precise angular estimates

attitude determination systems have found a firm place in the spectrum of attitude sensors.

GNSS signals are processed to obtain directional information by exploiting the interferometric principle: the difference between ranging measurements at two antennas tracking the same navigation satellite equals to the projection of the baseline vector – that is, the vectorial distance between the two antennas – onto the line-of-sight direction to the common satellite (Fig. 27.2). Each differential range measurement corresponds to a locus of potential baseline vector directions, which span a conical region of aperture $\alpha = \arccos(r/l)$, with $r$ the differential range and $l$ the baseline length. The baseline vector can then be estimated when three or more satellites are being simultaneously tracked. A single baseline enables direction measurements – for example the heading and pitch of a vehicle – whereas two or more noncollinear baselines are needed to perform full three-axis attitude determination.

The quality of angular estimation from differential range measurements depends on two factors: the baseline length and the differential ranging error. A simple rule of thumb to predict the angular estimation error $\sigma_\phi$ from a given combination of baseline length $l$ and differential ranging measurement error $\sigma$ is

$$\sigma_\phi = \frac{\sigma}{l} \,. \tag{27.1}$$

This relationship is shown in Fig. 27.3: subdegree accuracies are obtained by employing large antenna separations or reducing the differential measurement error.

The latter can be minimized in the context of GNSS attitude sensors by exploiting carrier-phase measurements. Whereas pseudorange differential measurement error is at decimeter level at best, the signal carrier phase can be measured at a fraction of the wavelength, enabling differential positioning with subcentimeter precision (Fig. 27.4). However, each carrier-phase measurement is ambiguous by an unknown integer number of cycles: only the fractional part of the differential signal phase can be observed (Fig. 27.5). Carrier-phase integer ambiguity resolution is the process of resolving the cycle ambiguities to their correct integer values (Chap. 23). After the integer ambiguities are removed, the differential carrier-phase observations act as very precise ranging measurements, yielding precise baseline estimations which are then converted to an estimate of the orientation angles. Typically, a GNSS carrier-phase-based attitude determination sensor enables orientation estimation with subdegree precision for baselines of about 1 m length and with precision higher than 0.1° for baselines spanning few meters.

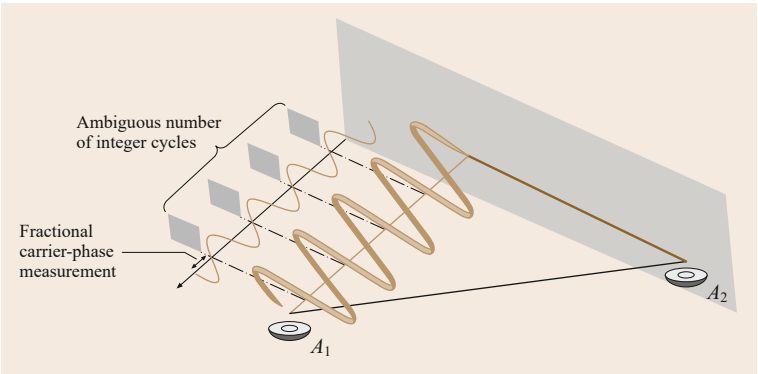

**Fig. 27.5** The differential carrier-phase measurement is ambiguous by an integer number of cycles, since only the fractional part of the signal phase can be observed. Integer ambiguity resolution is the key to precise attitude estimates

## 27.2 Attitude Parameterization

Prior to describing how to perform attitude determination with GNSS signals, a review of attitude representation methods is here given. The orientation of a body is described by defining the transformation matrix that rotates a coordinate system attached to the body onto a reference system of choice. Several alternatives for representing the mutual orientation of two frames are available. Each parameterizes the rotation by employing a small set of *attitude parameters*.

This section gives an introduction to the properties of the transformation matrix under the rigid-body hypothesis, and briefly reviews several alternatives to efficiently represent the rotation in terms of attitude parameters.

### 27.2.1 The Space of Rotations

An orthogonal frame $\mathcal{F}$ in the vector space $\mathbb{R}^3$ is defined by a basis, that is, a triplet of vectors $\{\boldsymbol{u}_1, \boldsymbol{u}_2, \boldsymbol{u}_3\}$ that satisfy the following two conditions

$$\boldsymbol{u}_i^\top \boldsymbol{u}_j = \delta_{ij} \,, \tag{27.2}$$

$$\boldsymbol{u}_1 \times \boldsymbol{u}_2 = \boldsymbol{u}_3 \,, \tag{27.3}$$

with $\delta_{ij}$ the Kronecker delta. The elements of the basis are thus orthogonal vectors of norm one, and define a right-handed coordinate system.

Any vector $\boldsymbol{x} \in \mathbb{R}^3$ can be expressed in terms of its projection onto the basis of $\mathcal{F}$

$$\boldsymbol{x} = \left(\boldsymbol{x}^\top \boldsymbol{u}_1\right) \boldsymbol{u}_1 + \left(\boldsymbol{x}^\top \boldsymbol{u}_2\right) \boldsymbol{u}_2 + \left(\boldsymbol{x}^\top \boldsymbol{u}_3\right) \boldsymbol{u}_3 \,. \tag{27.4}$$

The components of vector $\boldsymbol{x}$ in any two orthogonal frames $\mathcal{F}$ and $\mathcal{F}'$ sharing a common origin are related by the linear transformation

$$\boldsymbol{x}_{\mathcal{F}'} = \mathbf{R} \boldsymbol{x}_{\mathcal{F}} \,. \tag{27.5}$$

Matrix $\mathbf{R}$ defines the transformation that rotates the elements of the basis of $\mathcal{F}$ onto the elements of the basis of $\mathcal{F}'$. This transformation must preserve both the lengths and the angles between any two vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ in $\mathbb{R}^3$

$$\boldsymbol{x}_{\mathcal{F}'}^\top \boldsymbol{y}_{\mathcal{F}'} = \boldsymbol{x}_{\mathcal{F}}^\top \mathbf{R}^\top \mathbf{R} \boldsymbol{y}_{\mathcal{F}} \quad \Longrightarrow \quad \mathbf{R}^\top \mathbf{R} = \mathbf{I}_3 \,. \tag{27.6}$$

Thus, matrix $\mathbf{R}$ is orthonormal, that is, the vector columns $\boldsymbol{r}_i$ of $\mathbf{R}$ are unit vectors, pair-wise orthogonal

$$\boldsymbol{r}_i^\top \boldsymbol{r}_j = \delta_{ij} \,. \tag{27.7}$$

Condition (27.7) guarantees the invariance of the scalar product with respect to the linear transformation (27.5), whereas the vector product is invariant under rotations about the axis defined by $\boldsymbol{x}_{\mathcal{F}'} \times \boldsymbol{y}_{\mathcal{F}'}$ only for rotation matrices with positive determinant

$$\boldsymbol{x}_{\mathcal{F}'} \times \boldsymbol{y}_{\mathcal{F}'} = \det(\mathbf{R}) \mathbf{R} \left(\boldsymbol{x}_{\mathcal{F}} \times \boldsymbol{y}_{\mathcal{F}}\right) . \tag{27.8}$$

An orthonormal matrix with positive determinant is named an attitude matrix, or equivalently a matrix of rotations. An orthonormal matrix with negative determinant describes a combination of a rotation and a reflection about one or more axes, and for this reason it does not describe transformations of real rigid bodies. The group of orthonormal matrices with positive determinant is named a special group $\mathcal{SO}(3)$ [27.10].

Due to the orthonormality constraint, in the three-dimensional space the matrix of rotations $\mathbf{R}$ can be parameterized with a minimum of three independent variables.

### 27.2.2 Parameterization of the Rotation Matrix

The transformation between the basis of two orthonormal frames $\mathcal{F}$ and $\mathcal{F}'$ reads

$$\boldsymbol{u}_{i,\mathcal{F}'} = \sum_{j=1}^{3} r_{ij} \boldsymbol{u}_{j,\mathcal{F}} \;\;, \;\; i = 1, 2, 3 \,, \tag{27.9}$$

where $r_{ij}$ denotes the element of matrix $\mathbf{R}$. Applying relation (27.9) to the scalar product between vectors of the two bases yields

$$\boldsymbol{u}_{i,\mathcal{F}'}^\top \boldsymbol{u}_{j,\mathcal{F}} = r_{ij} \,. \tag{27.10}$$

The scalar $r_{ij}$ is the cosine of the angle between vectors $\boldsymbol{u}_{i,\mathcal{F}'}$ and $\boldsymbol{u}_{j,\mathcal{F}}$. The elements of the attitude matrix then corresponds to the nine direction cosines of the angles formed by the three vectors of basis $\mathcal{F}$ and the three vectors of basis $\mathcal{F}'$ (Fig. 27.6)

$$\mathbf{R} = \begin{bmatrix} \boldsymbol{u}_{1,\mathcal{F}'}^\top \boldsymbol{u}_{1,\mathcal{F}} & \boldsymbol{u}_{1,\mathcal{F}'}^\top \boldsymbol{u}_{2,\mathcal{F}} & \boldsymbol{u}_{1,\mathcal{F}'}^\top \boldsymbol{u}_{3,\mathcal{F}} \\ \boldsymbol{u}_{2,\mathcal{F}'}^\top \boldsymbol{u}_{1,\mathcal{F}} & \boldsymbol{u}_{2,\mathcal{F}'}^\top \boldsymbol{u}_{2,\mathcal{F}} & \boldsymbol{u}_{2,\mathcal{F}'}^\top \boldsymbol{u}_{3,\mathcal{F}} \\ \boldsymbol{u}_{3,\mathcal{F}'}^\top \boldsymbol{u}_{1,\mathcal{F}} & \boldsymbol{u}_{3,\mathcal{F}'}^\top \boldsymbol{u}_{2,\mathcal{F}} & \boldsymbol{u}_{3,\mathcal{F}'}^\top \boldsymbol{u}_{3,\mathcal{F}} \end{bmatrix} . \tag{27.11}$$

By employing nine direction cosines, the mutual orientation of two frames is described with six redundant parameters. A more efficient approach is obtained by exploiting Euler's rotation theorem [27.11]: any rotation of a rigid body in a three-dimensional space can be described with a single rotation with angle $\phi$ about an axis $\boldsymbol{n}$. The latter is identified by the three direction cosines that it forms with the basis of frame $\mathcal{F}$

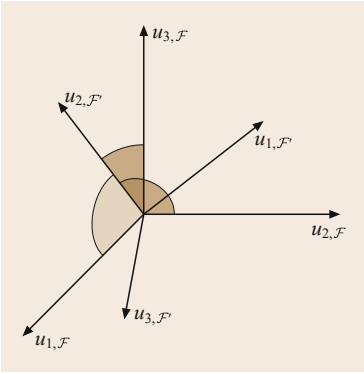

**Fig. 27.6** The nine angles formed by the axes of frame $\mathcal{F}$ and the axes of frame $\mathcal{F}'$ unambiguously define the mutual orientation of the two frames. Here, the three angles formed by axis $\boldsymbol{u}_{2,\mathcal{F}'}$ with respect to the three axes of frame $\mathcal{F}$ are shown

(Fig. 27.7). The Euler rotation formula gives the parameterization of the attitude matrix in terms of angle $\phi$ and the elements of vector $\boldsymbol{n}$

$$\mathbf{R}(\boldsymbol{n},\phi) = C_\phi \mathbf{I}_3 + (1-C_\phi)\boldsymbol{n}\boldsymbol{n}^\top - S_\phi [\boldsymbol{n}^+] \ , \quad (27.12)$$

where $C_\phi = \cos(\phi)$ and $S_\phi = \sin(\phi)$. The skew-symmetric matrix $[\boldsymbol{n}^+]$ is defined as

$$[\boldsymbol{n}^+] = \begin{bmatrix} 0 & -n_3 & n_2 \\ n_3 & 0 & -n_1 \\ -n_2 & n_1 & 0 \end{bmatrix} , \quad (27.13)$$

and counterclockwise rotations are described by a positive angle $\phi$. Expression (27.12) is used to describe the rotation in terms of four parameters, and it is known as *Euler axis-angle* attitude representation.

A closely related representation is the *Euler angles* parameterization. This follows from performing three consecutive rotations about the main axes of a frame, for which the rotation axis takes one of the forms $\boldsymbol{n}_1 = (1,0,0)^\top$, or $\boldsymbol{n}_2 = (0,1,0)^\top$, or $\boldsymbol{n}_3 = (0,0,1)^\top$. Any arbitrary rotation in the three-dimensional space can be obtained by a sequence $i \to j \to k$, with $i \neq j$ and $j \neq k$. An example is the sequence 321, in which the first rotation is about axis $\boldsymbol{u}_{3,\mathcal{F}}$ with angle $\psi$, the second is about the (new) axis $\boldsymbol{u}_{2,\mathcal{F}'}$ with angle $\theta$, and the last about the (new) axis $\boldsymbol{u}_{1,\mathcal{F}''}$ with angle $\varphi$. Sequence 321, illustrated in Fig. 27.8, is of common use in vehicle guidance applications, where the angles $\psi, \theta, \varphi$ are named yaw, pitch and roll angles, respectively (an alternative definition of the triad is heading, elevation and bank). For such a combination, the attitude matrix reads

$$\mathbf{R}(\psi,\theta,\varphi) = \mathbf{R}(\boldsymbol{u}_1,\varphi)\,\mathbf{R}(\boldsymbol{u}_2,\theta)\,\mathbf{R}(\boldsymbol{u}_3,\psi) = \begin{bmatrix} C_\psi C_\theta & +S_\psi C_\theta & -S_\theta \\ C_\psi S_\theta S_\varphi - S_\psi C_\varphi & S_\psi S_\theta S_\varphi + C_\psi C_\varphi & C_\theta S_\varphi \\ C_\psi S_\theta C_\varphi + S_\psi S_\varphi & S_\psi S_\theta C_\varphi - C_\psi S_\varphi & C_\theta C_\varphi \end{bmatrix} . \quad (27.14)$$

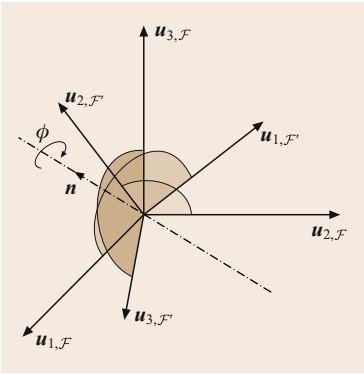

**Fig. 27.7** Euler's theorem: in the three-dimensional space, any rotation of a rigid body can be described by a rotation of angle $\phi$ about an axis $\boldsymbol{n}$

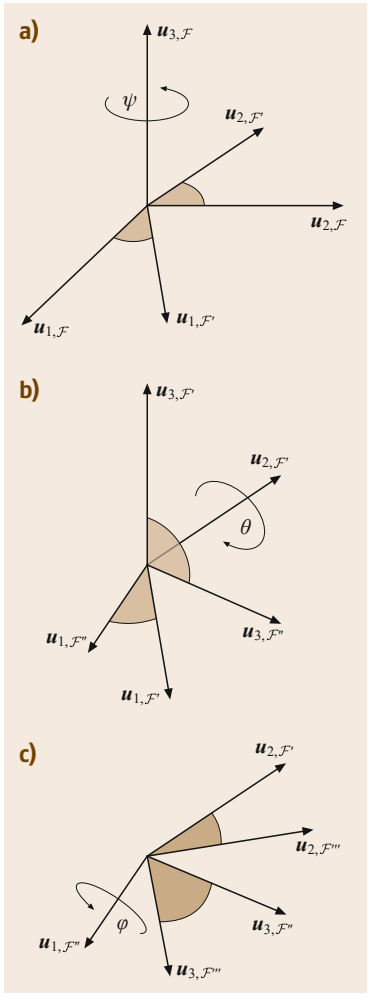

**Fig. 27.8a–c** Euler's angles sequence 321. The three consecutive rotation angles are commonly named yaw, pitch and roll. **(a)** First rotation with angle $\psi$ about axis $\boldsymbol{u}_{3,\mathcal{F}}$. **(b)** Second rotation with angle $\theta$ about axis $\boldsymbol{u}_{2,\mathcal{F}'}$. **(c)** Third rotation with angle $\varphi$ about axis $\boldsymbol{u}_{1,\mathcal{F}''}$

The sequence of three rotations that form the attitude matrix $\mathbf{R}$ is paramount, with different ordering yielding different attitude matrices.

Multiple Euler angles triads may represent the same orientation: this is usually avoided by limiting the parameter space. As an example, the sequence 321 is equivalently expressed as $\mathbf{R}(\psi, \theta, \varphi)$ and $\mathbf{R}(\psi + \pi, \pi - \theta, \varphi + \pi)$. Imposing $-\pi/2 < \theta \leq \pi/2$ and $-\pi < \psi, \varphi \leq \pi$ solves this multiplicity problem.

The Euler angles, although easily understood and thus of common use in attitude gages and indicators, are computationally less efficient and precise than other parameterizations, mainly due to the presence of trigonometric functions.

An alternative, widely used attitude parameterization is based on quaternion algebra [27.12, 13]. A quaternion is a real-valued, four-component entity $\mathsf{q}$, namely composed by a scalar part $q_0$ and a vectorial part $\boldsymbol{q} = (q_1, q_2, q_3)^\top$, that satisfies the following multiplication rule

$$\mathsf{q}\mathsf{q}' = q_0 \begin{pmatrix} q'_0 \\ \boldsymbol{q}' \end{pmatrix} + \begin{bmatrix} 0 & -\boldsymbol{q}^\top \\ \boldsymbol{q} & [\boldsymbol{q}^+] \end{bmatrix} \begin{pmatrix} q'_0 \\ \boldsymbol{q}' \end{pmatrix}, \tag{27.15}$$

where the skew-symmetric matrix $[\boldsymbol{q}^+]$ is obtained from the elements of the vectorial part of the quaternion as

$$[\boldsymbol{q}^+] = \begin{bmatrix} 0 & -q_3 & q_2 \\ q_3 & 0 & -q_1 \\ -q_2 & q_1 & 0 \end{bmatrix}. \tag{27.16}$$

Any quaternion of unit norm ($q_0^2 + \boldsymbol{q}^\top \boldsymbol{q} = 1$) represents a rotation, and it is defined as a *quaternion of rotation*. By linking the elements of a quaternion $\mathsf{q}$ to the rotation axis and angle as

$$\mathsf{q}(\phi, \boldsymbol{n}) = \begin{pmatrix} \cos\left(\frac{\phi}{2}\right) \\ \sin\left(\frac{\phi}{2}\right) \boldsymbol{n} \end{pmatrix}, \tag{27.17}$$

the Euler rotation formula (27.12) becomes

$$\mathbf{R}(\mathsf{q}) = \left(q_0^2 - \boldsymbol{q}^\top \boldsymbol{q}\right) \mathbf{I}_3 + 2\boldsymbol{q}\boldsymbol{q}^\top - 2q_0 [\boldsymbol{q}^+] = \begin{bmatrix} q_0^2 + q_1^2 - q_2^2 - q_3^2 & 2(q_1 q_2 + q_0 q_3) & 2(q_1 q_3 - q_0 q_2) \\ 2(q_1 q_2 - q_0 q_3) & q_0^2 - q_1^2 + q_2^2 - q_3^2 & 2(q_2 q_3 + q_0 q_1) \\ 2(q_1 q_3 + q_0 q_2) & 2(q_2 q_3 - q_0 q_1) & q_0^2 - q_1^2 - q_2^2 + q_3^2 \end{bmatrix}. \tag{27.18}$$

This is the *quaternion representation* of the attitude matrix. Note that $\mathbf{R}(\mathsf{q}) = \mathbf{R}(-\mathsf{q})$, thus any rotation can be represented by two quaternions. The quaternion representation is computationally more efficient than other representations that employ trigonometric functions. The main disadvantages of using unit quaternions are the additional unit norm constraint and the lack of a direct physical interpretation. The latter is the reason why the attitude is usually output in human-machine interfaces in terms of Euler angles, even though the underlying control operations may be performed with quaternions.

Aiming to reduce the number of attitude parameters used in the quaternion representation, two alternative parameterizations can be used. The first is the *Rodrigues vector representation* (also know as Gibbs vector), which relates to the quaternion and Euler axis-angle representations as

$$\boldsymbol{p} = \frac{\boldsymbol{q}}{q_0} = \boldsymbol{n} \tan\left(\frac{\phi}{2}\right). \tag{27.19}$$

By definition, a rotation angle $\phi = \pi$ about any axis cannot be represented (singularity). The Rodrigues vector representation introduces some computational advantages, for example the inverse of $\mathbf{R}(\boldsymbol{p})$ is simply obtained as $\mathbf{R}(-\boldsymbol{p})$.

A second choice is given by the *modified Rodrigues representation*, alternatively defined as

$$\boldsymbol{p}^+ = \frac{\boldsymbol{q}}{1 + q_0}, \tag{27.20}$$

or

$$\boldsymbol{p}^- = \frac{\boldsymbol{q}}{1 - q_0}. \tag{27.21}$$

This modification of the Rodrigues vector is used to shift the singularity of the Rodrigues representation to $2\pi$.

Finally, two additional attitude parameterizations could be used, both based on skew-symmetric matrices. The first is the *Cayley representation*, formulated from the skew-symmetric matrix associated to the Rodrigues vector $\boldsymbol{p}$ as

$$\mathbf{R}([\boldsymbol{p}^+]) = (\mathbf{I}_3 - [\boldsymbol{p}^+])^{-1} (\mathbf{I}_3 + [\boldsymbol{p}^+]). \tag{27.22}$$

The second is the *skew representation*, formulated as a matrix exponentiation

$$\mathbf{R}([\boldsymbol{v}^+]) = \exp([\boldsymbol{v}^+]), \tag{27.23}$$

with $\boldsymbol{v}$ any real-valued, three-component vector. The Euler rotation formula is obtained from (27.23) by replacing $\boldsymbol{v} = \boldsymbol{n}\phi$.

Each of attitude representations listed above provides the same attitude matrix $\mathbf{R}$ for the same body orientation. However, each attitude parameterization differs in terms of computational load, singularities (orientations that cannot be parameterized), multiple representations of the same attitude, and attitude estimation error in the parameter space. Further details about the attitude representations and their properties can be found in [27.14].

## 27.3 Attitude Estimation from Baseline Observations

The transformation between the coordinates of a vector expressed in two reference frames $\mathcal{F}$ and $\mathcal{F}'$ with common origin is realized by a rotation: $\boldsymbol{b}_{\mathcal{F}'} = \mathbf{R}\boldsymbol{b}_{\mathcal{F}}$. The solution of the inverse problem, that is, the determination of the relative orientation between frames $\mathcal{F}'$ and $\mathcal{F}$ from a set of baseline observations, is the objective of attitude estimation.

Before addressing the attitude estimation problem, a few definitions are given:

1. The *local* frame $\mathcal{F}$ is the frame attached to the body whose attitude has to be determined. The *reference* frame $\mathcal{B}$ is the frame used as a reference to compute the rotations.
2. The local baseline coordinates are cast in matrix

$$\mathbf{F} = \begin{bmatrix} \boldsymbol{f}_1 & \boldsymbol{f}_2 & \cdots & \boldsymbol{f}_m \end{bmatrix} . \tag{27.24}$$

   Each baseline $\boldsymbol{f}_i$ is expressed in the local coordinate frame $\mathcal{F}$. Vector $\boldsymbol{f}_i$ is a $p$-component vector, where the parameter $p$ assumes one of the following values: $p = 1$ for any configuration of $m$ aligned baselines; $p = 2$ for any noncollinear configurations of $m$ coplanar baselines; $p = 3$ for any noncoplanar configurations of $m$ baselines. The parameter $p$ defines the rank of matrix $\mathbf{F}$: $p = \mathrm{rk}(\mathbf{F})$. This definition of matrix $\mathbf{F}$ enables solving the single-baselines attitude determination problem (Compass) within the same framework employed for arrays composed by a larger number of antennas.
3. The baseline coordinates in the reference frame $\mathcal{B}$ are cast in matrix

$$\mathbf{B} = \begin{bmatrix} \boldsymbol{b}_1 & \boldsymbol{b}_2 & \cdots & \boldsymbol{b}_m \end{bmatrix} . \tag{27.25}$$

   Each baseline $\boldsymbol{b}_i$ is a three-component vector.
4. The matrix of rotations $\mathbf{R}$ has dimensions $3 \times p$, and is subject to the orthonormality constraint $\mathbf{R}^\top\mathbf{R} = \mathbf{I}_p$. In the following, $SO(3,p) \subset \mathbb{R}^{3\times p}$ denotes the group of *proper* $3 \times p$ rotation matrices, that is, orthonormal matrices with positive determinant. The positiveness of the matrix determinant is verified for $p = 2$ by adding the third (fully dependent) column of $\mathbf{R}$ as $\boldsymbol{r}_3 = \boldsymbol{r}_1 \times \boldsymbol{r}_2$, whereas for $p = 1$ the constraint is implicitly fulfilled. This generalization is introduced to address attitude estimation problems with single- or two-baseline observations [27.15].

### 27.3.1 Estimation of the Orthonormal Matrix of Rotations

Pseudorange and carrier-phase observations collected by the elements of a GNSS antenna array are processed to obtain baseline estimates, usually expressed in the Earth-Centered, Earth-Fixed (ECEF) frame or in the East-North-Up (ENU) frame. The link between the estimate of the baseline coordinates $\hat{\mathbf{B}}$ in these reference frames and the baseline coordinates $\mathbf{F}$ in the local body-attached frame $\mathcal{F}$ is

$$\hat{\mathbf{B}} = \mathbf{R}\mathbf{F} + \boldsymbol{\Theta} \quad ; \quad \mathbf{R} \in SO(3,p) . \tag{27.26}$$

Matrix $\boldsymbol{\Theta}$ denotes the baseline estimation error, and the unknown in (27.26) is the orthonormal matrix of rotations $\mathbf{R}$.

The simplest and oldest method to derive the attitude matrix is the three-axis attitude determination (TRIAD) method [27.16], which applies to two nonparallel baselines. The two baseline estimates and the local baseline vectors are cast in matrices

$$\hat{\mathbf{B}} = \begin{bmatrix} \hat{\boldsymbol{b}}_1 & \hat{\boldsymbol{b}}_2 \end{bmatrix}$$

and

$$\mathbf{F} = \begin{bmatrix} \boldsymbol{f}_1 & \boldsymbol{f}_2 \end{bmatrix} .$$

Two orthonormal bases are then formed, $\mathcal{V} = \{\boldsymbol{v}_1, \boldsymbol{v}_2, \boldsymbol{v}_3\}$ and $\mathcal{U} = \{\boldsymbol{u}_1, \boldsymbol{u}_2, \boldsymbol{u}_3\}$, with

$$\begin{aligned} \boldsymbol{v}_1 &= \frac{\hat{\boldsymbol{b}}_1}{\|\hat{\boldsymbol{b}}_1\|} , & \boldsymbol{u}_1 &= \frac{\boldsymbol{f}_1}{\|\boldsymbol{f}_1\|} , \\ \boldsymbol{v}_2 &= \frac{\hat{\boldsymbol{b}}_1 \times \hat{\boldsymbol{b}}_2}{\|\hat{\boldsymbol{b}}_1 \times \hat{\boldsymbol{b}}_2\|} , & \boldsymbol{u}_2 &= \frac{\boldsymbol{f}_1 \times \boldsymbol{f}_2}{\|\boldsymbol{f}_1 \times \boldsymbol{f}_2\|} , \\ \boldsymbol{v}_3 &= \boldsymbol{v}_1 \times \boldsymbol{v}_2 , & \boldsymbol{u}_3 &= \boldsymbol{u}_1 \times \boldsymbol{u}_2 . \end{aligned} \tag{27.27}$$

The sought orthonormal matrix is then completely defined by the nine direction cosines between the vectors

of the bases $\mathcal{U}$ and $\mathcal{V}$

$$\hat{\mathbf{R}}_{\text{TRIAD}} = \sum_{i=1}^{3} \boldsymbol{v}_i \boldsymbol{u}_i^{\top} \,. \tag{27.28}$$

Although simple to implement, the TRIAD method only applies to baseline couples, and does not incorporate any weighting of the elements of the baseline estimates.

The problem of estimating the attitude matrix $\mathbf{R}$ from an arbitrary set of baseline estimations $\hat{\mathbf{B}}$ can be formulated within the least-squares framework. The matrix of rotations is the orthonormal matrix that minimizes the squared weighted norm of the estimation errors $\boldsymbol{\Xi} = \hat{\mathbf{B}} - \mathbf{RF}$

$$\hat{\mathbf{R}} = \arg \min_{\mathbf{R} \in \mathcal{SO}(3,p)} \|\text{vec}\,(\boldsymbol{\Xi})\|^2_{\mathbf{Q}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}} \,, \tag{27.29}$$

where

$$\|\boldsymbol{x}\|^2_{\mathbf{Q}} = \boldsymbol{x}^{\top} \mathbf{Q}^{-1} \boldsymbol{x}$$

denotes the squared weighted norm, vec is the operator that stacks the columns of a matrix $m \times n$, yielding the corresponding $mn$-vector, and $\mathbf{Q}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}$ is the variance-covariance (v-c) matrix whose elements are the variances and covariances of and between the elements of the baseline estimation $\hat{\mathbf{B}}$. Expression (27.29) defines a nonlinear least-squares problem, where the nonlinearity is implicit to the orthonormality constraint. Depending on the shape of the weight matrix, different approaches for the minimization of (27.29) are available.

### 27.3.2 Orthogonal Procrustes Problem

If matrix $\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}$ is a block-diagonal matrix obtained as

$$\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}} = \mathbf{W} \otimes \mathbf{I}_3 \,,$$

with $\mathbf{W}$ a diagonal $m \times m$ matrix and $\otimes$ denoting the Kronecker product [27.17], expression (27.29) reduces to

$$\hat{\mathbf{R}} = \arg \min_{\mathbf{R} \in \mathcal{SO}(3,p)} \text{tr}\left[\mathbf{W}^{\frac{1}{2}} \boldsymbol{\Xi}^{\top} \boldsymbol{\Xi} \mathbf{W}^{\frac{1}{2}}\right] \,, \tag{27.30}$$

where tr denotes the trace operator. Problem (27.30) corresponds to those cases in which each baseline observation is weighted by its own factor $w_i$, and it is commonly referred to as Wahba's problem [27.18, 19], or the orthogonal Procrustes problem (OPP). The latter naming derives from the bandit Procrustes, who, according to Greek mythology, used to capture passers-by, lie them on an iron bed, and forced them to fit the bed length by stretching or cutting off their limbs. The modern terminology *Procrustes analysis* refers to those problems in which Euclidean transformations, such as translation, rotation and scaling, are applied to an object in order to fit predetermined constraints.

The solution of (27.26) is found by maximizing the following expression

$$\hat{\mathbf{R}} = \arg \max_{\mathbf{R} \in \mathcal{SO}(3,p)} \text{tr}\left[\mathbf{RFW}\hat{\mathbf{B}}^{\top}\right] \,. \tag{27.31}$$

If the matrix product $\mathbf{FW}\hat{\mathbf{B}}^{\top}$ is nonsingular, its singular value decomposition (SVD)

$$\mathbf{FW}\hat{\mathbf{B}}^{\top} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^{\top}$$

enables rewriting the term to maximize as

$$\sum_{i=1}^{n} x_{ii} d_i \,,$$

with $x_{ii}$ the diagonal elements of matrix $\mathbf{X} = \mathbf{V}^{\top}\mathbf{RU}$. Since $\mathbf{X}$ is a product of orthonormal matrices, and the determinant of $\hat{\mathbf{R}}$ must be positive, the maximizer of (27.31) is

$$\hat{\mathbf{R}} = \mathbf{V} \begin{bmatrix} \det(\mathbf{V}^{\top}\mathbf{U}) & 0 \\ 0 & \mathbf{I}_2 \end{bmatrix} \mathbf{U}^{\top} \,. \tag{27.32}$$

Expression (27.32) solves the attitude estimation problem (27.30) with the computation of a SVD [27.18]. The latter can be avoided by following an elegant reasoning based on the Davenport's *q-method* [27.20], which redefines the maximization problem (27.31) in terms of the quaternion used to represent the attitude matrix

$$\hat{\mathbf{q}} = \arg \max_{\|\mathbf{q}\|=1} \left(q_0, \boldsymbol{q}^{\top}\right) \mathbf{K} \left(q_0, \boldsymbol{q}^{\top}\right)^{\top} \,, \tag{27.33}$$

where the *Davenport matrix* $\mathbf{K}$ is built as

$$\begin{aligned} \mathbf{K} &= \begin{bmatrix} \mathbf{C} + \mathbf{C}^{\top} - \text{tr}(\mathbf{C})\mathbf{I}_3 & \boldsymbol{s} \\ \boldsymbol{s}^{\top} & \text{tr}(\mathbf{C}) \end{bmatrix} , \\ \mathbf{C} &= \hat{\mathbf{B}}\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}\mathbf{F}^{\top} \,, \\ \boldsymbol{s} &= \left(c_{2,3} - c_{3,2}, \quad c_{3,1} - c_{1,3}, \quad c_{1,2} - c_{2,1}\right)^{\top} , \end{aligned} \tag{27.34}$$

with $c_{i,j}$ denoting the $i,j$ component of matrix $\mathbf{C}$. The unknown is then the quaternion that maximizes the

bilinear term in (27.33), subject to the unit norm constraint, and it is found by selecting the eigenvector associated to the largest eigenvalue $\xi_{\max}$ of $\mathbf{K}$. The computational load for the eigenvalue decomposition of matrix $\mathbf{K}$ is comparable to the one of the SVD [27.21], but a very fast algorithm can nevertheless be devised, which avoids the direct calculation of the eigenvalues of $\mathbf{K}$. When precise baseline estimates are available, the largest eigenvalue $\xi_{\max}$ is close to the approximate solution

$$\xi_{\max} \approx \xi_0 = \frac{1}{2}\mathrm{tr}\left[\mathbf{W}^{\frac{1}{2}}\left[\hat{\mathbf{B}}^\top\hat{\mathbf{B}} + \mathbf{F}^\top\mathbf{F}\right]\mathbf{W}^{\frac{1}{2}}\right] . \quad (27.35)$$

The secular – or characteristic – fourth-order equation

$$f(\xi) = \det(\mathbf{K} - \xi\mathbf{I}_4) = 0 , \quad (27.36)$$

with $\xi_0$ as the initialization point, is then solved to extract the largest root, thus avoiding the computation of any decomposition [27.22].

Several methods exploiting the quaternion parameterization approach have been formulated and widely used in practice, such as the quaternion estimator (QUEST) [27.22, 23], the fast optimal attitude matrix (FOAM) [27.24], the estimator of the optimal quaternion (ESOQ) [27.25], and the second ESOQ (ESOQ2) [27.26] algorithms. These approaches, which only differ in the way the characteristic equation (27.36) is handled, are extremely numerically efficient, and as such are suitable for implementation also in low-grade processors [27.27–29].

### 27.3.3 Weighted Orthogonal Procrustes Problem

If matrix $\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}$ can be decomposed as

$$\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}} = \mathbf{I}_m \otimes \mathbf{\Gamma} ,$$

with $\mathbf{\Gamma}$ denoting a diagonal $3\times 3$ matrix, expression (27.29) reduces to

$$\hat{\mathbf{R}} = \arg\min_{\mathbf{R}\in SO(3,p)} \mathrm{tr}\left[\mathbf{\Xi}^\top\mathbf{\Gamma}\,\mathbf{\Xi}\right] . \quad (27.37)$$

In the minimization problem (27.37), each row of the baseline matrix $\hat{\mathbf{B}}$ is weighted differently. This is a viable weighting approach when operating with sensors that provide higher accuracies in certain directions, but does not give proper weighting to all the elements of the baseline estimates. Expression (27.37) defines a weighted orthogonal Procrustess problem (WOPP), and although less complex than the case of a fully populated matrix $\mathbf{Q}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}$, it can only be solved with numerical techniques. Efficient numerical schemes to guarantee fast convergence to a global minimum are reviewed in [27.30, 31].

### 27.3.4 Attitude Estimation with Fully Populated Weight Matrix

Generally, matrix $\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}$ cannot be reduced to one of the previous cases when working with GNSS baseline estimates. First, it is useful to operate a quadratic decomposition of the squared weighted norm in (27.29) as [27.32]

$$\left\|\mathrm{vec}(\hat{\mathbf{B}} - \mathbf{RF})\right\|^2_{\mathbf{Q}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}} = \left\|\mathrm{vec}(\hat{\mathbf{E}})\right\|^2_{\mathbf{Q}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}} + \left\|\mathrm{vec}(\hat{\mathbf{R}} - \mathbf{R})\right\|^2_{\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}} , \quad (27.38)$$

where $\hat{\mathbf{E}} = \hat{\mathbf{B}} - \hat{\mathbf{R}}\mathbf{F}$, and

$$\hat{\mathbf{R}} = \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}(\mathbf{F}^\top \otimes \mathbf{I}_3)^\top\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}\mathrm{vec}(\hat{\mathbf{B}}) ,$$
$$\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}} = \left[(\mathbf{F}^\top \otimes \mathbf{I}_3)^\top\mathbf{Q}^{-1}_{\hat{\mathbf{B}}\hat{\mathbf{B}}}(\mathbf{F}^\top \otimes \mathbf{I}_3)\right]^{-1} . \quad (27.39)$$

Matrices $\hat{\mathbf{R}}$ and $\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}$ denote the least-squares estimation of the attitude matrix and the corresponding v-c matrix when the orthonormality constraint is discarded in the estimation problem (27.29). The orthonormal matrix of rotations is then found by minimizing the squared weighted norm

$$\tilde{\mathbf{R}} = \arg\min_{\mathbf{R}\in SO(3,p)} \left\|\mathrm{vec}(\hat{\mathbf{R}} - \mathbf{R})\right\|^2_{\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}} , \quad (27.40)$$

where the variances of the elements of $\hat{\mathbf{R}}$ and their correlation are fully accounted for when weighting the attitude estimation residuals $\hat{\mathbf{R}} - \mathbf{R}$.

The sought orthonormal matrix is obtained by projecting the vector $\mathrm{vec}(\hat{\mathbf{R}})$, element of the $3p$-dimensional space, onto the curved manifold in the $0.5p(p+1)$-dimensional subspace defined by the constraints $\mathbf{R}^\top\mathbf{R} = \mathbf{I}_p$, where the metric of the projection is defined by matrix $\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}$. Figure 27.9 visualizes a single-baseline example ($p = 1$), where vector $\hat{\boldsymbol{r}}$ is projected onto the sphere $\mathbb{S} := \boldsymbol{r}^\top\boldsymbol{r} = 1$. The sought attitude solution $\tilde{\boldsymbol{r}}$ is the point of contact between the sphere $\mathbb{S}$ and the ellipsoid $\mathbb{E}$ centered in $\hat{\boldsymbol{r}}$ and shaped by the elements of matrix $\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}$.

The solution of the nonlinear constrained problem (27.40) can be computed via the Lagrangian multipliers method [27.33]. Alternative numerical solutions can be devised by employing a parameterization of the attitude matrix. For example, by representing matrix $\mathbf{R}$ with a triplet of Euler angles, the orthonormality constraints are implicitly fulfilled, and expression (27.40) reduces to a nonlinear least-squares minimization problem that can be solved via the Newton method or, disregarding the second-order derivatives, the Gauss–Newton method [27.34].

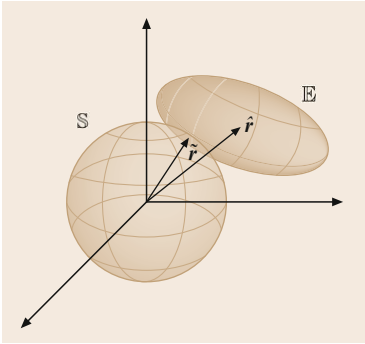

**Fig. 27.9** The point of contact between the unit sphere $\mathbb{S}$ and the ellipsoid $\mathbb{E}$, centered in $\hat{\boldsymbol{r}}$ and shaped by $\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}$, is the solution of the constrained least-squares problem (27.40) in the single-baseline case

### 27.3.5 On the Precision of Attitude Estimation

The precision of angular estimations from baseline observations depends on two factors: the length of the baselines employed and the baseline observation noise. Assuming that precise baseline observations are available, such that the dispersion of $\hat{\mathbf{R}}$ in (27.39) is small, a first-order description of the attitude estimation error is given by the v-c matrix $\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}$, whose entries depend on the quality of the baseline estimates through matrix $\mathbf{Q}_{\hat{\mathbf{b}}\hat{\mathbf{b}}}$ and on the geometrical properties of the antenna array through matrix $\mathbf{F}$. Relation (27.39) shows how these factors affect the quality of the GNSS attitude estimates. The attitude estimation error is inversely proportional to the geometrical size of the array (baseline lengths), and directly proportional to the observation noise. The latter can be effectively improved by exploiting GNSS carrier-phase measurements, as shown in more detail in Sect. 27.4.4.

Due to the nonlinear constraints in (27.40), it is not possible to obtain a measure of the attitude estimation error by linearly propagating the float v-c matrix $\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}$. The dispersion of the orthonormal matrix of rotations $\tilde{\mathbf{R}}$ can no longer be described by a normal distribution. An approximated measure of the estimation error can be computed by linearizing the function that maps matrix $\hat{\mathbf{R}}$ into the matrix of rotations $\tilde{\mathbf{R}}$ [27.22].

In many applications, an indication of the estimation error in the attitude parameters domain is preferred over knowing the precision of the elements of matrix $\tilde{\mathbf{R}}$. Let $\boldsymbol{\gamma}$ denote the $c$-component vector of attitude parameters chosen to represent the matrix of rotations (e.g., $c = 3$ for the Euler angles and $c = 4$ for the quaternion of rotation). The attitude parameters are in nonlinear correspondence with the elements of the attitude matrix, and their precision can be described with a first-order approximation by the v-c matrix $\mathbf{Q}_{\gamma\gamma}$, obtained as

$$\mathbf{Q}_{\gamma\gamma} = \mathbf{J}_{\gamma(\mathbf{R})}\mathbf{Q}_{\tilde{\mathbf{R}}\tilde{\mathbf{R}}}\mathbf{J}^{\top}_{\gamma(\mathbf{R})} , \tag{27.41}$$

with $\mathbf{J}_{\gamma(\mathbf{R})}$ denoting the $c \times 3p$ Jacobian matrix of the inverse function that maps from the elements of the attitude matrix to the chosen space of attitude parameters.

## 27.4 The GNSS Attitude Model

The previous two sections reviewed how the orientation of a frame can be described via a set of attitude parameters and how these are estimated from baseline measurements. In the context of GNSS-based attitude sensors, the (vectorial) baselines between the elements of the antenna array must be estimated from the pseudorange and carrier-phase measurements. A coherent theoretical framework for GNSS attitude determination is built by formulating a functional model that links the GNSS observables with the sought attitude parameters, while embedding all the available a priori geometrical constraints.

First, differential pseudorange and carrier-phase measurements are formed between two closely-separated (i. e., with a baseline not exceeding a few hundred meters) antennas tracking the same satellite, such that the differential ionospheric and tropospheric delays can be neglected (Chap. 20). The single difference (SD) measurements are free from the (common) satellite clock error, but may still contain differential receiver-clock errors and instrumental delays. A synchronization between the clocks at the two receivers and a correct calibration of the line biases is necessary to augment the strength of the observation model, without the necessity of introducing additional unknowns. An alternative method to eliminate the remaining differential biases is to form double difference (DD) measurements, in which the only remaining unknowns are the integer ambiguities and the baseline coordinates.

Assuming normally distributed measurements collected at $n$ channels (SD or DD) on $f$ frequencies, the following single-baseline observation model holds for any GNSS used

$$\boldsymbol{y} \sim \mathrm{N}\left(\mathbf{A}\boldsymbol{z} + \mathbf{G}\boldsymbol{b}, \mathbf{Q}_{\mathrm{yy}}\right) , \; \boldsymbol{z} \in \mathbb{Z}^{nf} , \; \boldsymbol{b} \in \mathbb{R}^3 , \tag{27.42}$$

with $\boldsymbol{y}$ the $2nf$-component differential data vector; $\mathbf{A}$ the $2nf \times 2nf$ design matrix defined as $\mathbf{A} = (0, 1)^{\top} \otimes \boldsymbol{\Lambda} \otimes \mathbf{I}_n$, with $\boldsymbol{\Lambda}$ the diagonal $f \times f$ matrix containing the wavelength(s); $\mathbf{G}$ the $2nf \times 3$ design matrix constructed

as $\mathbf{G} = \boldsymbol{e}_{2f} \otimes \mathbf{U}$, where $\boldsymbol{e}_{2f}$ denotes a $2f$-component vector of ones and $\mathbf{U}$ is the matrix of differenced line-of-sight unit vectors. The unknown parameters are the integer-valued vector of $nf$ carrier-phase ambiguities $\boldsymbol{z}$ and the real-valued 3-component vector of baseline coordinates $\boldsymbol{b}$. To ease the notation, the time dependency is not explicitly indicated.

The data vector $\boldsymbol{y}$ is generally assumed to be normally distributed, with dispersion captured by the $2nf \times 2nf$ v-c matrix $\mathbf{Q}_{\mathbf{yy}}$.

The linear model (27.42) is generalized for an array of $m+1$ GNSS antennas forming $m$ baselines as

$$\begin{aligned} &\mathrm{vec}(\mathbf{Y}) \sim \mathrm{N}\left(\mathrm{vec}\left(\mathbf{AZ}+\mathbf{GB}\right), \mathbf{Q}_{\mathbf{YY}}\right) \\ &\mathbf{Z} \in \mathbb{Z}^{nf\times m}\,,\ \mathbf{B} \in \mathbb{R}^{3\times m}\,. \end{aligned} \tag{27.43}$$

The $m$ vectors of $2nf$ differential observations of type (27.42) are the columns of matrix $\mathbf{Y}$; the $m$ carrier-phase integer ambiguity vectors are the columns of matrix $\mathbf{Z}$ and the $m$ baseline coordinates vectors are the columns of matrix $\mathbf{B}$. Matrix $\mathbf{A}$ remains unchanged with respect to the single-baseline model (27.42). Also, it is assumed that the same geometry matrix $\mathbf{G}$ applies to each baseline of the array. This is justified by considering a sufficiently small array size, with separations between antennas negligible with respect to the satellite-to-receivers distances (approximatively 20 000 km).

The stochastic properties of the measurement vector $\mathrm{vec}(\mathbf{Y})$ are described by the v-c matrix $\mathbf{Q}_{\mathbf{YY}}$. If each of the $m$ baseline measurements is fittingly described by the same v-c matrix $\mathbf{Q}_{\mathbf{yy}}$, and the baselines are formed by using a common reference antenna, matrix $\mathbf{Q}_{\mathbf{YY}}$ can be reduced to

$$\mathbf{Q}_{\mathbf{YY}} = \mathbf{P}_m \otimes \mathbf{Q}_{\mathbf{yy}}\,, \tag{27.44}$$

where $\mathbf{P}_m$ denotes the $m \times m$ matrix that introduces the correct covariance factors due to the differencing with respect to a common antenna. This matrix is computed as

$$\mathbf{P}_m = \frac{1}{2}\left(\mathbf{I}_m + \boldsymbol{e}_m \boldsymbol{e}_m^{\top}\right),$$

with $\boldsymbol{e}_m$ denoting an $m$-component vector of ones.

In a GNSS antenna array operating as an attitude sensor, the differential pseudorange and carrier-phase measurements are obtained from antennas at known relative positions. Under the rigid body hypothesis, with invariant relative positions between the elements of the array, the unknown baseline coordinates $\mathbf{B}$ in (27.43) are obtained through a rotation of the known local baseline coordinates $\mathbf{F}$. The baseline coordinates in $\mathbf{B}$ are expressed in a user-defined reference frame, such as the ECEF or ENU frames, whereas the known local baseline coordinates $\mathbf{F}$ are expressed in a reference frame attached to the body. The attitude of the body is estimated by computing the rotation matrix that describes the mutual orientation between the two frames. The GNSS attitude observation model is then formulated as [27.15]

$$\begin{aligned} &\mathrm{vec}(\mathbf{Y}) \sim \mathrm{N}\left(\mathrm{vec}\left(\mathbf{AZ}+\mathbf{GRF}\right), \mathbf{Q}_{\mathbf{YY}}\right) \\ &\mathbf{Z} \in \mathbb{Z}^{nf\times m}\,,\ \mathbf{R} \in \mathcal{SO}(3,p)\,, \end{aligned} \tag{27.45}$$

where the unknowns are the integer-valued matrix of carrier-phase ambiguities $\mathbf{Z}$ and the rotation matrix $\mathbf{R}$.

The GNSS attitude model (27.45) shows several useful properties. First, the number of unknown parameters does not linearly increase with the number of baselines employed, with a gain in the observations-to-unknowns redundancy equal to $3(m-p)$. For example, five GNSS antennas forming four noncoplanar baselines give twelve unknown baseline coordinates, but only nine unknown entries of $\mathbf{R}$ in (27.45). Moreover, due to the orthonormality constraint only three independent parameters of $\mathbf{R}$ have to be estimated, further increasing the observations-to-unknowns redundancy.

Second, the actual number of constraints associated to the transformation $\mathbf{B} = \mathbf{RF}$ may be larger than the $\frac{1}{2}p(p+1)$ nonlinear constraints that follow from the orthonormality of $\mathbf{R}$ [27.35]. The nonlinear constraints are explicit and always present, and their maximum number is six when employing four or more noncoplanar antennas. In addition, implicit $3(m-p)$ linear constraints exist when using three or more collinear antennas ($p = 1, m \geq 2$), four or more coplanar antennas ($p = 2, m \geq 3$), or any configuration of five or more antennas ($m > 3$). These implicit, linear constraints contribute to improve the overall estimation quality.

### 27.4.1 Potential Model Errors and Misspecification

The GNSS attitude model given in (27.45) neglects a number of parameters whose contributions may become significant, such as multipath, atmospheric delays, or antenna phase center variations.

Multipath accounts for the largest part of the measurement error in short baseline models. Multipath causes a degradation of the tracking capabilities of the receiver, which processes the sum of the direct signal and delayed signal replicas due to reflections and/or additional propagation paths. The multipath error depends on both magnitude and delay of the spurious contributes, which in turn depend on the relative geometry between antennas, GNSS satellites and surrounding objects, on the amplitude, frequency and polarization of the received signal, and on the platform dynamics.

Multipath does not behave as a random noise source, but rather as a time-changing observation bias, with dynamics proportional to the relative motion between satellite and receiving antenna. Multipath affects both code and phase tracking, introducing errors in pseudorange and carrier-phase measurements reaching meter-level and cm-level, respectively, which cannot be easily eliminated or estimated (Chap. 15). Techniques for the mitigation of multipath span from ad hoc antenna siting and physical design (e.g., choke rings, see Chap. 17) to narrow correlators, which attenuate the impact of reflected signals through narrower correlator spacing [27.36]. Also, the new generation of GNSS signals, based on the multiplexed binary offset carrier (MBOC) modulation, promises an improved multipath suppression [27.37, 38].

The atmospheric delays are usually neglected in differential applications employing short baselines, as the signals collected by antennas placed no further than a few hundred meters apart have traveled to a large extent the same path, thus experiencing similar delays that cancel out for the most part after differencing. However, the presence of strong ionospheric perturbations, such as scintillations or gradients, cannot be excluded a priori. These disturbances could alter the ranging signals introducing nonnegligible delays, loss of locks and additional observation noise.

An additional, potential source of estimation biases is the variation of the antenna phase centers (APCs). The signals collected at each antenna are by convention referenced to the corresponding APC (Chap. 17). The a priori knowledge of the distance between APCs is used to form the matrix of local baseline coordinates $\mathbf{F}$. Any modeling error of the local baseline coordinates, due to a wrong calibration of the APCs or due to their time-varying behavior not being accounted for, would directly translate into model misspecifications, possibly causing incorrect ambiguity resolution and attitude estimation biases. Variations of the APCs can also be caused by nonrigid bodies, in which the relative positions between the antennas change without the deformation being captured by the corresponding matrix of known local baseline coordinates.

A correct calibration and a suitable error detection and model misspecification testing procedures (Chap. 24) are usually implemented to avoid estimation biases due to the aforementioned error sources.

### 27.4.2 Resolution of the GNSS Attitude Model

The GNSS attitude model (27.45) links the measurement matrix to the unknown integer ambiguities and orthonormal rotation matrix. Although the relationship between measurements and unknowns is linear, the associated constraints yield a nonlinear estimation problem. Precise GNSS-based attitude estimations can only be achieved by fixing the carrier-phase ambiguities to their correct integer values. When this is accomplished successfully, the differential carrier-phase observations act as very precise differential range measurements, making available accurate baseline estimations that are used to precisely estimate the body attitude. Integer ambiguity resolution in the presence of geometrical constraints is a complex problem, even more so when aiming at reliable and fast methods that could provide instantaneous solutions, without requiring long observation time spans or ad hoc initializations.

Several ambiguity resolution methods that apply to the GNSS-based attitude determination problem have been proposed. A first, straightforward method is to accumulate carrier-phase observations over time, during which the integer ambiguities remain constant, until the decoupling between ambiguities and attitude parameters enables their separate estimation [27.39]. This technique requires a certain amount of relative motion during the observation time span, since it relies on variations of the line-of-sight vectors between the antenna array and the GNSS satellites. Several methods that exploit this principle have subsequently been developed – and are commonly referred to as motion-based methods – aiming to limit the amount of relative motion needed for convergence [27.40], to eliminate the need for an a priori attitude estimate [27.41], or to improve the convergence time by also performing a search in the space of the unknown ambiguity-attitude parameters [27.42–45].

A common, potential drawback of all motion-based procedures is that the relative motion may take some time to occur. These techniques may then suffer from long initialization times, especially in low-dynamic applications, and cannot provide an instantaneous solution. This shortfall of motion-based approaches is resolved by methods that can provide an instantaneous solution of the unknown ambiguity and attitude parameters. These methods minimize a given cost function by performing an exhaustive search in the space of the unknown parameters. The search applies either in the position domain, over the space of relative antenna positions, or in the ambiguity domain, over the space of integer vectors.

Examples of approaches performing a search in the position domain include those based on the ambiguity function method (AFM), which minimizes a cost function parameterized in terms of direction angles [27.46]. The function is evaluated over a grid of potential azimuth-elevation angles in single-baseline

arrays [27.47–49] or over a grid of potential three-axis attitude angles for multiple-baseline arrays [27.50]. However, due to the dense quantization of the search domain necessary to find the global minimum, the computation of a very large number of samples of the objective function is required. The computational effort demanded by these approaches may thus hinder real-time applications [27.44].

The alternative methods of searching in the integer domain explore a number of potential integer ambiguity solutions by evaluating whether the corresponding baseline estimations satisfy the known geometrical constraints. Some approaches search for a candidate integer vector [27.51–54], or a selected subset of the integer vector [27.55–57], and discard those candidates that do not generate baseline solutions lying on a sphere of known radius. Other methods also weigh the attitude solution that follows from estimating multiple baselines based on different candidate integer vectors, for example [27.58].

Several integer search-based approaches make use of the least-squares ambiguity decorrelation adjustment (LAMBDA) method [27.59, 60], thus applying the integer least-squares (ILS) principle to minimize over the integer domain (Chap. 23). The method is numerically efficient [27.61, 62], and it is demonstrated to be optimal, in terms of providing the highest probability of correct ambiguity resolution when applied to linear models [27.63, 64]. The LAMBDA method is widely used in the context of instantaneous GNSS-based attitude determination applications, see for example [27.51–54, 65, 66]. Many methods exploit the geometrical constraints by rejecting unlikely baseline solutions. This use of a priori known information is legitimate, and yields enhanced success rates, but does not guarantee to minimize the least-squares residual error. The optimal solution to the problem of joint ambiguity *and* attitude estimation is derived from the rigorous inclusion of the geometrical constraints into the integer ambiguity resolution process. The resulting nonlinear, mixed estimation problem can be resolved by an extension of the ILS principle, implemented in the multivariate constrained-LAMBDA (MC-LAMBDA) method [27.15, 67–69], in which the nonlinear constraints are fully integrated into the cost function. The constraints play an active role during the integer search, providing guidance towards an instantaneous, joint ambiguity-attitude solution.

### 27.4.3 The GNSS Ambiguity and Attitude Estimation

The solution of the GNSS attitude model (27.45) is found by addressing the associated least-squares problem with inclusion of the integer constraint on the carrier-phase ambiguities $\mathbf{Z}$ and of the orthonormality constraint on the attitude matrix $\mathbf{R}$

$$\{\check{\mathbf{Z}}, \check{\mathbf{R}}\} = \arg \min_{\substack{\mathbf{Z}\in\mathbb{Z}^{nf\times m},\\ \mathbf{R}\in SO(3,p)}} \|\mathrm{vec}(\mathbf{Y}-\mathbf{AZ}-\mathbf{GRF})\|^2_{\mathbf{Q}_{\mathbf{YY}}} \ . \tag{27.46}$$

This solution is optimal in a least-squares sense, that is, the squared weighted norm of the estimation residuals is minimized over the parameter space. The minimization problem (27.46) is resolved with a two-steps procedure. First, a so-called *float solution* is derived by disregarding both the integer and the orthonormality constraints. The precision of this unconstrained estimation is driven by the precision of the pseudorange measurements, thereby acting as an initial coarse solution. The float estimation is refined in a second step by jointly estimating the integer ambiguities and the matrix of rotations, accounting for both the integer and orthonormality constraints. The two steps of the resolution procedure are detailed as follows.

#### Step I: Float Solution

The float solution of model (27.45) is the solution of the least-squares minimization problem

$$\{\hat{\mathbf{Z}}, \hat{\mathbf{R}}\} = \arg \min_{\substack{\mathbf{Z}\in\mathbb{R}^{nf\times m},\\ \mathbf{R}\in\mathbb{R}^{3\times p}}} \|\mathrm{vec}\,(\mathbf{Y}-\mathbf{AZ}-\mathbf{GRF})\|^2_{\mathbf{Q}_{\mathbf{YY}}} \ . \tag{27.47}$$

In this step, the estimation of the carrier-phase ambiguities is real-valued, and the matrix of rotations is not orthonormally constrained. The least-squares estimations $\hat{\mathbf{Z}}$ and $\hat{\mathbf{R}}$ are obtained by solving the associated set of normal equations

$$\mathbf{M}\begin{pmatrix}\mathrm{vec}(\hat{\mathbf{Z}})\\ \mathrm{vec}(\hat{\mathbf{R}})\end{pmatrix} = \begin{bmatrix}\mathbf{I}_m\otimes\mathbf{A}^\top\\ \mathbf{F}\otimes\mathbf{G}^\top\end{bmatrix}\mathbf{Q}^{-1}_{\mathbf{YY}}\mathrm{vec}\,(\mathbf{Y}) \ , \tag{27.48}$$

with

$$\mathbf{M} = \begin{bmatrix}\mathbf{I}_m\otimes\mathbf{A}^\top\\ \mathbf{F}\otimes\mathbf{G}^\top\end{bmatrix}\mathbf{Q}^{-1}_{\mathbf{YY}}\begin{bmatrix}\mathbf{I}_m\otimes\mathbf{A} & \mathbf{F}^\top\otimes\mathbf{G}\end{bmatrix}. \tag{27.49}$$

For a measurement v-c matrix constructed as $\mathbf{Q}_{\mathbf{YY}} = \mathbf{P}_m\otimes\mathbf{Q}_{yy}$, the float estimations $\hat{\mathbf{Z}}$ and $\hat{\mathbf{R}}$ are explicitly computed as

$$\hat{\mathbf{R}} = \left[\bar{\mathbf{G}}^\top\mathbf{Q}^{-1}_{yy}\bar{\mathbf{G}}\right]^{-1}\bar{\mathbf{G}}^\top\mathbf{Q}^{-1}_{yy}\mathbf{Y}\mathbf{P}^{-1}_m\mathbf{F}^\top\left[\mathbf{F}\mathbf{P}^{-1}_m\mathbf{F}^\top\right]^{-1}$$

$$\hat{\mathbf{Z}} = \left[\mathbf{A}^\top\mathbf{Q}^{-1}_{yy}\mathbf{A}\right]^{-1}\mathbf{A}^\top\mathbf{Q}^{-1}_{yy}\left[\mathbf{Y}-\mathbf{G}\hat{\mathbf{R}}\mathbf{F}\right] \ , \tag{27.50}$$

with $\bar{\mathbf{G}} = \mathbf{P}_{\mathbf{A}}^{\perp}\mathbf{G}$. Matrix $\mathbf{P}_{\mathbf{C}}^{\perp} = \mathbf{I} - \mathbf{P}_{\mathbf{C}}$ denotes the orthogonal complement of the projector matrix

$$\mathbf{P}_{\mathbf{C}} = \mathbf{C}\left[\mathbf{C}^{\top}\mathbf{Q}_{yy}^{-1}\mathbf{C}\right]^{-1}\mathbf{C}^{\top}\mathbf{Q}_{yy}^{-1}.$$

The float estimations are normally distributed, with dispersion computed by inverting the normal matrix $\mathbf{M}$

$$\begin{bmatrix} \mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}} & \mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{R}}} \\ \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{Z}}} & \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}} \end{bmatrix} = \mathbf{M}^{-1}\,. \tag{27.51}$$

### Step II: Ambiguity-Attitude Estimation

In this second step the float solution is refined by estimating the integer carrier-phase ambiguities. The squared norm in (27.46) is decomposed in terms of a sum-of-squares as [27.32]

$$\begin{aligned} &\|\mathrm{vec}\,(\mathbf{Y} - \mathbf{A}\mathbf{Z} - \mathbf{G}\mathbf{R}\mathbf{F})\|^2_{\mathbf{Q}_{\mathbf{YY}}} \\ &\quad = \|\mathrm{vec}(\boldsymbol{\Psi})\|^2_{\mathbf{Q}_{\mathbf{YY}}} + \left\|\mathrm{vec}\left(\hat{\mathbf{Z}} - \mathbf{Z}\right)\right\|^2_{\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}}} \\ &\qquad + \left\|\mathrm{vec}\left(\hat{\mathbf{R}}(\mathbf{Z}) - \mathbf{R}\right)\right\|^2_{\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}}, \end{aligned} \tag{27.52}$$

where matrix $\boldsymbol{\Psi}$ denotes the float estimation error, matrix $\hat{\mathbf{R}}(\mathbf{Z})$ denotes the conditional attitude matrix, that is, the (generally not orthonormal) attitude matrix conditioned on the ambiguity residual $\mathrm{vec}(\hat{\mathbf{Z}} - \mathbf{Z})$, and matrix $\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}$ denotes the v-c matrix of the conditional solution. The conditional attitude matrix $\hat{\mathbf{R}}(\mathbf{Z})$ is computed by considering the integer ambiguities as known and solving the associated (unconstrained) model $\mathrm{E}(\mathbf{Y} - \mathbf{A}\mathbf{Z}) = \mathbf{G}\mathbf{R}\mathbf{F}$ in a least-squares sense, obtaining

$$\begin{aligned} \mathrm{vec}\left(\hat{\mathbf{R}}(\mathbf{Z})\right) &= \mathrm{vec}\left(\hat{\mathbf{R}}\right) - \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{Z}}}\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}}^{-1}\mathrm{vec}\left(\hat{\mathbf{Z}} - \mathbf{Z}\right), \\ \mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})} &= \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}} - \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{Z}}}\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}}^{-1}\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{R}}}\,. \end{aligned} \tag{27.53}$$

The conditional attitude solution is largely more precise than its float solution, as it mainly depends on the precision of the carrier-phase observables (Sect. 27.4.4).

The ambiguity-attitude estimation problem that follows from (27.52) reads [27.15]

$$\begin{aligned} \check{\mathbf{Z}} &= \arg\min_{\mathbf{Z}\in\mathbb{Z}^{nf\times m}} C(\mathbf{Z})\,, \\ C(\mathbf{Z}) &= \left\|\mathrm{vec}(\hat{\mathbf{Z}} - \mathbf{Z})\right\|^2_{\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}}} + J(\mathbf{Z})\,. \end{aligned} \tag{27.54}$$

The function to be minimized is the sum of two dependent terms. The first term is the square distance between the integer candidate $\mathbf{Z}$ to the ambiguity float solution $\hat{\mathbf{Z}}$, in the metric of the v-c matrix $\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}}$. The second term $J(\mathbf{Z})$ is computed as

$$\begin{aligned} J(\mathbf{Z}) &= \left\|\mathrm{vec}\left(\hat{\mathbf{R}}(\mathbf{Z}) - \check{\mathbf{R}}(\mathbf{Z})\right)\right\|^2_{\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}}, \\ \check{\mathbf{R}}(\mathbf{Z}) &= \arg\min_{\mathbf{R}\in\mathcal{SO}(3\times p)} \left\|\mathrm{vec}\left(\hat{\mathbf{R}}(\mathbf{Z}) - \mathbf{R}\right)\right\|^2_{\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}}, \end{aligned} \tag{27.55}$$

and weighs the squared distance between the conditional float solution $\hat{\mathbf{R}}(\mathbf{Z})$ and the corresponding orthonormal solution $\check{\mathbf{R}}(\mathbf{Z})$, in the metric of $\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}$.

The minimization of the cost function in (27.54) entails an integer search, in which the evaluation of $C(\mathbf{Z})$ at point $\mathbf{Z}$ requires the corresponding attitude solution $\check{\mathbf{R}}(\mathbf{Z})$ to be derived. This requires solving the nonlinear constrained problem in (27.55), whose solution was discussed in Sect. 27.3. Integer ambiguities that return unlikely attitude solutions – in terms of the weighted distance to the corresponding float estimation – yield proportionally larger values for the objective function $C(\mathbf{Z})$.

The integral ambiguity-attitude minimization problem (27.54) is solved by applying an extension of the ILS principle (Chap. 23), modified so as to deal with the additional nonlinear geometrical constraints, which largely strengthen the estimation procedure. The integer-valued minimizer $\check{\mathbf{Z}}$ is searched within a subset of the integer domain $\mathbb{Z}^{nf\times m}$: the search space is defined as

$$S\left(\chi^2\right) = \left\{\mathbf{Z}\in\mathbb{Z}^{n\times m} \mid C(\mathbf{Z}) \le \chi^2\right\}, \tag{27.56}$$

with $\chi^2$ a positive scalar chosen to limit the branches of the search tree.

The integer search in the constrained ILS approach is numerically complex. This is due to a combination of two factors. First, the evaluation of the cost function $C(\mathbf{Z})$ requires the solution of the constrained minimization problem (27.55). Second, the scalar $\chi^2$ has to be chosen to be small enough to avoid unnecessary computations of the cost function. These two issues are effectively and efficiently solved by performing the integer search with functions that bound the original cost function $C(\mathbf{Z})$ and are computationally easier to evaluate. Formally, two integer search procedures can be devised, depending on whether one works with lower or upper bounds of function $C(\mathbf{Z})$.

*Search-and-Expand Algorithm.* Let $C_{\mathrm{l}}(\mathbf{Z}) \le C(\mathbf{Z})$ be a suitable lower bound of $C(\mathbf{Z})$. The search space

associated to $C_l(\mathbf{Z})$, defined as

$$S_l\left(\chi^2\right) = \left\{\mathbf{Z} \in \mathbb{Z}^{n\times m} \mid C_l(\mathbf{Z}) \le \chi^2\right\} \tag{27.57}$$

is a superset of the original search space (27.56)

$$S\left(\chi^2\right) \subseteq S_l\left(\chi^2\right) \ . \tag{27.58}$$

First, the search space $S_l\left(\chi_0^2\right)$, with initial value $\chi_0$ chosen to be arbitrarily small, is explored aiming for integer candidates within its boundaries. If a nonempty set of integer candidate is found, function $C(\mathbf{Z})$ is evaluated for each element of the set, thus enumerating integer candidates within the original search space $S\left(\chi_0^2\right)$. Should set $S\left(\chi_0^2\right)$ be nonempty, the potential candidates $\mathbf{Z}_i$ are sorted according to the value of $C(\mathbf{Z}_i)$, and the candidate that returns the smallest value of the cost function is the sought integer minimizer $\check{\mathbf{Z}}$. If set $S\left(\chi_0^2\right)$ is empty, the search iteratively continues with the same modalities, by increasing the scalar $\chi_{s+1}^2 > \chi_s^2$ at each loop.

*Search-and-Shrink Algorithm.* Let $C_u(\mathbf{Z}) \ge C(\mathbf{Z})$ be an upper bound of $C(\mathbf{Z})$, with associated search space

$$S_u\left(\chi^2\right) = \left\{\mathbf{Z} \in \mathbb{Z}^{n\times m} \mid C_u(\mathbf{Z}) \le \chi^2\right\} \ , \tag{27.59}$$

where $S_u\left(\chi^2\right) \subseteq S\left(\chi^2\right)$. First, an initial value for the scalar $\chi^2 = \chi_0^2$ is chosen such to guarantee the nonemptiness of $S_u\left(\chi_0^2\right)$. As soon as an integer matrix $\mathbf{Z}_1 \in S_u\left(\chi_0^2\right)$ is found, such that $C_u(\mathbf{Z}_1) < \chi_0^2$, the search space is shrunk by replacing $\chi_1^2 = C_u(\mathbf{Z}_1)$, and the search continues in the shrunken set $S_u\left(\chi_1^2\right)$, looking for an integer candidate $\mathbf{Z}_2$ that returns $C_u(\mathbf{Z}_2) < \chi_1^2$. The search proceeds iteratively until the minimizer of $C_u(\mathbf{Z})$, denoted with $\check{\mathbf{Z}}_u$, is found. Since $C_u(\check{\mathbf{Z}}_u) \le C(\check{\mathbf{Z}}_u)$, the integer matrix $\check{\mathbf{Z}}_u$ may differ from the sought minimizer $\check{\mathbf{Z}}$. Thus, a final search is performed within the search space $S\left(\overline{\chi}^2\right)$, with $\overline{\chi}^2 = C_u(\check{\mathbf{Z}}_u)$. This final search is performed in a largely shrunk set, and only a few candidates need to be tested in order to extract the integer minimizer of $C(\mathbf{Z})$ [27.70].

The advantages of the constrained integer search algorithms described above are twofold. First, the size of the search space is iteratively adjusted during the search, avoiding the computation of the cost function for a large number of integer candidates. Second, the bounds used can be chosen among a class of *easy-to-compute* functions, avoiding the computational complexity of $C(\mathbf{Z})$. An example of lower and upper bounds is obtained by taking the smallest ($\xi_{\min}$) and the largest ($\xi_{\max}$) eigenvalues of the inverse of matrix $\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}$, which yield the following inequalities

$$\begin{aligned}\xi_{\min} &\left\|\mathrm{vec}(\hat{\mathbf{R}}(\mathbf{Z}) - \check{\mathbf{R}}(\mathbf{Z}))\right\|_{\mathbf{I}}^2 \\ &\le \left\|\mathrm{vec}(\hat{\mathbf{R}}(\mathbf{Z}) - \check{\mathbf{R}}(\mathbf{Z}))\right\|_{\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}}^2 \\ &\le \xi_{\max}\left\|\mathrm{vec}(\hat{\mathbf{R}}(\mathbf{Z}) - \check{\mathbf{R}}(\mathbf{Z}))\right\|_{\mathbf{I}}^2 \ .\end{aligned} \tag{27.60}$$

The first and last squared norms in (27.60) are decomposed as

$$\sum_{i=1}^{p} \|\hat{\boldsymbol{r}}_i(\mathbf{Z})\|^2 + 1 - 2\,\|\hat{\boldsymbol{r}}_i(\mathbf{Z})\|\cos(\alpha_i) \ ,$$

with $\alpha_i$ the angle formed by vectors $\hat{\boldsymbol{r}}_i(\mathbf{Z})$ and $\check{\boldsymbol{r}}_i(\mathbf{Z})$, which denote the $i$-th columns of $\hat{\mathbf{R}}$ and $\check{\mathbf{R}}$, respectively. Thus, two bounds $C_l(\mathbf{Z})$ and $C_u(\mathbf{Z})$ are defined as

$$\begin{aligned}C_l(\mathbf{Z}) &= \left\|\mathrm{vec}(\hat{\mathbf{Z}} - \mathbf{Z})\right\|_{\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}}}^2 \\ &\quad + \xi_{\min}\sum_{i=1}^{p}\left(\|\hat{\boldsymbol{r}}_i(\mathbf{Z})\| - 1\right)^2 \ , \\ C_u(\mathbf{Z}) &= \left\|\mathrm{vec}(\hat{\mathbf{Z}} - \mathbf{Z})\right\|_{\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}}}^2 \\ &\quad + \xi_{\max}\sum_{i=1}^{p}\left(\|\hat{\boldsymbol{r}}_i(\mathbf{Z})\| - 1\right)^2 \ .\end{aligned} \tag{27.61}$$

The evaluation of these functions does not require the solution of the constrained least-squares problem in (27.55), but only the computation of squared norms, thereby reducing the computational burden.

The choice of the bounds follows two criteria. First, the evaluation of the bound should be numerically efficient, avoiding nonlinear estimation problems. Second, the bounds should be tight enough with respect to the original function $C(\mathbf{Z})$ to guarantee fast convergence to the sought integer minimizer. Examples of efficient alternative bounds can be found in [27.71].

### 27.4.4 The Quality of Ambiguity and Attitude Estimations

In the first step of the attitude-ambiguity estimation procedure, float estimators are derived as linear functions of the observables. Thus, the float estimations distribute as

$$\begin{pmatrix}\mathrm{vec}(\hat{\mathbf{Z}})\\ \mathrm{vec}(\hat{\mathbf{R}})\end{pmatrix} \sim \mathrm{N}\left(\begin{pmatrix}\mathrm{vec}(\mathbf{Z})\\ \mathrm{vec}(\mathbf{R})\end{pmatrix}, \begin{bmatrix}\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}} & \mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{R}}}\\ \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{Z}}} & \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}\end{bmatrix}\right). \tag{27.62}$$

**Table 27.1** $10^5$ data samples simulation of the single-baseline ($p = 1$), single-epoch, single-frequency ($f = 1$) success rates for the LAMBDA and MC-LAMBDA methods. The success rates are given per number of channels, and per code (pr) and phase noise (cp) levels combinations

In order to highlight the single terms that contribute to the precision of the float estimation, the v-c matrix of the observations is assumed to be decomposed as $\mathbf{Q}_{\mathbf{YY}} = \mathbf{P}_m \otimes \mathbf{Q}_{yy}$. This enables the decomposition of the float ambiguity and attitude v-c matrices in (27.62) as

$$\begin{aligned}\mathbf{Q}_{\hat{\mathbf{Z}}\hat{\mathbf{Z}}} &= \left[\mathbf{P}_m^{-1}\mathbf{P}_{\mathbf{F}^\top}^{\perp} \otimes \tilde{\mathbf{A}}^\top \mathbf{Q}_{yy}^{-1}\tilde{\mathbf{A}}\right. \\ &\quad \left. + \mathbf{P}_m^{-1} \otimes \bar{\mathbf{A}}^\top \mathbf{Q}_{yy}^{-1}\bar{\mathbf{A}}\right]^{-1} , \\ \mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}} &= \left[\mathbf{F}\mathbf{P}_m^{-1}\mathbf{F}^\top\right]^{-1} \otimes \left[\bar{\mathbf{G}}^\top \mathbf{Q}_{yy}^{-1}\bar{\mathbf{G}}\right]^{-1} ,\end{aligned} \tag{27.63}$$

with $\tilde{\mathbf{A}} = \mathbf{P}_{\mathbf{G}}\mathbf{A}$ and $\bar{\mathbf{A}} = \mathbf{P}_{\mathbf{G}}^{\perp}\mathbf{A}$. The precision of both float estimators $\hat{\mathbf{Z}}$ and $\hat{\mathbf{R}}$ depends on the number of satellites and frequencies tracked, on the satellite geometry ($\mathbf{G}$), and on the quality of the observations ($\mathbf{Q}_{yy}$). In details, it is the precision of the pseudorange observations that influences the float estimation error [27.32, 69]. The quality of the float estimation also depends on the mutual geometry of the baselines formed by the elements of the antenna array. By increasing the size of the antenna array $\mathbf{F}$ with a scaling factor $g$, the elements of the float attitude v-c matrix reduce by a factor $1/g^2$, thus capturing the impact of longer baselines. Also the angles formed by the baselines play a role in defining the entries of $\mathbf{Q}_{\hat{\mathbf{R}}\hat{\mathbf{R}}}$, although this dependency is somewhat more complicated to figure. As a general rule, a balanced baseline configuration, intended as a distribution of baselines directed so to achieve maximum angular separations, should be preferred for a more precise estimation of the whole set of attitude parameters [27.72]. On the contrary, multiple aligned baselines may be used to enhance the estimation of rotations about a particular axis.

Differently from float attitude estimates, the precision of the float ambiguities is independent of any arbitrary scaling of the antenna array. However, the ambiguity float estimation does benefit from certain geometries of the GNSS antenna array. The orthogonal projector $\mathbf{P}_{\mathbf{F}^\top}^{\perp}$ in (27.63) differs from zero for any baseline arrangement characterized by $p < m$ (Sect. 27.4). Thus, lower entries of the ambiguity float v-c matrix are obtained when employing:

1. Three or more collinear antennas
2. Four or more coplanar antennas
3. Any configuration of five or more antennas [27.35, 73].

The reason why these configurations yield improved float ambiguity estimation is the presence of implicit linear constraints in the GNSS attitude model (27.45), as discussed in Sect. 27.4.

An analysis of the quality of the constrained ambiguity-attitude estimation is somewhat more complex. As with the unconstrained ILS, the precision of the ambiguity estimation depends on the quality of the float estimation. However, the latter does not completely define the success rate of the constrained approach, due to the additional geometrical constraints in (27.54). By estimating the integer ambiguities and the platform's attitude in an integral manner, fully exploiting the known body geometry of the multiantenna configuration, the ambiguity resolution performance is greatly improved with respect to unconstrained integer ambiguity resolution methods [27.67, 69]. The enhancement of the ambiguity resolution performance can be appreciated through simulations, which provide a comparison between the performance of unconstrained and constrained ILS estimation in a controlled environment. Tables 27.1–27.2 give the success rate,

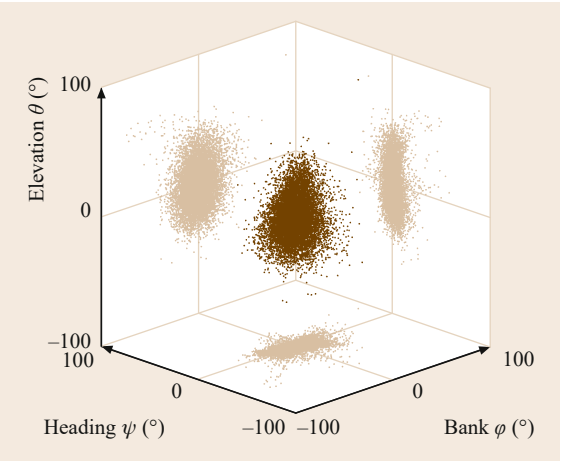

**Fig. 27.10** Float attitude angles, estimated from 9000 GPS data epochs from nine satellites tracked by two static baselines, each 2 m long

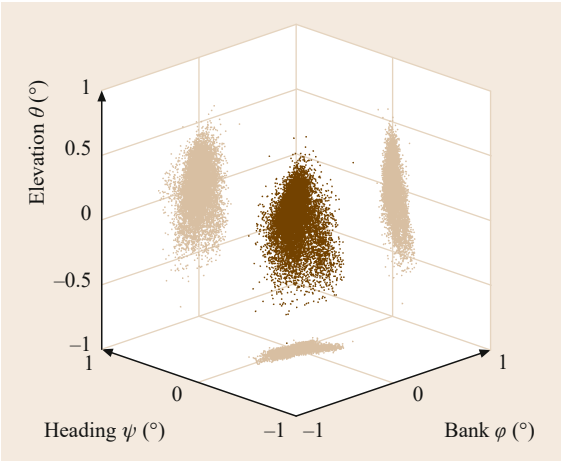

**Fig. 27.11** Attitude angles after successful ambiguity resolution, estimated from 9000 GPS data epochs from nine satellites simultaneously tracked by two static baselines, each 2 m long

defined as the ratio of samples in which the correct integer ambiguity matrix is found, as function of number of measurement channels ($n$) and observation noise.

The results from two single-epoch, single-frequency ($f = 1$) scenarios are given, for a single-baseline ($p = m = 1$) and a two-baseline ($p = m = 2$) antenna array, with local baseline coordinate matrices.

The improvement in terms of successful ambiguity resolution when applying the constrained ambiguity-attitude estimation procedures is rather large, particularly for the weaker scenarios, that is, with fewer measurements and higher observation noise. Increasing the number of baselines has a very important impact on the constrained success rate, with success rates equal or close to one on all the simulated scenarios. As expected, the inclusion of additional constraints largely strengthens the GNSS observation model, and substantially affects the ambiguity success rate, even for an array formed by a limited number of antennas (two or three in the examples reported).

$$\mathbf{F}_{p=1} = 1 \quad ; \quad \mathbf{F}_{p=2} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} . \tag{27.64}$$

Assuming the carrier-phase ambiguities as fixed to their correct integer values $\mathbf{Z}$, the conditional attitude solution is obtained as in (27.53). The precision of the conditional attitude estimation would then be described by a normal distribution with v-c matrix $\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}$. However, the statistics of the integer estimation must also be taken into account. The integer ambiguities distribute according to a probability mass function (PMF), obtained by integrating the normal distribution of the float estimation $\hat{\mathbf{Z}}$ over the pull-in regions associated to the ambiguity-attitude estimator. The result is a multimodal distribution of type [27.74]

$$f_{\check{\mathbf{R}}(\check{\mathbf{Z}})}(x) = \sum_{\mathbf{N}\in\mathbb{Z}^{n\times m}} f_{\hat{\mathbf{R}}(\mathbf{N})}(x) P(\check{\mathbf{Z}} = \mathbf{N}) \, , \tag{27.65}$$

where $f_{\hat{\mathbf{R}}(\mathbf{N})}(x)$ denotes the probability density function of the conditional attitude estimation and $P(\check{\mathbf{Z}} = \mathbf{N})$ denotes the PMF of the fixed ambiguities evaluated at $\mathbf{N}$. When the success rate $P_s = P(\check{\mathbf{Z}} = \mathbf{Z})$ is sufficiently close to the unit, the distribution of the conditional attitude solution is well approximated by the normal distribution with v-c matrix $\mathbf{Q}_{\hat{\mathbf{R}}(\mathbf{Z})\hat{\mathbf{R}}(\mathbf{Z})}$, which provides a first-order approximation of the dispersion of the attitude estimator $\check{\mathbf{R}}$. The precision of the attitude solution is driven by the precision of the carrier-phase observables [27.15] and by the geometry of the antenna array, for which the same considerations drawn for the attitude float solution apply: longer baselines should be employed to achieve smaller angle estimation errors, compatibly with structural and physical limitations imposed by the object or platform whose attitude has to be measured.

The large improvement in terms of angular estimation accuracy after successful ambiguity resolution is clear when comparing Fig. 27.10 with Fig. 27.11, in which the attitude angles before and after ambiguity resolution are shown for a two-baseline static array, where each baseline is 2 m long. The precision of each of the attitude angles improves by two orders of magnitudes when the carrier-phase ambiguities are successfully fixed to the correct integer values (Table 27.3).

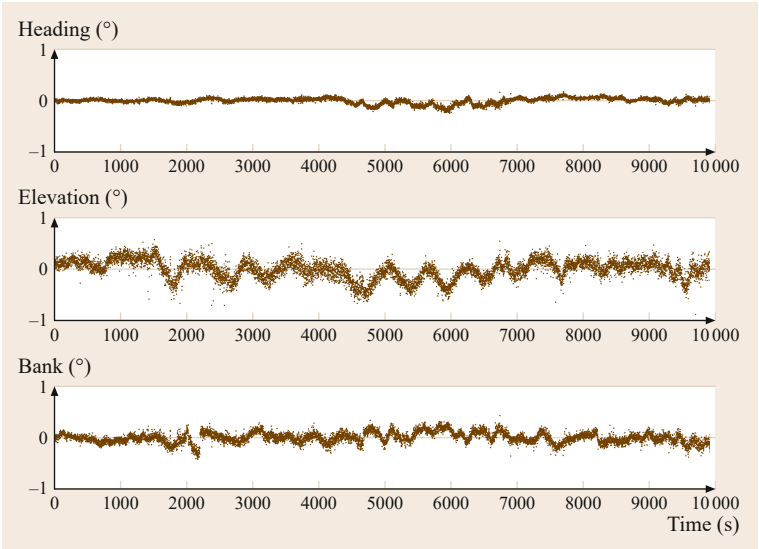

**Fig. 27.12** Time series of the three attitude angles after successful ambiguity resolution, 9000 GPS data epochs from nine satellites tracked by two static baselines, each 2 m long

**Table 27.3** Comparison between the precision of attitude estimation before and after successful ambiguity resolution. RMS: root mean square

| Component | Float | Fixed |
|---|---|---|
| Heading (°), RMS | 6.35 | 0.05 |
| Elevation (°), RMS | 16.01 | 0.19 |
| Bank (°), RMS | 12.51 | 0.10 |

The differences among the estimation errors for the three orientation angles highlight a common property of GNSS-based attitude sensors (Table 27.3). The two baselines of the static array used in the previous test lie on a locally horizontal plane. Both elevation and bank angles are then estimated with a lower precision than the heading angle, due to the poorer geometric dilution of precision that characterizes the vertical component of the observations. In general, one may expect better angular estimations for rotations about the direction of the line-of-sight vectors to the navigation satellites.

Figure 27.12 shows the heading, elevation and bankangles as output epoch-by-epoch by the three-antenna GNSS attitude sensor after the integer ambiguities are correctly resolved. The effect of multipath is clearly visible. This shows as a varying, time-correlated error in all three angular estimates, superimposed to the Gaussian-like estimation noise. The magnitude of the bias varies with time, with peaks reaching in the worst case half a degree, in agreement with a centimeter-level multipath error on the two-meter-long baselines. The error introduced by multipath is also differently amplified in each of the three angular estimates, with the heading output being the least affected.

## 27.5 Applications

### 27.5.1 Space Operations

The use of multiple GNSS antennas to keep track of the orientation in spacecraft and space structures was investigated at a very early stage of the satellite navigation era. Early in the 1990s, a Trimble Navigation TANS (acronym of Trimble Advanced Navigation Systems) Quadrex [27.39, 75], fittingly modified by Stanford University, was flown in the National Aeronautics and Space Administration (NASA) space mission RADCAL (Radar Calibration, 1993) [27.76]. The RADCAL mission first tested the performance of spacecraft attitude determination via the GPS, although only in post-processing, achieving 1° (root mean squared [RMS]) attitude precision with four half-meter baseline lengths. In 1994 the CRISTA-SPAS (Cryogenic Infrared Spectrometers and Telescopes for the Atmosphere – Shuttle Palette Satellite) mission [27.77], designed and developed by the University of Wuppertal to measure infrared emissions of the Earth's atmosphere, demonstrated the capabilities of real-time GPS-based attitude determination (Fig. 27.13). Shortly after, an updated version of Quadrex GPS receiver, the Trimble Quad Vector, was developed and used on board the NASA mission APEX (Advanced Photovoltaic and Electronic Experiments) [27.78], and on several shuttle flights [27.77].

In 1996 the REX-II (Radiation Experiment Satellite, second mission) satellite, equipped with an updated TANS receiver, achieved the first successful implementation of a real-time GPS-based attitude estimation for closed-loop control. In the REX-II spacecraft the combination of carrier-phase readings from four GPS antennas tracking at most six satellites were coupled to magnetic field measurements, fulfilling the mission requirements of 2° (RMS) angular accuracy. The performance of a standalone GPS attitude sensor was also evaluated at 5° (RMS). An issue related to the GPS attitude sensor was availability, with frequent dropouts caused by insufficient number of satellites, poor satellite geometry, and noisy signals [27.79].

GNSS-based attitude estimation has been implemented in a number of space missions, such as, for example, the GPS Attitude/Navigation Experiment (GANE), the GPS-based Meteorology (GPS/MET), the SSTL satellites UoSat-12 and the Tactical Operational Satellite (TopSat) [27.80, 81]. Notably, an array of GNSS antennas was also carried on the Gravity Probe-B Relativity Mission, whose data were used to support the post-processing necessary to validate two predictions of Einstein's theory of general relativity: the geodetic and frame-dragging effects [27.82].

A four-antenna attitude system is currently operational on board the International Space Station (ISS) (Fig. 27.14). The system provides attitude information that fulfills the requirements (set to 0.5° error, three sigma) only in combination with the onboard inertial navigation system (INS) [27.83]. The main issue of a GNSS array installed on large space structures is the potentially large multipath environment, created by both the craft structures and the solar panels. Satellite blockages may also occur, due to obstruction from the structure itself, from mobile appendixes (such as the robotic arm and deployed solar panels on the ISS), and eventually from docked vehicles.

Despite the lower precision, GNSS attitude systems on board spacecraft retain several advantages when compared to horizon sensors and star trackers, principally in terms of maintenance, cost and weight. These advantages make GNSS attitude systems a viable alternative to other sensors for small satellites flying in low Earth orbits (LEOs) when the accuracy requirements are not too stringent, as the precision of angular estimates is usually limited by the small size of the space platform.

The availability of attitude sensing depends on the actual spacecraft rotational motion: a GNSS attitude sensor on spinning satellites may experience frequent satellite losses and reacquisitions. This aspect could be mitigated by the large number of navigation satellites expected to be operational in the near future.

Space application of GNSS attitude sensors also include support of rendezvous [27.84] and reentry maneuvering. However, the latter application has been so far rejected in favor of a combination of inertial measurement units (IMUs) and star trackers. The limiting factor of a GNSS attitude system during the Earth reentry phases is satellite visibility: the typical flight envelope is characterized by several rotations of the platform, and adequate visibility cannot be guaranteed [27.85].

### 27.5.2 Aeronautics Applications

Starting from the 1990s, with the development of more powerful, smaller and less expensive receivers, GNSS antenna arrays as orientation sensors became widely used in aeronautics applications, either as standalone systems or, more often, integrated with IMUs.

GNSS attitude sensors are an effective navigation aid for the guidance of civil and military airborne vehicles in all the phases of flight: takeoff, en-route, formation flying, landing and taxiing [27.50, 86–89]. A multiple-GNSS antenna system is often integrated in the autonomous guidance control system of unmanned airborne vehicles (UAVs) [27.90], which take advantage of the low-cost, power-efficient and driftless properties of GNSS attitude sensors. In addition, GNSS attitude information is a valuable input for georeferencing, that is, the post processing of data acquired remotely from aircraft or other flying platforms [27.91, 92].

The use of a GNSS multiantenna system provides attitude information that remains unaffected by drift and magnetic variations. Also, the typical size of an aircraft, with fuselage and wingspan longer than a few meters, contributes to enhance the GNSS-based angular estimation precision. An example is shown in Fig. 27.15, which reports the heading angle provided epoch-by-epoch by a standalone three-antenna GNSS attitude system. The three antennas are located on the nose, on the left wing and on the central section of the fuselage of a Cessna Citation II, forming the following matrix of local baseline coordinates

$$\mathbf{F} = \begin{bmatrix} 4.90 & -0.39 \\ 0 & 7.60 \end{bmatrix} \text{[m]} \,. \tag{27.66}$$

The precise heading angle provided from an inertial reference system (IRS), a *Honeywell LaseRef*, is also shown in Fig. 27.15: the difference between the GNSS and IRS output amounts to 0.07° (RMS). The cumulative error between the GNSS-based attitude output and the IRS for the three attitude angles (heading, pitch and roll) is shown in Fig. 27.16. Of the three angles, the heading is the most accurate, whereas the pitch angle shows the noisiest behavior. The RMS of the IRS-to-GNSS output difference is 0.12° for the roll angle and 0.3° for the pitch angle. These values, related to the baseline lengths used, are typical for a GNSS attitude system operating on airborne structures. The accuracy of GNSS-based attitude estimates is limited by the combination of two main factors: multipath and structural flexibility.

Multipath usually has an important impact on the accuracy of the angular estimates in aeronautics applications due the siting of the GNSS antennas. These must be placed on the metallic surface of an aircraft without significantly altering its aerodynamic properties, thereby imposing limitations on the shape and size of the antennas employed. The primary effect of these limitations are measurements of somewhat lesser quality, with two consequences: potentially wrong ambiguity resolution and larger angular estimation errors and/or biases. These effects are clearly shown in Fig. 27.17, which reports the carrier-phase estimation residuals for a portion of the four-hour flight examined above: the residuals are noisy and for the most part biased. The culprit is a disturbed signal received at the nose antenna from a satellite at low elevation and azimuth opposite to the flight direction. Correctly identifying such degraded measurements is of primary impor-

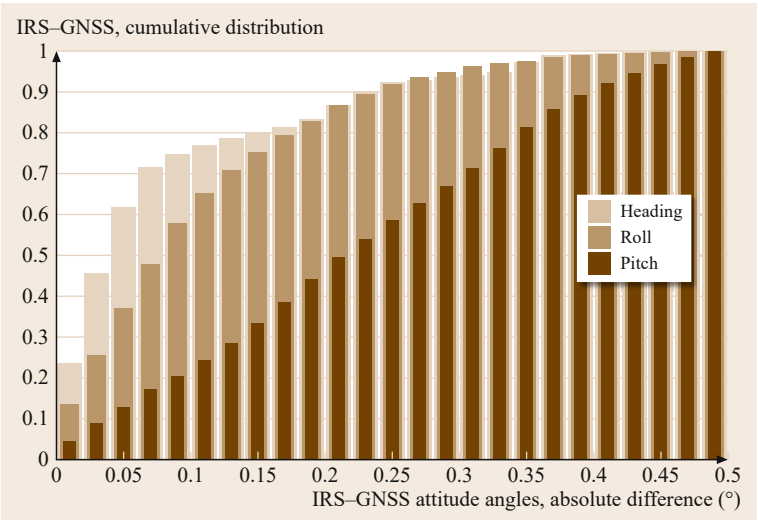

**Fig. 27.16** Cumulative distribution of the IRS-GNSS attitude angle output differences during a four-hour flight

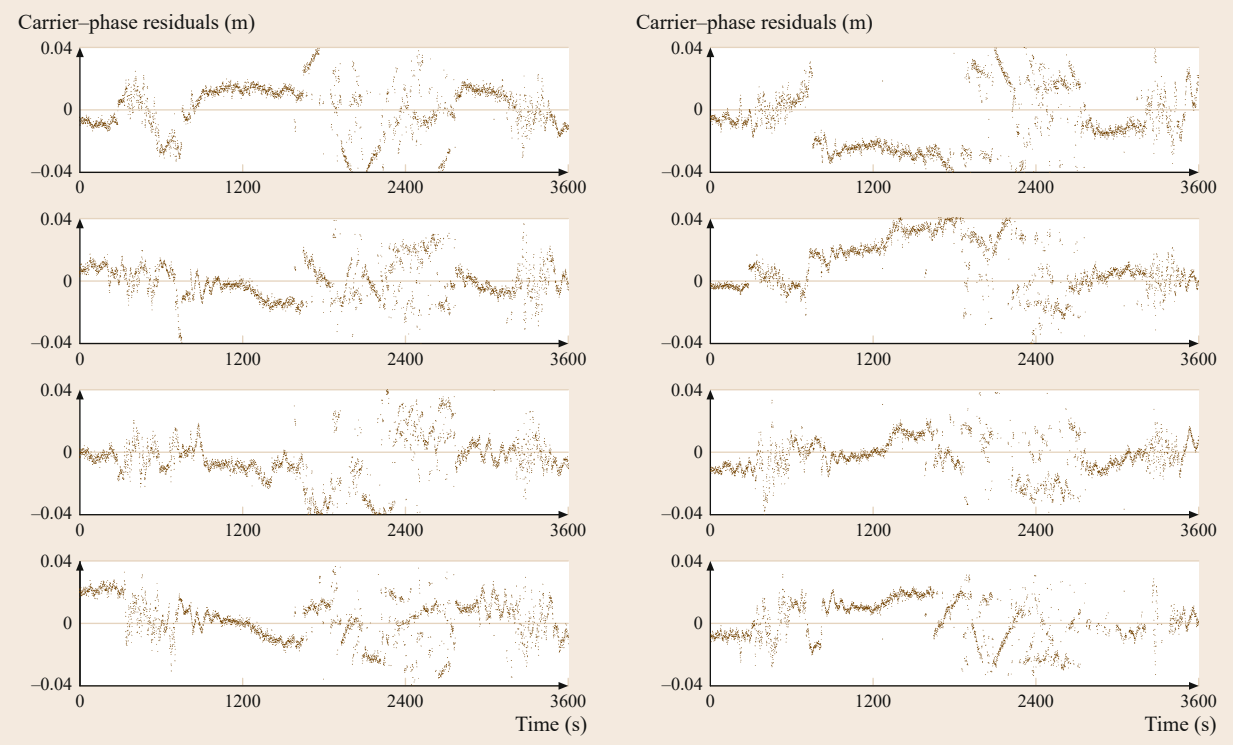

**Fig. 27.17** Carrier-phase estimation residuals prior to elimination of a disturbed signal, during a portion of a four-hour flight

tance to avoid estimation biases: Fig. 27.18 shows the carrier-phase residuals after eliminating the disturbed signal. After correction, the time characteristic of the residuals only shows a small remaining time-correlated error, superimposed to the expected millimeter-level carrier-phase measurement noise.

The second, potentially large error source in aeronautics applications is the platform flexibility. In order to fully exploit the size of an aircraft, one (or more) antennas should be mounted as close to the wingtip as possible. However, such placement would likely introduce errors caused by misalignment of the baseline

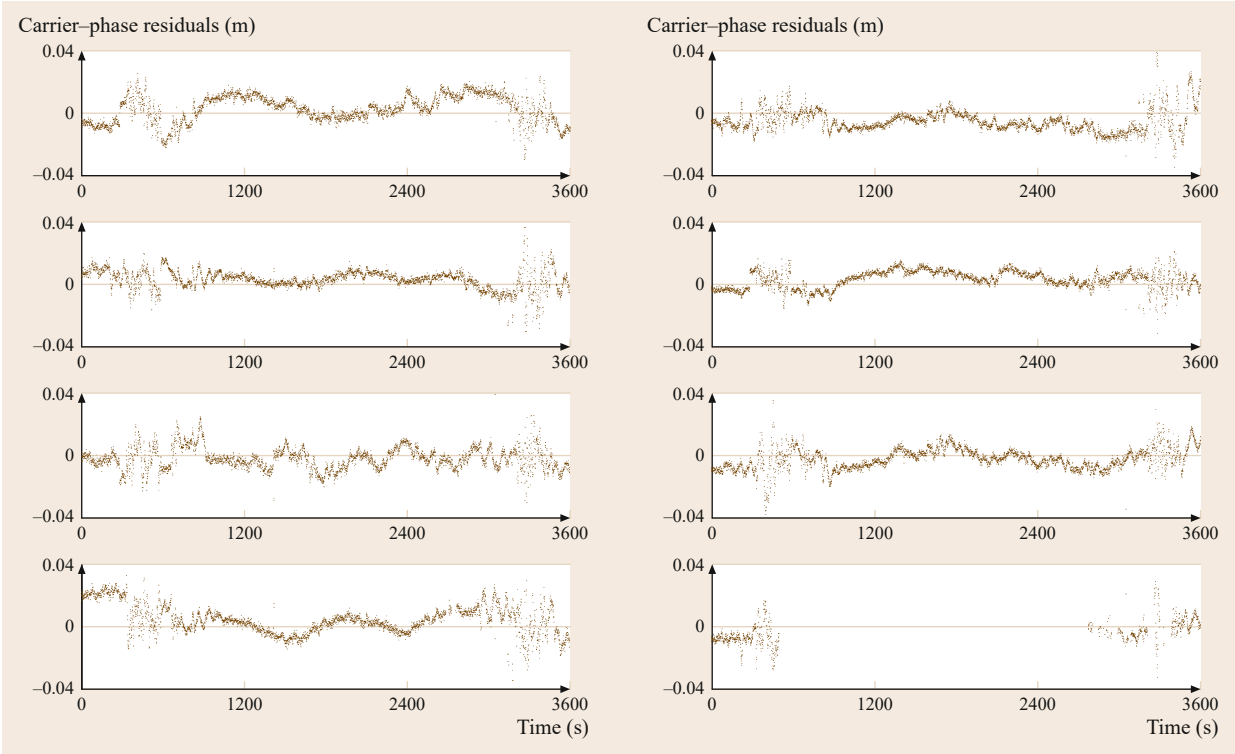

**Fig. 27.18** Carrier-phase estimation residuals after the elimination of a disturbed signal, during a portion of a four-hour flight

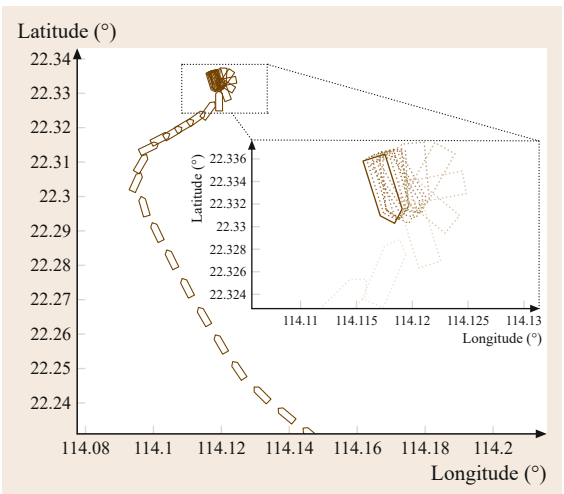

**Fig. 27.19** The heading of a large container ship being finely tracked by a GNSS attitude sensor during its final approach to the quay

coordinates in the local frame, due to deformations caused by maneuvering, turbulence, and fuel consumption, all of which alter the wing load. If these changes are not correctly modeled, estimation errors and biases may occur, degrading the GNSS attitude output.

### 27.5.3 Marine Navigation

Among all possible applications of GNSS as attitude sensor, marine navigation is arguably the one that may benefit the most from GNSS orientation guidance. Firstly, navigation on waterways usually offers a clear-sky, low-dynamic environment, in which all the signals can be received without excessive degradation. Secondly, antennas of any type can be installed on boats such to form baselines ranging from a few meters to several hundreds meters, reducing multipath from the boat's own structures and/or load through the use of antenna masts.

GNSS antenna arrays are currently used on ships of different classes to provide either heading estimation and full three-axis orientation, aiding the guidance during navigation in open waters [27.93–98], enhancing the ship attitude monitoring when navigating in shallow waters in order to control the underkeel clearance and perform grounding avoidance [27.47, 99], and during berthing maneuvers [27.100].

An example of the latter application is given in Fig. 27.19, where the heading of a large container ship is shown during its final approach to the quay at the Hong Kong harbor. The heading is extracted from a three-antenna array system with two antennas on the

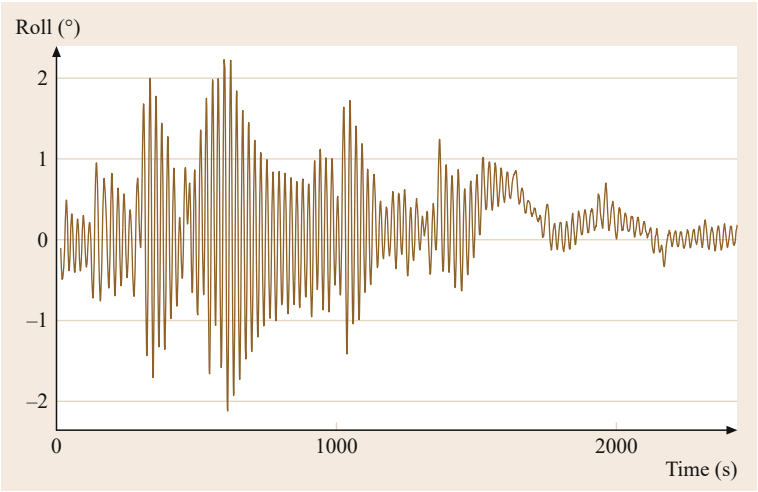

**Fig. 27.20** Tracking of a vessel's rolling during the transition from open water to the calmer harbor area

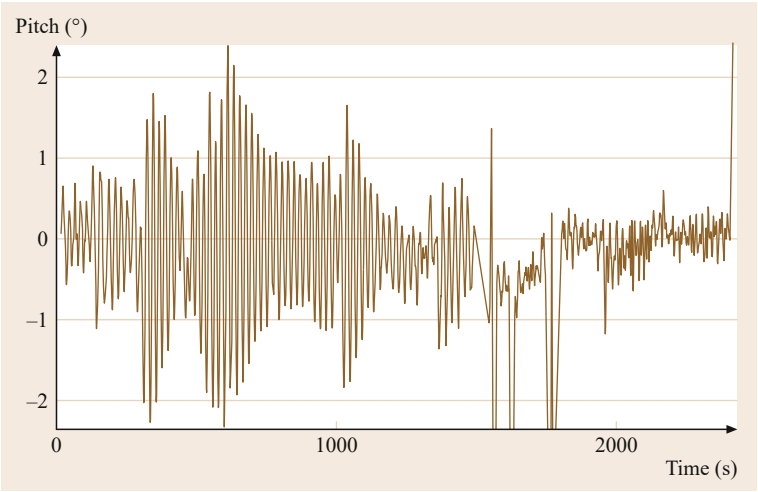

**Fig. 27.21** Tracking of a vessel's pitching during the transition from open water to the calmer harbor area

bridge – one at port and one at starboard side, distant 40 m – and one antenna at the bow, at 213 m from each of the antennas on the bridge. The very long baselines employed guarantee heading estimation precision in the region of $10^{-2}$–$10^{-3}$ degrees. Only slightly lower precision is achieved in the estimation of the roll and pitch angles. These are given in Figs. 27.20 and 27.21, which track the vessel attitude during its entrance in the harbor area. Both pitching and rolling reduce considerably during the transition, and both movements can be perfectly tracked by the GNSS attitude sensor.

Two error sources are most likely to have an impact on GNSS attitude systems on board vessels. The first is again multipath, which can be reduced by proper antenna siting and employing ad hoc antennas such as choke rings. The second, predominant on large vessels, is the boat structural deformation. This can be rather large on ships whose length exceeds more than a few tens of meters, and cannot be easily decoupled from actual rotations without an external aid or proper filtering. The effect of longitudinal deformations can be reduced by designing baseline lengths that maximize the accuracy without amplifying the estimation biases caused by mismodeling of the local body frame.

### 27.5.4 Land Applications

GNSS-based attitude determination is extensively used in the realm of land navigation. Multiantenna GNSS systems are being adopted in the automotive sector for the determination of heading, roll and pitch angles, to derive slip angle measurements, or to assist lorry drivers in maneuvering the truck and trailer [27.51, 101, 102]. Figure 27.22 shows a portable digital heading gage implemented on a tablet, which can be fed by low-cost GNSS antennas mounted on a vehicle rooftop.

**Fig. 27.22** Low-cost GNSS-based digital heading gage and tracking system developed for automotive applications, ANavS, Munich. Credit: ANavS

**Fig. 27.23** Example of an unmanned ground vehicle equipped with a two-antenna GNSS heading system

Although GNSS attitude systems are capable of meeting the accuracy required in most automotive applications, the availability and continuity of the attitude output still represents an issue, due to signal obstructions from tunnels or surrounding structures (e.g., urban canyons), thereby requiring integration with other navigation means.

GNSS antenna arrays in combination with inertial guidance are often a primary navigation instrument for unmanned ground vehicles (UGVs), ranging from large agricultural machinery (precision farming) [27.103] to small robotic platforms [27.104, 105], as in Fig. 27.23.

Further potential uses of GNSS attitude determination include heading systems for trains [27.106], support in the orientation control of large structures such as antennas or antenna arrays, and tracking of the mobile arm of cranes. Furthermore, GNSS antenna arrays are of common use in remote sensing campaigns, providing an attitude reference for georeferencing of sensed data [27.107–110].

## 27.6 An Overview of GNSS/INS Sensor Fusion for Attitude Determination

Because of the complementary advantages of each system, GNSSs and INSs are ideally suited for an integrated attitude solution, with the INS platform providing lower measurement noise, higher output rate and overall improved tracking robustness, and the GNSS supplying a stable reference solution for initialization and recalibrations.

INSs exploit self-contained inertial measurement units (IMUs) to sensethe variations in the body position and orientation. In an inertial system, the angular motion is sensed with gyroscopes. These can be based on mechanical principles, such in gimbaled gyros or gyrostats, which maintain angular momentum in the presence of rotational forces; on optical principles, such in fiber optic or laser gyros, based on the *Sagnac effect* [27.111] (rotation-induced perturbations on light beams interferometry); on quantum-mechanical phenomena, such as in London-moment gyroscopes [27.112]; and on electromechanic principles, such in MEMSs (Micro Electro-Mechanical Systems), which measure the Coriolis force generated from vibrating elements subject to rotations of the plane of vibration. The wide range of inertial orientation sensors differ in terms of cost, weight, structural complexity, and measurement sensitivity, but most are superior to GNSS-based attitude sensors in terms of (instantaneous) angular measurement precision and output rate. Also, INSs do not suffer from outages due to lack of external references caused by jamming or signal blocking. However, the common trait of most INSs is the derivation of the body orientation through integration of rotational accelerations, starting from a known initial state (dead reckoning). Thus, the INSs require an initialization step, followed by periodic recalibrations due to the lack of long-term stability.

Several GNSS/INS architectures can be realized, depending on the required navigation quality and robustness. The coupling of the two systems can be implemented at different levels of tightness [27.113, 114]:

- Loose integration, where the two systems are kept separated, providing two independent navigation

solutions that are subsequently filtered to output an enhanced common navigation solution. A feedback channel is usually designed to attenuate the INS drift.

- Tight integration, in which the coupling is implemented in the measurement domain, with GNSS pseudoranges, carrier-phase and/or Doppler observations linked to the INS output to enhance observability, reduce measurement noise and improve fault detectability [27.115].
- Ultratight integration, in which the coupling is realized already in the GNSS tracking loop, with improvements in GNSS tracking robustness, noise reduction, fault recovery and overall robustness with respect to the platform dynamics [27.116].

Any of the aforementioned architectures, exhaustively covered in Chap. 28, improves the quality of the integrated system with respect to the standalone solutions.

The fusion of GNSS and INS output is usually realized with linear or nonlinear filters, in which the measurement vector comprises the body angular displacement, velocity and/or acceleration. The rotational accelerations are sensed by the INS and integrated over time to extract attitude angles. These are complemented by the GNSS antenna array output, which provides the orientation angles of the reference system integral with the body with respect to the reference frame. The measurements are then processed by designing a proper fusion scheme for the nonlinear filter, where the body kinematics, the measurement error and the error propagation are modeled (Chap. 28). Four issues need to be addressed when realizing an integrated GNSS/INS solution: frame alignment, time synchronization and latency, GNSS integrity, and measurement fusion:

*Frame alignment*. An IMU senses the rotational accelerations and velocities around the inertial axes, that is, the axes (not necessarily orthogonal [27.117]) about which the gyro is capable of detecting rotations. The inertial axes do not necessarily coincide with the local body axes: linear (lever arm) and angular displacements between the two frames must be derived and compensated with an initial calibration (Chap. 28). Any misalignment would produce an erroneous interpretation of the INS angular output.

*Time synchronization and latency*. The IMU and the GNSS operate by sampling at different times, with a delay between measurements. This requires a synchronization scheme between the two systems. A coherent time reference can be achieved by exploiting the timing signal output by the GNSS receiver to time-reference the inertial measurements from the IMU [27.118]. Furthermore, the latency of processing the GNSS raw measurements yields delayed delivery of the GNSS output to the filter. This may hinder real-time applications with high-dynamic platforms [27.119], and a latency compensation step must be considered in the designed fusion algorithm.

*GNSS integrity*. Outliers from the GNSS subsystem need to be detected and isolated to prevent large error propagations in the filter (Chap. 24). The task of monitoring the GNSS integrity is somewhat less complex in the integrated GNSS/INS approach than in the standalone case, as the inertial solution aids error and bias detection by providing a prediction of the GNSS measurements to be compared with the actual output.

*Measurement fusion*. The INS and the GNSS operate in different domains. The former samples angular accelerations and/or velocities around its own inertial axes, whereas the latter estimates the orientation of the body frame with respect to the reference frame. The two types of measurements are coupled by relating the INS output with the chosen set of attitude parameters. Assuming the inertial platform axes to be aligned with the local body frame $\mathcal{F}$, the angular parameters output by the INS need to be converted into rate of change of Euler angles or of quaternion of rotation. Denoting with $\boldsymbol{\omega}_I = (\omega_{I,1}, \omega_{I,2}, \omega_{I,3})^\top$ the vector of angular velocities obtained with an inertial sensor aligned with the body frame, the rate of variation of the Euler angles is obtained as [27.120, 121]

$$\begin{pmatrix} \dot{\psi}_I \\ \dot{\theta}_I \\ \dot{\varphi}_I \end{pmatrix} = \mathbf{T}\boldsymbol{\omega}_I \,, \tag{27.67}$$

with $\mathbf{T}$ a $3\times 3$ transformation matrix associated to the Euler angle sequence chosen. The complete list of values assumed by the elements of $\mathbf{T}$ for each sequence can be found in [27.120].

The rates of change of the quaternion elements are computed from the inertial angular velocity measurements as [27.121]

$$\begin{pmatrix} \dot{q}_0 \\ \dot{\boldsymbol{q}} \end{pmatrix} = \frac{1}{2} \begin{bmatrix} 0 & \omega_{I,3} & -\omega_{I,2} & \omega_{I,1} \\ -\omega_{I,3} & 0 & \omega_{I,1} & \omega_{I,2} \\ \omega_{I,2} & -\omega_{I,1} & 0 & \omega_{I,3} \\ -\omega_{I,1} & -\omega_{I,2} & -\omega_{I,3} & 0 \end{bmatrix} \begin{pmatrix} q_0 \\ \boldsymbol{q} \end{pmatrix} . \tag{27.68}$$

Relations (27.67)–(27.68) enable a coherent fusion between the angular measurements of INS and GNSS, aligned so as to refer to the same body reference system.

# 28. GNSS/INS Integration

Jay A. Farrell, Jan Wendel

This chapter discusses the role of global navigation satellite systems (GNSSs) and inertial measurements in the estimation of the state vector for a maneuvering system. The chapter considers the main objectives of accuracy, continuity, availability, and integrity; and, the contributions that the different types of sensors make toward achieving these objectives. The chapter includes an example design. Then, the chapter reviews the concepts of loose, tight, and ultratight or deeply coupled systems. Throughout, the advantages, disadvantages, and tradeoffs between alternative approaches are discussed.

Although global navigation satellite systems (GNSSs) are often referred to as positioning systems, when used in combination with inertial sensors, they have a much greater utility in helping to maintain the accuracy of the system state, which includes position, velocity, acceleration, attitude, and angular rate [28.1, Sect. 2.4]. These quantities are necessary in applications that involve safety augmentation, control, or trajectory or mission planning. In addition, a navigation system that maintains the system state can have improved performance, perhaps coasting through short durations while GNSS signals are not available. These concepts are discussed in greater detail in the following subsections.

## 28.1 State Estimation Objectives

For commercial applications, cost is a critical design metric. The fact that the cost of computation and sensors has been rapidly declining over the last few decades has given rise to a large and growing interest in aided inertial navigation systems for commercial applications. In previous decades, such systems were only cost effective for military and life-critical commercial vehicles. Now they are becoming commercially available in hand-held devices.

While navigation system accuracy metrics (e.g., horizontal position error less than 2.0 m with 95% probability) are widely understood, other navigation system metrics such as integrity, continuity, and availability require a little more explanation [28.2]. These terms are also introduced in Sect. 12.1.1:

- *Integrity* relates to the extent to which the information supplied by the navigation system can be trusted or to the ability of the navigation system to detect and to provide timely warning to the user about when the specified accuracy should not be trusted.
- *Continuity* relates to the probability that a specified level of accuracy will be maintained throughout a given operation or experiment, assuming that the specification is met at initialization.
- *Availability* relates to the percentage of time that a specified level of accuracy, integrity, and continuity is available and useable within a specified area.

The navigation system design tradeoffs to address the above metrics are diverse; however, the following are somewhat fundamental. Addition of sensors typically enhances accuracy, integrity, and availability, but at an increasing cost and additional risk of sensor failure.

Integrity is enhanced via redundant signals that enable detection and possible removal of anomalous events that might otherwise affect the navigation system accuracy in an undetected manner. Signal redundancy can be achieved directly. Examples include using signals from more than four Global Positioning System (GPS) satellites in a position solution or using signals from more than one GNSS [28.3, 4]. Signal redundancy can also be analytic or indirect [28.5, 6]. This chapter focus on the indirect form of redundancy that is achieved by combining GNSS with specific force and angular rate measurements provided by an inertial measurement unit (IMU). The IMU measurements are mathematically manipulated to maintain high-bandwidth, high-rate estimates of the IMU position, velocity, acceleration, attitude, and angular rate. These estimates allow the GNSS measurements to be predicted. The fact that the GNSS predicted and actual measurements can be compared shows that the IMU and GNSS systems are analytically or indirectly redundant.

The utility of redundant measurements is enhanced when the factors that affect measurement availability are distinct for the different measurements. Reception of GNSS signals can be affected by radio frequency interference, terrain, foilage, and man-made structures. When a sufficient number of GNSS satellite signals are unavailable, then no GNSS position solution can be computed. The IMU measurements are not affected by terrain, foliage, external electromagnetic signals, or man-made structures. The fact that the IMU measurements are immune to the factors that disrupt GNSS signals allows the combined system to *coast through* periods of GNSS outages, enhancing continuity and availability.

All sensors are affected by measurement noise and (possibly time-varying) calibration errors. The inertial navigation system (INS) that computes the estimated vehicle state from the IMU measurements is an integrative process. The integration of measurement noise and calibration errors causes the INS estimate of the vehicle state $\hat{\boldsymbol{x}}(t)$ to diverge from the true vehicle state $\boldsymbol{x}(t)$ as time passes. This divergence can be accurately modeled as a function of time. High-end INSs are designed to meet a specified accuracy for a stated duration of time (months). Commercial microelectromechanical system (MEMS)-based INS typically require aiding by external sensors at much higher rates (seconds to minutes); otherwise, the error would eventually become too large to be useful. In a well-designed system, aiding will both correct the estimated state and improve the system calibration such that the rate of divergence will be slower in the future. The GNSS/IMU integrated navigation system accuracy as a function of the sensor characteristics and duration of outage can be accurately characterized.

To design an aided INS system well, the analyst must understand the INS kinematic model, the GNSS and IMU sensor models, the tradeoffs between the various integration approaches, methods for estimating the state and sensor calibration errors, factors affecting the observability of those errors, methods for detecting invalid measurements, and methods for analyzing system performance. The purpose of this chapter is to highlight various factors that are of critical importance and to motivate further investigation using any of the various books that discuss these topics in greater detail [28.7–12].

## 28.2 Inertial Navigation

This section introduces key concepts related to inertial navigation. The discussion has been organized to separate models and theory (i. e., Sects. 28.2.1, 28.2.2, and 28.2.4) from items that are available on and computed by the navigation computer (i. e., Sects. 28.2.3 and 28.2.5).

### 28.2.1 Problem Statement

The vehicle carrying the INS will be referred to as the *rover*. The rover navigation state vector is $\boldsymbol{x} = [\boldsymbol{p}^\top, \boldsymbol{v}^\top, \boldsymbol{q}^\top]^\top \in \mathbb{R}^n$, where $\boldsymbol{p}$ is the position, $\boldsymbol{v}$ is the velocity, and $\boldsymbol{q}$ is a representation of the attitude of the rover with respect to the navigation frame of reference [28.13]. Attitude parameterization is discussed further in Sect. 28.4.2. The inertial acceleration and angular rate vector is $\boldsymbol{u} = [\boldsymbol{a}^\top, \boldsymbol{\omega}^\top]^\top \in \mathbb{R}^6$. The kinematic equation for the rover navigation state vector is

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u}) \,, \tag{28.1}$$

where the vector $\boldsymbol{f} : \mathbb{R}^n \times \mathbb{R}^6 \to \mathbb{R}^n$ is accurately known (Sect. 28.4 or [28.8, Chap. 11]). Note that both $\boldsymbol{x}$ and $\boldsymbol{u}$ are unknown.

The navigation system assumes the availability of IMU measurements $\tilde{\boldsymbol{u}}_k = \tilde{\boldsymbol{u}}(\tau_k)$ where $\tau_k = k\tau$ for $k = 0, 1, 2, \ldots$, aiding measurements $\tilde{\boldsymbol{y}}(t_j)$ where $t_j = jT$ with $\tau \ll T$, and an initial distribution for the state $\boldsymbol{x}(0) \sim \mathrm{N}(\boldsymbol{x}_0, \mathbf{P}_{\boldsymbol{x}_0})$. The notation $\boldsymbol{x}(0) \sim \mathrm{N}(\boldsymbol{x}_0, \mathbf{P}_{\boldsymbol{x}_0})$ means that $\boldsymbol{x}(0)$ is normally distributed with mean $\boldsymbol{x}_0$, and covariance matrix $\mathbf{P}_{\boldsymbol{x}_0}$. This notation will be used throughout this chapter.

The navigation system design problem is to use the IMU and aiding sensor information, the initial condition distribution, and (28.1) to compute an estimate $\hat{\boldsymbol{x}}(t)$ for all $t = k\tau$ for $k = 0, 1, 2, \ldots$. The ideal design would be optimal within the constraints imposed by the system cost.

### 28.2.2 Sensor Models

The IMU measurements $\tilde{\boldsymbol{u}}$ are related to the inertial quantities in $\boldsymbol{u}$ through a set of calibration factors denoted by $\boldsymbol{c}_\mathrm{u}(t) \in \mathbb{R}^{n_\mathrm{u}}$ which could, for example, account for the scale factor (SF), alignment, or bias errors. An example of a simple IMU measurement model is

$$\tilde{\boldsymbol{u}}(t) = \boldsymbol{u}(t) + \boldsymbol{c}_\mathrm{u}(t) + \boldsymbol{\nu}_\mathrm{u}(t) \,, \tag{28.2}$$

$$\dot{\boldsymbol{c}}_\mathrm{u}(t) = -\lambda_\mathrm{u}\boldsymbol{c}_\mathrm{u}(t) + \boldsymbol{\nu}_{\boldsymbol{c}_\mathrm{u}}(t) \,. \tag{28.3}$$

The IMU provides only the measurement $\tilde{\boldsymbol{u}}(t)$. The quantities $\boldsymbol{c}_\mathrm{u}$, $\lambda_\mathrm{u} > 0$, $\boldsymbol{\nu}_\mathrm{u}(t)$, and $\boldsymbol{\nu}_{\boldsymbol{c}_\mathrm{u}}(t)$ are all unknown. Typical assumptions are that $\boldsymbol{\nu}_\mathrm{u}(t)$ and $\boldsymbol{\nu}_{\boldsymbol{c}_\mathrm{u}}(t)$ are both white Gaussian noise processes with power spectral density (PSD) [28.14–16] matrices denoted by $\mathbf{Q}_1$ and $\mathbf{Q}_2$, respectively. The IMU manufacturer typically provides *Allan* variance [28.17] information to the designer, which is useful for specifying parameters such as $\lambda_\mathrm{u}$, $\mathbf{Q}_1$, and $\mathbf{Q}_2$ to quantify the IMU state space error model.

Each vector of simultaneous aiding measurements is modeled as

$$\tilde{\boldsymbol{y}}(t_j) = \boldsymbol{h}(\boldsymbol{x}(t_j), \boldsymbol{c}_\mathrm{y}(t_j)) + \boldsymbol{\eta}_\mathrm{y}(t_j) \,, \tag{28.4}$$

$$\dot{\boldsymbol{c}}_\mathrm{y}(t) = -\lambda_\mathrm{y}\boldsymbol{c}_\mathrm{y}(t) + \boldsymbol{\nu}_{\boldsymbol{c}_\mathrm{y}}(t) \,, \tag{28.5}$$

where $\boldsymbol{c}_\mathrm{y}(t) \in \mathbb{R}^{n_\mathrm{y}}$ is a vector of sensor calibration variables. The aiding sensor provides only the measurement $\tilde{\boldsymbol{y}}(t)$. The quantities $\boldsymbol{c}_\mathrm{y}(t)$, $\lambda_\mathrm{y} > 0$, $\boldsymbol{\eta}_\mathrm{y}(t)$, and $\boldsymbol{\nu}_{\boldsymbol{c}_\mathrm{y}}(t)$ are all unknown. The noise process $\boldsymbol{\eta}_\mathrm{y}(t) \sim \mathrm{N}(\mathbf{0}, \mathbf{R}(t))$ is assumed to be white with covariance matrix $\mathbf{R}(t)$. The noise process $\boldsymbol{\nu}_{\boldsymbol{c}_\mathrm{y}}(t)$ is assumed to be white and Gaussian with the PSD matrix denoted by $\mathbf{Q}_3$. In the context of GNSS, $\boldsymbol{c}_\mathrm{y}$ could be used to account for the time correlated multipath errors, for example.

Stochastic processes and modeling are important. Topics such as white noise, Markov processes, and Allan variance are discussed in [28.14, 15].

### 28.2.3 INS Computations

Given the initial condition for the estimated rover state vector $\hat{\boldsymbol{x}}(0) = \boldsymbol{x}_0$ and the IMU measurements $\tilde{\boldsymbol{u}}$, the INS computes an estimate of the rover state by solving

$$\dot{\hat{\boldsymbol{x}}}(t) = \boldsymbol{f}(\hat{\boldsymbol{x}}(t), \hat{\boldsymbol{u}}(t)) \tag{28.6}$$

via numeric integration in real time. The INS only has IMU and aiding measurements at discrete time instants; therefore, the INS numerically solves

$$\begin{aligned}\hat{\boldsymbol{x}}(\tau_{k+1}) &= \boldsymbol{\phi}\left(\hat{\boldsymbol{x}}(\tau_k), \hat{\boldsymbol{u}}(\tau_k)\right) \\ &= \hat{\boldsymbol{x}}(\tau_k) + \int_{\tau_k}^{\tau_{k+1}} \boldsymbol{f}(\hat{\boldsymbol{x}}(\tau), \hat{\boldsymbol{u}}(\tau))\mathrm{d}\tau \,.\end{aligned} \tag{28.7}$$

The result of the numeric integration of (28.7) is the INS state estimate $\hat{\boldsymbol{x}}(\tau_{k+1})$ given $\hat{\boldsymbol{x}}(\tau_k)$ and $\hat{\boldsymbol{u}}(\tau_k)$.

The quantity $\hat{\boldsymbol{u}}(t)$ is computed from $\tilde{\boldsymbol{u}}(t)$ using the best available estimates $\hat{\boldsymbol{c}}_\mathrm{u}(t)$ of the IMU calibration factors. For example, given the IMU model of (28.2), $\hat{\boldsymbol{u}}(t) = \tilde{\boldsymbol{u}}(t) - \hat{\boldsymbol{c}}_\mathrm{u}(t)$.

A variety of INS mechanization design factors influence the system performance, such as choice of reference frames, IMU model, numeric integration method, and coning and sculling computations [28.18].

Note that as long as the IMU continues to provide measurements, the INS will continue to use those measurements to provide state estimates. The ability of the INS to compute the state estimate is independent of external magnetic fields, terrain, and so on. This enhances continuity, integrity, and availability with respect to GNSS only solutions. It must be noted, however, that the accuracy of the unaided INS solution will deteriorate as the time from the last aiding signal increases.

Also, note that the bandwidth of the INS state estimation system is determined by the bandwidth of the IMU, which can be in the 0.1–1.0 kHz range. This is critical when the state estimates are inputs to a control system.

The numeric integration repeats using the sequence of IMU measurements to propagate the state measurements between the times of aiding measurements. Given the INS state vector $\hat{\boldsymbol{x}}$, the estimated sensor calibration parameter vector $\hat{\boldsymbol{c}}_{\mathrm{y}}$, and the model of the aiding measurements in (28.4), the predicted value of the aiding measurements is

$$\hat{\boldsymbol{y}}(t_j) = \boldsymbol{h}\left(\hat{\boldsymbol{x}}(t_j), \hat{\boldsymbol{c}}_{\mathrm{y}}(t_j)\right) . \tag{28.8}$$

The aiding measurement times can be unequally spaced in time without causing any complications. Missing measurements are also easy to accommodate.

Let

$$\hat{\boldsymbol{z}} = \left[\hat{\boldsymbol{x}}^{\top}, \hat{\boldsymbol{c}}_{\mathrm{u}}^{\top}, \hat{\boldsymbol{c}}_{\mathrm{y}}^{\top}\right]^{\top} \in \mathbb{R}^{n+n_{\mathrm{y}}+n_{\mathrm{u}}} .$$

The vector $\hat{\boldsymbol{z}}$ contains all the quantities required by the INS to compute (28.7) and (28.8). The on-line navigation algorithms are designed to compute $\hat{\boldsymbol{z}}(t)$ as an estimate of $\boldsymbol{z}(t) = [\boldsymbol{x}^{\top}, \boldsymbol{c}_{\mathrm{u}}^{\top}, \boldsymbol{c}_{\mathrm{y}}^{\top}]^{\top}$. Although $\hat{\boldsymbol{x}}$ is the only quantity required for the navigation solution, estimation of $\hat{\boldsymbol{c}}_{\mathrm{u}}$ enhances the accuracy of the time propagation step of (28.7), and estimation of $\hat{\boldsymbol{c}}_{\mathrm{y}}$ enhances the accuracy of the aiding measurement correction step to be discussed in Sect. 28.7.

### 28.2.4 INS Error State

Due to initial condition errors, calibration errors, and measurement noise, a state estimation error

$$\delta\boldsymbol{z}(t) = \boldsymbol{z}(t) - \hat{\boldsymbol{z}}(t) \tag{28.9}$$

develops over time. The state error vector evolves in time according to the standard (linearized) discrete-time model

$$\delta\boldsymbol{z}(t_{j+1}) = \boldsymbol{\Phi}_j \delta\boldsymbol{z}(t_j) + \boldsymbol{\nu}_{\mathrm{d}_j} , \tag{28.10}$$

where $\boldsymbol{\nu}_{\mathrm{d}_j}$ is the discrete-time noise resulting from the accumulation of the random process vector

$$\boldsymbol{\nu}^{\top}(t) = \left[\boldsymbol{\nu}_{\mathrm{u}}^{\top}(t), \boldsymbol{\nu}_{c_{\mathrm{u}}}^{\top}(t), \boldsymbol{\nu}_{c_{\mathrm{y}}}^{\top}(t)\right]$$

by the system over the time interval $t \in [t_j, t_{j+1}]$. The error state transition matrix $\boldsymbol{\Phi}_j$, the process noise $\boldsymbol{\nu}_{\mathrm{d}_j} \sim N(\boldsymbol{0}, \mathbf{Q}_j)$, and the stochastic properties of this state estimation error are well understood [28.7–9, 11, 12]. The on-line computations provide both $\mathbf{Q}_j$ and $\boldsymbol{\Phi}_j$ [28.8, Sect. 7.2.5.2].

Note that the estimation problem has three quantities changing as functions of time: $\boldsymbol{z}(t)$ is unknown, $\hat{\boldsymbol{z}}(t)$ is available on the navigation computer, and $\delta\boldsymbol{z}(t)$ is unknown. Of these three quantities, only two of the vectors are linearly independent. Given any two of the vectors, the third vector can be computed by manipulation of (28.9).

As previously discussed, the INS is an integrative process. Integration decreases the effects of high-frequency sensor errors (e.g., high-frequency content in $\boldsymbol{\nu}_{c_{\mathrm{u}}}$ and $\boldsymbol{\nu}_{\mathrm{u}}$), but amplifies the effects of low frequency sensor errors (e.g., $\boldsymbol{c}_{\mathrm{u}}$). To gain market share, IMU manufacturers have incentives to remove all deterministic error effects and to decrease $\lambda_{\mathrm{u}}$, $\boldsymbol{c}_{\mathrm{u}}$, $\mathbf{Q}_1$, and $\mathbf{Q}_2$. Therefore, $\delta\boldsymbol{z}(t)$ is a slowly varying random process that will be estimated in real time.

### 28.2.5 Performance Characterization

Given the error covariance $\mathbf{P}_{z_j} = \mathrm{cov}(\delta\boldsymbol{z}(t_j))$ valid at time $t_j$, using (28.10) the error covariance at time $t_{j+1}$ can be predicted as

$$\mathbf{P}_{z_{j+1}} = \boldsymbol{\Phi}_j \mathbf{P}_{z_j} \boldsymbol{\Phi}_j^{\top} + \mathbf{Q}_j . \tag{28.11}$$

This equation models the time propagation of INS errors. The effect of measurement corrections will be discussed in Sect. 28.7. Equation (28.11) can be iterated as necessary to compute $\mathbf{P}_{z_i}$ for $t_i > t_j$. Without aiding, the diagonal of $\mathbf{P}_{z_i}$ typically increases with time. The fact that $\mathbf{P}_{z_i}$ is available in real time facilitates integrity analysis, as the system can predict the time duration until specified accuracy limits are expected to be violated.

Such performance predictions are dependent on past motion and assumptions regarding future motion. Given the same satellite configuration, different prior motion patterns will affect the system observability, and hence, determine the current value of $\mathbf{P}_{z_j}$. Assumptions about the future motion determine the extent to which each portion of $\mathbf{P}_{z_j}$ affects $\mathbf{P}_{z_i}$ for $t_i > t_j$. These topics relate to the subject of *observability* [28.19–22].

Note that in the GNSS-aided INS applications, the portions of $\boldsymbol{\Phi}_j$ and $\mathbf{Q}_j$ attributable to the IMU and INS are not *tuning parameters*. They are physical quantities defined by the kinematics of the system and the IMU characteristics.

## 28.3 Inertial Sensors

The purpose of this section is to introduce the different categories of inertial sensors, to discuss their error characteristics, and to give specific examples of the inertial sensor calibration quantities $\boldsymbol{c}_{\mathrm{u}}(t)$ as defined in Sect. 28.2.2.

A general nomenclature (e.g., $\boldsymbol{a}_{\mathrm{ib}}^{\mathrm{b}}$) is required to unambiguously identify quantities like accelerations, velocities, angular rates, and so on. In this nomenclature, the upper index indicates the reference frame in which the respective quantity is represented. The second lower index defines which coordinate frame moves with respect to the coordinate frame specified by the first lower index. Therefore, $\boldsymbol{a}_{\mathrm{ib}}^{\mathrm{b}}$ is the acceleration of the body frame with respect to the inertial frame represented in body frame coordinates. The common reference frames are defined in Sect. 28.4.1.

### 28.3.1 Gyroscopes

A gyroscope provides measurements of its (inertial) angular rate vector defined relative to its sensitive axis, that is, $\boldsymbol{\omega}_{\mathrm{ib}}^{\mathrm{b}}$. Alternatively, the integral of the angular rate over the sampling time interval can be provided, which is referred to as an angle increment. Different types of gyroscopes suitable for strapdown INS implementations can be distinguished [28.10, 23–25].

#### Vibrating Structure Gyroscopes

*Vibrating structure gyroscopes* (VSGs) measure the angular rate by observing the Coriolis acceleration that occurs when the sensor rotates. An example of a possible realization is a proof mass that is forced to perform a linear oscillatory motion in one direction, namely the drive direction. The sense direction is perpendicular to the drive direction. The sensitive axis is perpendicular to both the sense and the drive directions. When a rotation occurs around the sensitive axis, the Coriolis acceleration causes the proof mass to follow an ellipsoidal trajectory in the plane perpendicular to the sensitive axis. The amplitude of this motion in the sense direction is proportional to the angular rate and is measured capacitively. Various alternative realizations of this principle exist that use a string, a beam, a tuning fork, or other structures as a vibrating element. At present, this type of gyroscope is usually a low-cost device with poor accuracy, mostly implemented using MEMS technology. MEMS technology combines integrated circuit technology with small mechanical structures, typically on a single chip. These mechanical structures, for example, a proof mass, are generated using different techniques such as surface micromachining, etching, and photolithographic processes. An example for a MEMS gyroscope manufactured in dry etching technology is shown in Fig. 28.1.

#### Fiber Optic Gyroscopes

*Fiber optic gyroscopes* (FOGs) take advantage of the Sagnac effect, which is based on the fact that the speed of light is independent of the speed of the light source. Laser light is sent clockwise and counter-clockwise through a fiber optic coil. When the structure rotates while the light is traveling through the coil, the optical path length for one of the beams is increased, whereas it is reduced for the other beam. The resulting phase shift between the beams is proportional to the angular rate and is measured interferometrically. Usually, FOGs offer better accuracy than MEMS gyroscopes.

#### Ring Laser Gyroscopes

*Ring laser gyroscopes* (RLGs) are also based on the Sagnac effect; the closed optical path is realized using appropriately placed mirrors. A clockwise and a counter-clockwise laser beam establish standing waves within the structure. If the optical path lengths change due to rotation, the wavelength of one beam increases whereas the wavelength of the other one decreases to maintain the standing waves. This causes a shift in the laser frequencies. One of the mirrors is semi-transparent, which allows the frequency difference of the laser beams to be measured by interfering them outside of the cavity. In case no rotation is present, the interference pattern is stationary, otherwise the interference pattern moves, which is detected using photo diodes. Ring laser gyroscopes offer the best performance of the gyroscopes discussed so far.

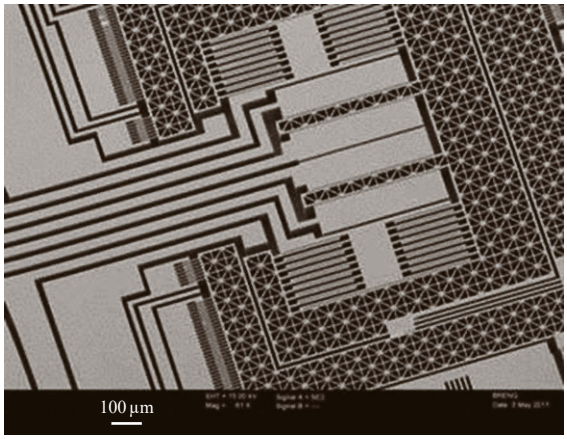

**Fig. 28.1** MEMS gyroscope manufactured in dry etching technology (courtesy of Northrop Grumman LITEF GmbH)

Only a simplified view on the most common gyroscopes is provided, other types like the spinning mass gyroscope, or the nuclear magnetic resonance gyroscope, are beyond the scope of this discussion.

### 28.3.2 Accelerometers

Most practically relevant accelerometers measure the specific force using a proof mass connected to the accelerometer case by a spring. In free space, away from any large masses exerting gravitational effects, for a nonaccelerating accelerometer, the equilibrium position of the proof mass relative to the case would be interpreted as zero acceleration. When the case undergoes an external force, the acceleration is transmitted to the proof mass through the spring deflection. This deflection is measured and scaled to units of acceleration. Near the Earth (or any other large mass), an accelerometer that is not accelerating will have its proof mass deflected from its equilibrium position by the effects of gravity, measuring one $g$. Conversely, an accelerometer that is in free fall accelerating at one $g$ has its proof mass in its equilibrium position relative to the case, and measures zero acceleration. Both scenarios are illustrated in Fig. 28.2.

Accelerometers measure the specific force vector, $\boldsymbol{f}_{\mathrm{ib}}^{\mathrm{b}}$, which is the difference between the acceleration of an accelerometer triad with respect to an inertial frame, $\boldsymbol{a}_{\mathrm{ib}}^{\mathrm{b}}$, and the local gravity vector, $\boldsymbol{g}^{\mathrm{b}}$. This can be expressed as

$$\boldsymbol{f}_{\mathrm{ib}}^{\mathrm{b}} = \boldsymbol{a}_{\mathrm{ib}}^{\mathrm{b}} - \boldsymbol{g}^{\mathrm{b}} \,. \tag{28.12}$$

Therefore, acceleration is computed from the measured specific force vector by compensating for the effects of gravity.

Two types of accelerometers [28.10, 23–25], the pendulous accelerometer and the vibrating beam accelerometer, provide suitable examples.

#### Pendulous Accelerometer

*Pendulous accelerometers* are often manufactured from micromachined silicon by etching. Silicon is removed from the wafer so that a mass–spring system results. The deflection of the proof mass from equilibrium can be measured capacitively. In open-loop operation, the specific force is calculated from measured deflection of the proof mass. The accuracy of this mode of operation is limited, as the nonlinearity of the small silicon bridge acting as a spring is not known perfectly. In closed-loop operation, a force feedback is used to reset any deflection of the proof mass from equilibrium, often electrostatically. Hereby, the current required to maintain the proof mass in the equilibrium position is a measure of the specific force acting on the proof mass. As an example, the proof mass of a silicon MEMS accelerometer manufactured in wet etching technology is shown in Fig. 28.3.

#### Vibrating-Beam Accelerometer

*Vibrating-beam accelerometers* (VBAs) use beams of quartz or silicon that constrain the motion of the proof mass in the direction of the sensitive axis. The specific force acting in this direction compresses one beam and stretches the other. Hereby, the resonant frequencies of the beams change, the resulting frequency difference can be measured with high accuracy, allowing assessment of the specific force acting in the direction of the sensitive axis.

### 28.3.3 Inertial Sensor Errors

The measurement of the angular rate and specific force vectors using inertial sensors is always prone to imperfections, referred to as sensor errors. A portion of the effect of these errors is removed by factory calibration. When integrated with GNSS, the remaining systematic errors can be estimated by the data fusion algorithm and compensated. However, some imperfections always remain that cause the navigation solution of the INS to deteriorate with time, so that persistent aiding of the INS is mandatory.

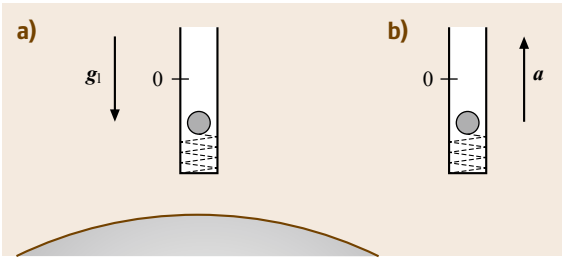

**Fig. 28.2a,b** Two indistinguishable scenarios. **(a)** Accelerometer at rest in the Earth's gravity field. **(b)** Accelerometer accelerated in upward direction, no gravity

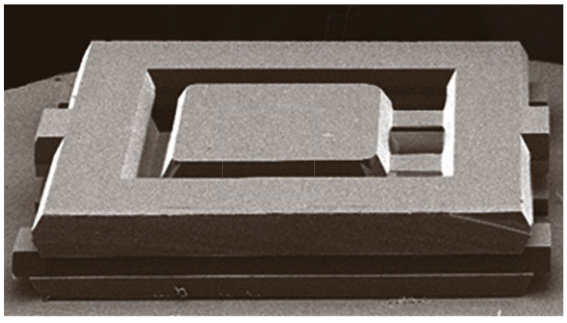

**Fig. 28.3** MEMS accelerometer manufactured in wet etching technology (courtesy of Northrop Grumman LITEF GmbH)

More detailed IMU error models than that described in Sect. 28.2.2 are often useful. A specific model for the measurements provided by a triad of inertial sensors at epoch $k$, may it be gyroscopes or accelerometers, is given by

$$\tilde{\boldsymbol{u}}_k = \mathbf{M}\boldsymbol{u}_k + \boldsymbol{b}_{\mathrm{u},k} + \boldsymbol{\nu}_{\mathrm{u},k} \,, \tag{28.13}$$

where

$$\mathbf{M} = \begin{pmatrix} 1+s_x & \delta_{z_x} & \delta_{y_x} \\ \delta_{z_y} & 1+s_y & \delta_{x_y} \\ \delta_{y_z} & \delta_{x_z} & 1+s_z \end{pmatrix} . \tag{28.14}$$

Here, the components $s_x$, $s_y$, and $s_z$ represent the sensor scale factor errors; the off-diagonal elements in this matrix are misalignment errors. The vector $\boldsymbol{b}_{\mathrm{u},k}$ denotes additive sensor biases, and $\boldsymbol{\nu}_{\mathrm{u},k}$ is the sensor noise vector.

In the following, these errors are discussed briefly. Hereby, it has to be kept in mind that each of these errors has a fixed component that is always present, an additional component that varies from run to run, a further component that varies during the operation of the unit, and a component that is temperature dependent. However, depending on the specific sensor, some of these components might not be relevant and can be ignored.

Typically, the designer specifies a Gauss–Markov state space model for these random processes [28.15], using the manufacturer specifications, so that these terms can be estimated (i. e., calibrated) while in use.

### Scale Factor

The scale factor error has a linear and a nonlinear component. The linear component causes an error that is proportional to the true specific force or angular rate. For the error caused by the SF nonlinearity, it is often sufficient to assume a quadratic dependency relative to the true value.

### Misalignment

Misalignment refers to the nonorthogonality of the sensitive axes of the sensors in a sensor triad. Due to this nonorthogonality, each sensor also senses a part of the specific force or angular rate perpendicular to the nominal direction of the sensitive axis of the sensor.

### Bias

Ideally, the bias vector $\boldsymbol{b}_{\mathrm{u},k}$ is the average reading each sensor shows in case the quantity to be measured, angular rate or specific force, is zero. More practically, the bias term represents a slowly varying random quantity. In addition, especially for MEMS gyroscopes, the bias can have a component that is dependent on the specific force, known as the $g$-dependent bias.

### Noise

The sensor-inherent noise is usually modeled accurately as white, zero-mean, and Gaussian. It is specified in datasheets via its PSD or Allan variance. Most inertial sensors are integrating sensors, for which the relation between PSD $R$ and variance $R_k$ is given by

$$R_k = \frac{R}{\tau} \,, \tag{28.15}$$

where $\tau$ is the IMU sampling period, the reciprocal of the sampling rate. The PSD offers a way to describe the sensor noise independent from the sampling rate. For gyroscopes, the square root of the PSD is referred to as angular random walk (ARW). For accelerometers, this is denoted as velocity random walk (VRW). The PSD allows the designer to assess easily the effect of the ARW and VRW noise effects.

As an example, let us consider the construction of a gyroscope random walk error model. Let $\mu_k$ denote white, Gaussian noise with standard deviation $\sigma_\mu = 1$. Let $\nu_{\omega,k}$ denote the gyroscope noise with variance $R_k$. Drawing $\mu_k$ from a random number generator, the sensor noise can be generated using

$$\nu_{\omega,k} = \sqrt{R_k}\mu_k = \sqrt{\frac{R}{\tau}}\mu_k \,. \tag{28.16}$$

Most gyroscopes provide angular increments. For the noise corrupting such an angular increment

$$\Delta\theta_k = \tau\, \nu_{\omega,k} = \sqrt{R\,\tau}\,\mu_k \,, \tag{28.17}$$

with variance

$$\sigma^2_{\Delta\theta} = R\,\tau\,\sigma^2_\mu = R\,\tau \,. \tag{28.18}$$

If $m$ angular increments are summed over a time interval $T = m\tau$, the variance of the resulting angle error is given by

$$\sigma^2_\theta = m\,\sigma^2_{\Delta\theta} = m\,R\,\tau = R\,T \,, \tag{28.19}$$

the standard deviation is given by

$$\sigma_\theta = \sqrt{R}\,\sqrt{T} \,. \tag{28.20}$$

Specifying the sensor noise via the square root of the PSD $R$ allows the analyst to calculate the standard deviation of the resulting angle or velocity error simply by multiplying with the square root of the time interval $T$.

However, the dominant contribution to the noise corrupting the IMU measurements is often not the sen-

**Table 28.1** Gyroscope errors

| Error | RLG | FOG | VSG |
|---|---|---|---|
| Bias $g$-indep. (°/h) | 0.001–10 | 0.1–100 | 1–3600 |
| $g$-dep. (°/h/g) | 0 | 1 | 10–200 |
| SF (ppm) linear | 1–100 | 100–1000 | $< 10^5$ |
| SF (ppm) nonlinear | $10^{-5}$ | $> 10^{-4}$ | 0.01 |
| ARW ($°/\sqrt{h}$) | 0.001 | 0.03–0.1 | $> 0.06$ |

sor inherent noise, but vibration-induced noise, which is usually non-white [28.26]. Furthermore, in the presence of vibrations, SF nonlinearities and misalignment errors cause a sensor error that appears like a vibration-dependent bias, known as a vibration rectification error (VRE) [28.12].

**Table 28.2** Accelerometer errors

| Error | VBA | Pendulous |
|---|---|---|
| Bias (mg) | 0.1–1 | 0.1–10 |
| Bias stability (mg) | 0.1 | 1 |
| SF (ppm) | 100 | 1000 |
| VRW ($\frac{m}{s}/\sqrt{h}$) | 0.01 | 0.04 |

Tables 28.1 and 28.2 present typical orders-of-magnitude of the accelerometer and gyroscope errors.

## 28.4 Strapdown Inertial Navigation

In a strapdown inertial navigation system, the IMU is rigidly attached to the rover. This is in contrast with gimbaled inertial systems where the IMU is attached to a stabilized platform that maintains its inertial orientation as the rover maneuvers. For gimballed systems, the rover attitude is measured from the angles of the platform gimbals relative to the rover. Strapdown systems are typically significantly lower in cost and size than gimballed systems.

In a strapdown algorithm (SDA), the measurements provided by the IMU gyros are processed to maintain an estimate of the rover attitude, so that the accelerometer measurements can be processed to compute the navigation frame velocity and position. The attitude, position, and velocity are each portions of the rover state vector that are propagated forward in time by integrating the IMU measurements through the system kinematic model (Sect. 28.2.3). Without aiding, the deviation of the SDA state from the true rover state increases with time. The speed of growth of these errors depends on the accuracy of the initialization, and on the IMU quality. Table 28.3 lists typical performance and cost for different IMU grades.

The purpose of the following sections is to clearly define the function $\boldsymbol{f}$ and rover state vector $\boldsymbol{x}$ in (28.1) of Sect. 28.2.1, which form the basis for the strapdown calculations.

**Table 28.3** IMU grades

| IMU grade | Bias (mg) | Bias (°/h) | Cost ($) |
|---|---|---|---|
| Marine | 0.01 | 0.001 | $\gg 100$ k |
| Aviation | 0.03–0.1 | 0.01 | 100 k |
| Intermed. | 0.1–1 | 0.1 | 20–50 k |
| Tactical | 1–10 | 1–100 | 2–30 k |
| Consumer | $> 10$ | $> 100$ | $\geq 10$ |

### 28.4.1 Coordinate Systems

The strapdown calculations involve several coordinate systems, which are defined in the following and illustrated in Fig. 28.4.

#### Inertial Frame

This frame is denoted with the index i, the $x$- and $y$-axes lie in the Earth's equatorial plane and are fixed (i. e., not rotating or accelerating). The $z$-axis coincides with the Earth's rotational axis.

#### Earth Frame

This frame, referred to as Earth-centered Earth-fixed (ECEF) frame, is denoted with index e. The $x$- and

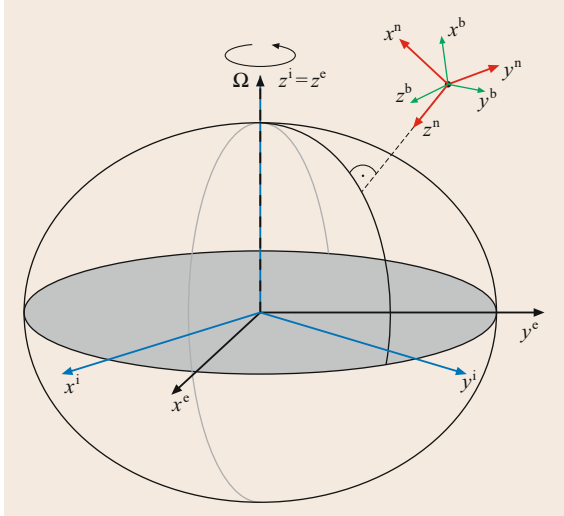

**Fig. 28.4** Relative positions and orientations of the various coordinate systems

$y$-axes lie in the Earth's equatorial plane, the $x$-axis intersects the Greenwich meridian. The $z$-axis coincides with the Earth's rotational axis. The e-frame rotates with respect to the i-frame with angular rate $\boldsymbol{\omega}_{\mathrm{ie}}$.

#### Navigation Frame

The origin of this frame is within the vehicle, the axes are aligned with the directions north, east, and local vertical (i. e., down). Therefore, this frame is also called local level or NED frame. This frame is denoted with the index n.

#### Body Frame

The origin of this frame coincides with the origin of the navigation frame, which is often defined to be the location of the IMU. The axis of the body frame is usually aligned with the directions front, right, and down as viewed from the vehicle. For the sake of simplicity, it is assumed in the following that these axes also coincide with the sensitive axes of the inertial sensors. This frame is denoted by the index b.

In the following, the calculations performed in a strapdown algorithm are addressed. Herein, an n-frame mechanization is assumed. The advantage of an n-frame mechanization is its familiarity, as attitude is given with respect to a local level frame, and velocity is provided in the north, east, and down directions. However, the differential equations in an n-frame mechanization become singular at the Earth's poles; therefore a n-frame mechanization cannot be used if the rover is expected to travel in these regions. When polar travel cannot be precluded, the easiest solution is to use a mechanization in the e-frame, although other alternatives such as the wander azimuth mechanization can be considered as well [28.27].

### 28.4.2 Attitude Calculations

The attitude of the rover is typically expressed either using Euler angles, a direction cosine matrix (DCM), a quaternion, or the Bortz orientation vector. Attitude representations and their relative tradeoffs have been extensively studied [28.13, 18, 28, 29]. In the attitude calculation implemented in a strapdown algorithm, the differential equations for the selected attitude representation are solved using the angular rate measurements provided by the IMU.

The Euler angles describe the attitude of the body frame with respect to the navigation frame by a series of three rotations. The first rotation is performed through the yaw angle $\psi$ around the $z$-axis of the navigation frame, which is also referred to as the down axis. The second rotation is performed through the pitch angle $\theta$ around the new $y$-axis. The final rotation through the roll-angle $\phi$ around the new $x$-axis finally leads to the body frame. The Euler angle differential equations are given by

$$\dot{\phi} = (\omega^{\mathrm{b}}_{\mathrm{nb},y} \sin\phi + \omega^{\mathrm{b}}_{\mathrm{nb},z} \cos\phi) \tan\theta + \omega^{\mathrm{b}}_{\mathrm{nb},x} \,, \tag{28.21}$$

$$\dot{\theta} = \omega^{\mathrm{b}}_{\mathrm{nb},y} \cos\phi - \omega^{\mathrm{b}}_{\mathrm{nb},z} \sin\phi \,, \tag{28.22}$$

$$\dot{\psi} = \frac{(\omega^{\mathrm{b}}_{\mathrm{nb},y} \sin\phi + \omega^{\mathrm{b}}_{\mathrm{nb},z} \cos\phi)}{\cos\theta} \,, \tag{28.23}$$

where $\boldsymbol{\omega}^{\mathrm{b}}_{\mathrm{nb}} = [\omega^{\mathrm{b}}_{\mathrm{nb},x}, \omega^{\mathrm{b}}_{\mathrm{nb},y}, \omega^{\mathrm{b}}_{\mathrm{nb},z}]^{\top}$. This set of equations reveals an important drawback. The differential equations for roll and yaw become singular for pitch angles of $\pm 90°$. The reason is that in this case, the first rotation around the $z$-axis takes place around the same axis as the last rotation around the new $x$-axis. In other words, the Euler angles become ambiguous in the sense that an arbitrary number of roll-yaw angle pairs can be found that describe a given attitude involving $\pm 90°$ pitch. Therefore, while an attitude involving $\pm 90°$ pitch can be expressed without problems using Euler angles, the differential equation singularity does not allow for an implementation of the attitude calculation in a strapdown algorithm based on Euler angles, for attitudes near $\pm 90°$ pitch. A second disadvantage is that solution of these differential equations require evaluation of several trigonometric functions at the high rate of the IMU gyro integration. The main advantage of Euler angles is their human understandability. However, because the Euler angles can be extracted from the other representations at the low rates at which they are required, the three equations above are rarely implemented.

The DCM or rotation matrix is a $3 \times 3$ matrix that defines the transformation of a vector from one coordinate frame to the other. For example, a velocity vector in b-frame coordinates is transformed to n-frame coordinates using the DCM $\mathbf{C}^{\mathrm{n}}_{\mathrm{b}}$ as follows

$$\boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}} = \mathbf{C}^{\mathrm{n}}_{\mathrm{b}} \boldsymbol{v}^{\mathrm{b}}_{\mathrm{eb}} \,. \tag{28.24}$$

The DCM is an orthonormal matrix, therefore,

$$\mathbf{C}^{\mathrm{b}}_{\mathrm{n}} = \left(\mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\right)^{-1} = \left(\mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\right)^{\top} . \tag{28.25}$$

The DCM differential equation is given by

$$\dot{\mathbf{C}}^{\mathrm{n}}_{\mathrm{b}} = \mathbf{C}^{\mathrm{n}}_{\mathrm{b}} [\boldsymbol{\omega}^{\mathrm{b}}_{\mathrm{nb}} \times] \,, \tag{28.26}$$

where

$$[\boldsymbol{\omega}^{\mathrm{b}}_{\mathrm{nb}} \times] = \begin{pmatrix} 0 & -\omega^{\mathrm{b}}_{\mathrm{nb},z} & \omega^{\mathrm{b}}_{\mathrm{nb},y} \\ \omega^{\mathrm{b}}_{\mathrm{nb},z} & 0 & -\omega^{\mathrm{b}}_{\mathrm{nb},x} \\ -\omega^{\mathrm{b}}_{\mathrm{nb},y} & \omega^{\mathrm{b}}_{\mathrm{nb},x} & 0 \end{pmatrix} \tag{28.27}$$

is the skew symmetrix matrix corresponding to $\boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}}$.

Euler's rotation theorem [28.30] states that any two reference frames related via an arbitrary sequence of rotations can be equivalently represented by a finite rotation about a single axis. This single fixed axis is known as the Euler axis. The Euler axis has the same representation in both reference frames. This demonstrates that the Euler axis is an eigenvector of the DCM corresponding to the eigenvalue 1.

The *Bortz* orientation vector [28.28] is a time-varying vector $\boldsymbol{\vartheta}(t)$ defined by the differential equation

$$\dot{\boldsymbol{\vartheta}} = \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} + \frac{1}{2}\boldsymbol{\vartheta} \times \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} + \frac{1}{\vartheta^2}\left(1 - \frac{\vartheta \sin(\vartheta)}{2(1-\cos\vartheta)}\right)\boldsymbol{\vartheta} \times (\boldsymbol{\vartheta} \times \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}}) \,. \tag{28.28}$$

The length of the orientation vector $\vartheta = \|\boldsymbol{\vartheta}\|$ defines the angle of rotation about the unit vector $\frac{\boldsymbol{\vartheta}}{\vartheta}$ (i. e., Euler axis) such that the navigation frame coincides with the body frame. Therefore, an orientation vector of length $\vartheta$ describes the same attitude as the orientation vectors defining the same axis of rotation, but with length $\vartheta \pm 2\pi m$, where $m$ is an arbitrary integer.

The Bortz orientation vector is often the foundation of high-rate attitude integration algorithms designed to address coning [28.10, 11, 31]. For a short period of integration, such that $\vartheta$ remains small, (28.28) simplifies to

$$\dot{\boldsymbol{\vartheta}} \approx \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} + \frac{1}{2}\boldsymbol{\vartheta} \times \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} + \frac{1}{12}\boldsymbol{\vartheta} \times (\boldsymbol{\vartheta} \times \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}}) \,. \tag{28.29}$$

At the end of the $k$-th integration period the value of the Bortz orientation vector $\boldsymbol{\vartheta}(\tau_k)$ is saved and the next period of integration starts with zero initial conditions. The sequence of outputs $\boldsymbol{\vartheta}(\tau_k)$ defines a sequence of rotations that can be combined through quaternion multiplication to define the full rotation.

A quaternion [28.29, 32] can be represented as a four element vector, which can be constructed from the Bortz orientation vector as follows

$$\mathsf{q}_{\mathrm{b}}^{\mathrm{n}} = \begin{pmatrix} \cos\left(\frac{\vartheta}{2}\right) \\ \left(\frac{\vartheta_x}{\vartheta}\right)\sin\left(\frac{\vartheta}{2}\right) \\ \left(\frac{\vartheta_y}{\vartheta}\right)\sin\left(\frac{\vartheta}{2}\right) \\ \left(\frac{\vartheta_z}{\vartheta}\right)\sin\left(\frac{\vartheta}{2}\right) \end{pmatrix} . \tag{28.30}$$

Note that this is a unit quaternion. Quaternion multiplication can be expressed as a matrix–vector multiplication. For two quaternions, $\mathsf{a} = (a_0, a_1, a_2, a_3)$ and $\mathsf{b} = (b_0, b_1, b_2, b_3)$, their product is defined by

$$\mathsf{a} \bullet \mathsf{b} = \begin{pmatrix} a_0 & -a_1 & -a_2 & -a_3 \\ a_1 & a_0 & -a_3 & a_2 \\ a_2 & a_3 & a_0 & -a_1 \\ a_3 & -a_2 & a_1 & a_0 \end{pmatrix} \bullet \begin{pmatrix} b_0 \\ b_1 \\ b_2 \\ b_3 \end{pmatrix} . \tag{28.31}$$

If $\mathsf{q}_k$ represents the quaternion corresponding to body rotation $\boldsymbol{\vartheta}(\tau_k)$, then the quaternion for the full rotational sequence is

$$\mathsf{q}_0^k = \mathsf{q}_k \bullet \mathsf{q}_{k-1} \bullet \cdots \bullet \mathsf{q}_1 \,. \tag{28.32}$$

Rotations can also be concatenated as follows

$$\mathsf{q}_{\mathrm{b}}^{\mathrm{n}} = \mathsf{q}_{\mathrm{e}}^{\mathrm{n}} \bullet \mathsf{q}_{\mathrm{b}}^{\mathrm{e}} \,. \tag{28.33}$$

Instead of using the Bortz orientation vector for implementation, the quaternion can be integrated directly. The quaternion differential equation is given by

$$\dot{\mathsf{q}}_{\mathrm{b}}^{\mathrm{n}} = \frac{1}{2}\mathsf{q}_{\mathrm{b}}^{\mathrm{n}} \bullet \begin{pmatrix} 0 \\ \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} \end{pmatrix} . \tag{28.34}$$

Strapdown algorithm implementation requires the differential equations for one of the attitude representations to be solved numerically at high rates. Note that the DCM, quaternion, and simplified Bortz ordinary differential equations can be integrated without evaluation of trigonometric functions.

An IMU provides the angular rate vector $\boldsymbol{\omega}_{\mathrm{ib}}^{\mathrm{b}}$ – or the integral thereof, the angle increments. The $\boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}}$ is calculated from $\boldsymbol{\omega}_{\mathrm{ib}}^{\mathrm{b}}$ using

$$\boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} = \boldsymbol{\omega}_{\mathrm{ib}}^{\mathrm{b}} - \left(\mathbf{C}_{\mathrm{b}}^{\mathrm{n}}\right)^{\top}\left(\boldsymbol{\omega}_{\mathrm{ie}}^{\mathrm{n}} + \boldsymbol{\omega}_{\mathrm{en}}^{\mathrm{n}}\right) , \tag{28.35}$$

where the Earth angular rate vector in the n-frame is

$$\boldsymbol{\omega}_{\mathrm{ie}}^{\mathrm{n}} = (\Omega\cos\varphi, 0, -\Omega\sin\varphi)^{\top} \,. \tag{28.36}$$

$\Omega$ is the scalar Earth rate of rotation, and $\varphi$ denotes the geographic latitude. The term

$$\boldsymbol{\omega}_{\mathrm{en}}^{\mathrm{n}} = \begin{pmatrix} +\frac{v_{\mathrm{eb,e}}^{\mathrm{n}}}{R_{\mathrm{e}}-h} \\ -\frac{v_{\mathrm{eb,n}}^{\mathrm{n}}}{R_{\mathrm{n}}-h} \\ -\frac{v_{\mathrm{eb,e}}^{\mathrm{n}}\tan\varphi}{R_{\mathrm{e}}-h} \end{pmatrix} \tag{28.37}$$

is the transport rate, and

$$\boldsymbol{v}_{\mathrm{eb}}^{\mathrm{n}} = \left[v_{\mathrm{eb,n}}^{\mathrm{n}}, v_{\mathrm{eb,e}}^{\mathrm{n}}, v_{\mathrm{eb,d}}^{\mathrm{n}}\right]^{\top} .$$

The transport rate takes into account that the navigation frame has to rotate when moving with respect to

Earth's surface, otherwise the $z$-axis of the n-frame would not maintain its down direction. The Earth's radii of curvature in the north and east directions, $R_\mathrm{n}$ and $R_\mathrm{e}$, respectively, are specified in the WGS84 model of the reference ellipsoid.

From the quaternion, the DCM can be calculated using

$$\mathbf{C}_\mathrm{b}^\mathrm{n} = \left(\mathbf{C}_\mathrm{b}^\mathrm{n}(:,1) \quad \mathbf{C}_\mathrm{b}^\mathrm{n}(:,2) \quad \mathbf{C}_\mathrm{b}^\mathrm{n}(:,3)\right), \tag{28.38}$$

with

$$\mathbf{C}_\mathrm{b}^\mathrm{n}(:,1) = \begin{pmatrix} (q_0^2+q_1^2-q_2^2-q_3^2) \\ 2(q_1q_2+q_0q_3) \\ 2(q_1q_3-q_0q_2) \end{pmatrix}, \tag{28.39}$$

$$\mathbf{C}_\mathrm{b}^\mathrm{n}(:,2) = \begin{pmatrix} 2(q_1q_2-q_0q_3) \\ (q_0^2-q_1^2+q_2^2-q_3^2) \\ 2(q_2q_3+q_0q_1) \end{pmatrix}, \tag{28.40}$$

$$\mathbf{C}_\mathrm{b}^\mathrm{n}(:,3) = \begin{pmatrix} 2(q_1q_3+q_0q_2) \\ 2(q_2q_3-q_0q_1) \\ (q_0^2-q_1^2-q_2^2+q_3^2) \end{pmatrix}. \tag{28.41}$$

A rotation from body to the navigation frame is mandatory for velocity calculations in a strapdown algorithm because the specific force is measured in b-frame coordinates whereas velocity and position are required in n-frame coordinates. This rotation can either be accomplished using the DCM or directly from the quaternion. The presentation of the next section assumes that the DCM is computed so that standard matrix–vector notation can be used.

### 28.4.3 Velocity Calculations

The velocity differential equation in n-frame mechanization is given by

$$\dot{\boldsymbol{v}}_\mathrm{eb}^\mathrm{n} = \mathbf{C}_\mathrm{b}^\mathrm{n}\boldsymbol{f}_\mathrm{ib}^\mathrm{b} - \left(2\boldsymbol{\omega}_\mathrm{ie}^\mathrm{n} + \boldsymbol{\omega}_\mathrm{en}^\mathrm{n}\right) \times \boldsymbol{v}_\mathrm{eb}^\mathrm{n} + \boldsymbol{g}^\mathrm{n}\,. \tag{28.42}$$

The specific force $\boldsymbol{f}_\mathrm{ib}^\mathrm{b}$ is provided by the IMU. The multiplication with $\mathbf{C}_\mathrm{b}^\mathrm{n}$ yields the specific force in n-frame coordinates. Adding the local gravity vector $\boldsymbol{g}^\mathrm{n}$ yields the rover acceleration, (28.12),

$$\mathbf{C}_\mathrm{b}^\mathrm{n}\boldsymbol{f}_\mathrm{ib}^\mathrm{b} + \boldsymbol{g}^\mathrm{n} = \boldsymbol{a}_\mathrm{ib}^\mathrm{n}\,. \tag{28.43}$$

The local gravity vector is a function of position and can be computed, for example, using the Somigliana formula [28.33]. The term

$$-\left(2\boldsymbol{\omega}_\mathrm{ie}^\mathrm{n} + \boldsymbol{\omega}_\mathrm{en}^\mathrm{n}\right) \times \boldsymbol{v}_\mathrm{eb}^\mathrm{n}$$

is the Coriolis acceleration, an apparent acceleration experienced in rotating coordinate systems, such as the n-frame in which the equation is mechanized. In rotating coordinate systems, a moving object behaves as if this Coriolis acceleration acts on the object. This acceleration cannot be measured by accelerometers; therefore, the Coriolis acceleration has to be added in (28.42). As an example, for the Coriolis acceleration, assume that an object is at rest on the Earth's surface in the equatorial plane. Viewed from an inertial frame, the object trajectory is a circle with a radius that equals the semi-major axis of the Earth ellipsoid. Assume now that an acceleration acts on the object that causes a velocity perpendicular to Earth's surface, so that the height above ground of the object increases. Then, viewed from Earth's surface it is observed that the object is deflected in the west direction by the Coriolis force. In fact, the speed tangential to Earth's surface is not increased; therefore, at a greater distance from the Earth's axis of rotation, the tangential speed of the object is not sufficient to keep up with the point on the Earth's surface from which the object started.

### 28.4.4 Position Calculations

In the position calculations, the following differential equations are solved numerically

$$\dot{\varphi} = \frac{v_\mathrm{eb,n}^\mathrm{n}}{R_\mathrm{n} - h}\,, \tag{28.44}$$

$$\dot{\lambda} = \frac{v_\mathrm{eb,e}^\mathrm{n}}{(R_\mathrm{e} - h)\cos\varphi}\,, \tag{28.45}$$

$$\dot{h} = v_\mathrm{eb,d}^\mathrm{n}\,, \tag{28.46}$$

where

$$\boldsymbol{v}_\mathrm{eb}^\mathrm{n} = \left[v_\mathrm{eb,n}^\mathrm{n},\ v_\mathrm{eb,e}^\mathrm{n},\ v_\mathrm{eb,d}^\mathrm{n}\right]^\top\,.$$

In these equations, the height above ground is negative, because the $z$-axis of the navigation frame is pointing in the down direction.

Equations (28.42) and (28.44)–(28.46) can be solved numerically, for example, using a Runge–Kutta algorithm [28.34].

## 28.5 Analysis of Error Effects

The growth of the errors of the INS solution is influenced by the accuracy of the initialization of the strapdown algorithm, the integration algorithm, and by the quality of the inertial sensors. It is useful to distinguish short-term and long-term error characteristics, as is done in the next two sections.

### 28.5.1 Short-Term Effects

The short-term characteristics are dominant during the first phase of unaided inertial navigation, from initialization or the last aiding measurement time until some minutes afterwards. The impact of the sensor noise was already described in Sect. 28.3.3; the impact of misalignment and SF errors largely depends on the trajectory characteristics. Therefore, the following discussion focuses on the impact of attitude errors and accelerometer and gyroscope biases.

#### Attitude Errors

Attitude errors lead to errors in the navigation solution, because the specific force is not transformed from b-frame to n-frame coordinates correctly by the first term in (28.42). For example, an acceleration in the north direction measured in b-frame coordinates is not computed as an acceleration in the north direction unless the yaw angle is known perfectly. The effect of attitude errors is more observable when the vehicle is maneuvering; however, even without maneuvering attitude errors can affect the accuracy of the INS position solution. For example, because accelerometers measure the specific force, which is the difference between rover acceleration and gravity, calculation of the rover acceleration requires compensation of gravity. Attitude errors in roll and pitch may lead to an imperfect compensation of the gravity, the uncompensated part is interpreted as rover acceleration and integrated in the SDA, leading to the increase in velocity and position errors. For small angle errors, the uncompensated gravity leads to an erroneous acceleration given by

$$\delta \boldsymbol{a}_{\mathrm{nb}}^{\mathrm{b}} = \begin{pmatrix} -\delta\theta \\ \delta\phi \\ 0 \end{pmatrix} g \,, \qquad (28.47)$$

where $g = |\boldsymbol{g}^{\mathrm{n}}|$.

Figure 28.5 illustrates a pitch attitude error. In this example, the true pitch angle is zero, whereas the SDA provides a positive, nonzero pitch angle $\delta\theta$. Because of this computed pitch angle, when the SDA computes the navigation frame acceleration by (28.43), the gravity compensation in the $x$-direction is incorrect by $-g\,\delta\theta$; erroneous compensation of the gravity leads to an erroneous acceleration in the negative body $x$-direction (28.47). The down direction is less affected by this mechanism, as the erroneous gravity compensation in down direction is proportional to

$$1 - \cos(\delta\phi)\cos(\delta\theta) \,,$$

which is close to zero for small angle errors.

A similar assessment can be made for a roll angle error. Therefore, in the short-term, roll and pitch attitude errors cause horizontal acceleration error, leading to a linear growth of velocity errors and a quadratic growth of position errors with time, whereas the vertical channel is less sensitive to attitude errors.

#### Gyroscope Biases

As long as the attitude errors are sufficiently small, gyroscope biases lead to a linear growth of attitude errors with time. Combined with the results from the previous paragraph, it can be concluded that this causes an acceleration error in the horizontal channels that grows linearly with time, leading to a quadratic growth of the velocity errors and cubic growth of the position errors.

#### Accelerometer Biases

An uncompensated accelerometer bias is interpreted as a rover acceleration, leading to a linear growth of velocity errors and quadratic growth of position errors with time.

#### Summary

From the above discussion, it is clear that INS errors grow at rates faster than linear growth. Note that it is possible for horizontal accelerometer bias errors to exactly cancel attitude errors. When this occurs, the errors have no effect, and are said to lie in the unobservable space. Aiding the INS with other sensors tends to drive these errors to the unobservable space.

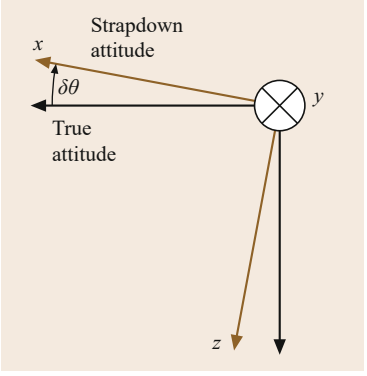

**Fig. 28.5** Illustration of a pitch error

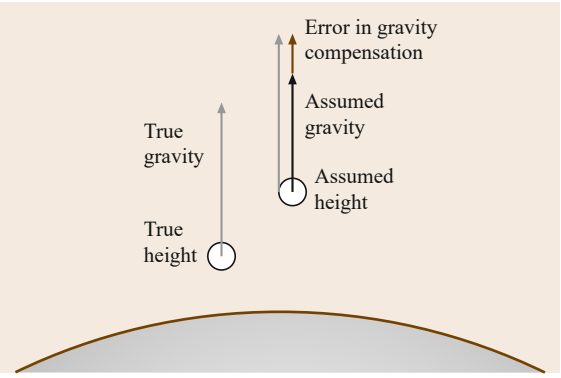

**Fig. 28.6** INS vertical channel instability

## 28.5.2 Long-Term Effects

For the long-term error characteristics of an INS, the instability of the vertical channel and the Schuler oscillations become important.

### Instability of the Vertical Channel

Computation of acceleration from the measured specific force vector requires gravity compensation. This compensation computes the expected gravity at the estimated position using a suitable model (e.g., Somigliana gravity formula). The magnitude of the gravity vector reduces with increasing height above ground. Because the strapdown algorithm provides an erroneous height, the expected magnitude of the gravity vector does not match the true gravity vector. For example, when the computed height of the rover above ground is higher than the true position (Fig. 28.6), the computed magnitude of the gravity vector is too small. Therefore, only a part of the gravity contributing to the measured specific force is compensated, whereas the remaining part is interpreted erroneously as an acceleration of the rover. Unfortunately, the vertical channel error dynamics are unstable; therefore, this erroneous acceleration increases the present height error.

Due to this instability, an initial height error of only 10 m causes a height error of several thousand meters after 1 h of unaided inertial navigation. Therefore, any INS that operates autonomously for longer periods of time requires aiding of the vertical channel, for example, using a barometric altimeter, for stabilization.

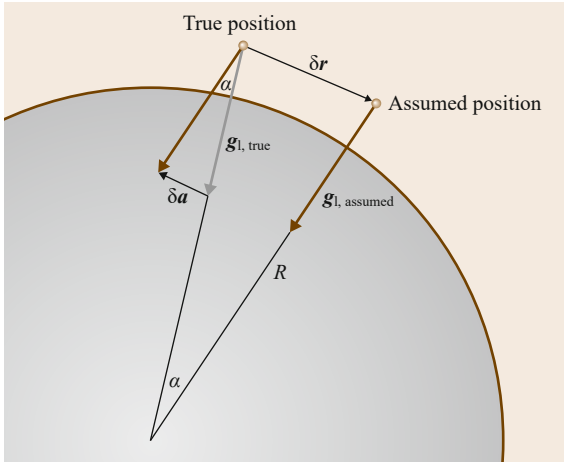

**Fig. 28.7** Illustration of the Schuler oscillation mechanism

### Schuler Oscillations

Although the gravitational errors destabilize the vertical channel, they provide a stabilizing effect on the horizontal channels, resulting in *Schuler oscillations* [28.35].

The mechanism that leads to Schuler oscillations is illustrated in Fig. 28.7. Due to a horizontal position error $\delta\boldsymbol{r}$, the strapdown algorithm computes a slightly erroneous direction of the gravity vector. Therefore, the gravity measured with the specific force is not compensated correctly in the velocity calculation of the strapdown algorithm. The uncompensated portion is interpreted erroneously as rover acceleration. Fortunately, this acceleration error $\delta\boldsymbol{a}$ is pointing in the direction toward the true rover position, that is, acting against the position error. From Fig. 28.7, the following approximate relation is obtained

$$\frac{\delta\boldsymbol{r}}{R} = -\frac{\delta\boldsymbol{a}}{g} \,. \tag{28.48}$$

This leads to

$$\delta\ddot{\boldsymbol{r}} + \frac{g}{R}\delta\boldsymbol{r} = 0 \,, \tag{28.49}$$

which is the differential equation of a harmonic oscillator. The resulting Schuler oscillations of the position and velocity errors of the INS solution show a period of approximately 84 min.

## 28.6 Aided Navigation

The INS achieves a high-bandwidth rover state vector estimate $\hat{\boldsymbol{x}}(t)$ by propagating (28.7) through time using the function $\boldsymbol{f}$ described in Sect. 28.4. The time propagation only uses the IMU sensor data.

At time $t_j$, the INS provides an estimate $\hat{\boldsymbol{z}}_j = \hat{\boldsymbol{z}}(t_j)$ of the vector $\boldsymbol{z}_j = \boldsymbol{z}(t_j)$. Section 28.2.1 discussed the definition of the vector $\boldsymbol{z}$ that depends on the rover state $\boldsymbol{x}$ and the sensor calibration parameters $\boldsymbol{c}_\mathrm{u}$ and $\boldsymbol{c}_\mathrm{y}$. The navigation system also maintains an estimate of the error covariance matrix $\mathbf{P}_{z_j}$.

The definition, causes, and effects of INS state errors are discussed in Sects. 28.2.4, 28.3.3, and 28.5. The rate of error accumulation is dependent on the quality of the IMU and the accuracy of $\hat{\boldsymbol{c}}_\mathrm{u}$. The need for aiding of the INS by additional sensors is clear. Each aiding sensor measurement provides information useful for correcting the rover state vector $\hat{\boldsymbol{x}}$ and the IMU calibration parameters $\hat{\boldsymbol{c}}_\mathrm{u}$, decreasing the INS error vector $\delta\boldsymbol{z}$ in certain directions of the state space. In the process, the accuracy of the aiding sensor calibration vector $\hat{\boldsymbol{c}}_\mathrm{y}$ will also be enhanced.

This process is called state estimation. The subsequent sections will consider INS aiding (i. e., state estimation) in various forms using GNSS observables as the aiding signals.

## 28.7 State Estimation

This section briefly introduces the main state estimation algorithm. This algorithm can be derived from multiple perspectives, maximum a posteriori (MAP) or minimum mean squared error [28.14, 16, 36–38] (Chap. 22).

For a linear system with appropriate assumptions, the optimal algorithm is known as the *Kalman* filter [28.39]. Because the INS time propagation and measurement models are nonlinear, the extended Kalman filter is often utilized in aided inertial navigation applications. A few alternative estimation approaches are discussed later in Sect. 28.10.

The extended Kalman filter (EKF) state estimator uses the new information in the measurement to compute an improved, ideally optimal, posterior state estimate $\hat{\boldsymbol{z}}_j^+$ with error covariance $\mathbf{P}_{z_j}^+$. In this notation, an upper index $\{.\}^+$ denotes a quantity in which the measurement information has already been incorporated, known as an a posteriori quantity, and an upper index $\{.\}^-$ denotes an a priori quantity, for which the measurement information has not yet been incorporated.

Assume that at $t_j$, an aiding measurement $\tilde{\boldsymbol{y}}_j = \tilde{\boldsymbol{y}}(t_j)$ is available. Using the INS state estimate $\hat{\boldsymbol{z}}_j^-$, the INS predicts the value of the aiding measurement $\hat{\boldsymbol{y}}_j^-$ using (28.8). The residual measurement is

$$\boldsymbol{r}_j = \tilde{\boldsymbol{y}}_j - \hat{\boldsymbol{y}}_j^- \,. \tag{28.50}$$

Under the assumptions that linearization errors are small enough to be ignored and that

$$\delta\boldsymbol{z}(t_j) \sim N(\mathbf{0}, \mathbf{P}_{z_j}^-),$$

where $\mathbf{P}_{z_j}^-$ is the error covariance matrix computed by the INS, then

$$\boldsymbol{r}_j \sim N(\mathbf{0}, \mathbf{S}_j) \,,$$

where

$$\mathbf{S}_j = \mathbf{H}_j \mathbf{P}_{z_j}^- \mathbf{H}_j^\top + \mathbf{R}_j \,, \tag{28.51}$$

$$\mathbf{H}_j = \left.\frac{\partial \boldsymbol{h}}{\partial \boldsymbol{z}}\right|_{z=\hat{z}_j} \,. \tag{28.52}$$

The fact that $\boldsymbol{r}_j \sim N(\mathbf{0}, \mathbf{S}_j)$ with both $\boldsymbol{r}_j$ and $\mathbf{S}_j$ computed on-line allows the measurement validity to be evaluated in real-time using the chi-squared variable $\boldsymbol{r}_j^\top \mathbf{S}_j^{-1} \boldsymbol{r}_j$ (Chap. 24).

When the measurement is deemed to be valid, the improved state estimate and its error covariance are computed as

$$\hat{\boldsymbol{z}}_j^+ = \hat{\boldsymbol{z}}_j^- + \mathbf{K}_j \boldsymbol{r}_j \,, \tag{28.53}$$

$$\mathbf{P}_{z_j}^+ = \mathbf{P}_{z_j}^- - \mathbf{K}_j \mathbf{S}_j \mathbf{K}_j^\top \,, \tag{28.54}$$

where

$$\mathbf{K}_j = \mathbf{P}_{z_j}^- \mathbf{H}_j^\top (\mathbf{H}_j \mathbf{P}_{z_j}^- \mathbf{H}_j^\top + \mathbf{R}_j)^{-1} \,.$$

If the measurements are deemed to be invalid, then the corrections due to those measurements would not be applied (equivalently, $\mathbf{K}_j = \mathbf{0}$).

Equation (28.54) shows that aiding measurements decrease the error covariance in a direction determined by $\mathbf{K}_j$. Any single measurement will only correct a certain linear subspace of the state space, which leaves

the error to accumulate in the complementary subspace, which is said to be unobservable from this measurement. As long as each subspace of the state space is corrected sufficiently often, the overall state estimate remains accurate. The error covariance matrix keeps track of these details over time.

It is well known [28.20] that for an INS observability is dependent on the rover motion. For example, certain subspaces that contain the attitude errors and IMU biases will be unobservable from position or velocity aiding, during time intervals when the rover is nonaccelerating. This means that the estimation error will accumulate in those unobservable subspaces. It also means that the accumulated errors will have no effect on the measured outputs during the period they are not observable. Depending on the amount of error accumulation, their effect can be significant when the rover motion causes the errors to become observable.

## 28.8 GNSS and Aided INS

This section presents an overview of a few typical GNSS-aided INS formulations. Each subsection presents one approach along with a brief discussion. The discussion and figures should be interpreted in a general sense. Designers have implemented many variations on the general ideas described herein.

To allow a straightforward comparison of approaches, this section will neglect lever arm corrections. The lever arm is the vector from the GNSS antenna to the IMU effective location. When the lever arm is significant relative to the accuracy that the system is designed to achieve, lever arm compensation must be taken into account. A detailed discussion of lever arm corrections is presented in Sect. 28.9.2.

### 28.8.1 Loose (Position Domain) Coupling

Figure 28.8 shows a typical block diagram for a loosely coupled approach. The GNSS receiver uses the observed satellite signals to compute the *measurement* of the GNSS antenna position $\tilde{\boldsymbol{p}}$ and velocity $\tilde{\boldsymbol{v}}$. The INS uses its state vector $\hat{\boldsymbol{z}}$ to compute the estimate of the GNSS antenna position $\hat{\boldsymbol{p}}$ and velocity $\hat{\boldsymbol{v}}$. The EKF uses the position and velocity residual vectors along with the error models to estimate the error state $\delta\hat{\boldsymbol{z}}$, which is fed back into the INS, which removes the estimated errors from the system.

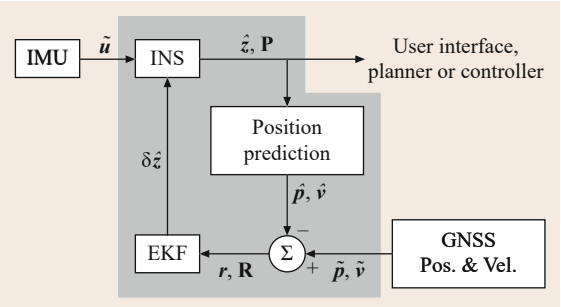

**Fig. 28.8** GNSS loosely coupled INS aiding block diagram

Loosely coupled approaches require the least amount of GNSS knowledge by the navigation system designer. The designer need not understand the ephemeris computations, clock models, receiver specific implementation issues, or various other items discussed in the GNSS interface documentation.

Various factors come into play related to the computation of the GNSS position and velocity *measurements* by the receiver. These factors are manufacturer dependent and may not be fully understandable or controllable by the user:

- Position and velocity are not the basic measurements of a GNSS receiver. Instead, position and velocity can be computed by the receiver at any time when signals from at least four satellites are available. The accuracy of the position and velocity solutions depends on the number and geometry of the available satellites. This accuracy can change significantly over time. Some receivers output quantities such as horizontal dilution of precision (HDOP), GDOP, and so on, which are useful, but they do not allow complete determination of the measurement covariance matrix $\mathbf{R}$ (28.4) that is used by the EKF to determine the optimal gain $\mathbf{K}_i$. When the complete $\mathbf{R}$ matrix is unknown, the design is forced to fill in the missing knowledge with assumptions that are not necessarily correct, resulting in a suboptimal design.
- The receiver may include internal filters (Sect. 28.10.1). Such filters are problematic for INS aiding, as the EKF in the INS is designed based on the assumption that the error (or noise) $\boldsymbol{\eta}_y$ in (28.4) is white; however, the GNSS receiver filters may make this assumption invalid.

Without an internal navigation filter, the GNSS receiver will not produce any position and velocity outputs

at times when signals from fewer than four satellite vehicles are available. At these time instants, the information from the available satellites is lost. The internal filter is often preferred by GPS-only users of the receiver, but is a complication that can cause anomalous behavior in GNSS-aided INS implementations. For INS aiding, the receiver settings should eliminate its internal navigation filter.

### 28.8.2 Tight (Observable Domain) Coupling

Figure 28.9 shows a typical block diagram for a tightly coupled approach. The GNSS receiver tracks the radio frequency signals using phase-lock and delay-lock loops to extract information to determine the measurements of pseudorange $\tilde{\boldsymbol{\rho}}$, Doppler $\tilde{\boldsymbol{D}}$, and carrier-phase $\tilde{\boldsymbol{\varphi}}$, along with various signal quality indicators and satellite ephemeris data (Chaps. 14 and 15). The INS uses its estimated state $\hat{\boldsymbol{z}}$ along with the satellite ephemeris data and equations describing the satellite orbits (Chap. 3) to predict the pseudorange $\hat{\boldsymbol{\rho}}$, Doppler $\hat{\boldsymbol{D}}$, and carrier phase $\hat{\boldsymbol{\varphi}}$. The EKF uses some combination of the pseudorange, Doppler, and carrier-phase residuals to estimate the error state $\delta\hat{\boldsymbol{z}}$, which is fed back into the INS to remove the estimated errors from the system.

The tightly coupled approach requires more effort and knowledge on the part of the designer and more computation by the INS computer. The INS must implement the satellite ephemeris equations to compute the satellite position and velocity necessary for predicting the pseudorange, Doppler, and carrier-phase. The designer must also understand certain intricacies (e.g., clock models and interpretations of quality indicators) of the GNSS receiver with which they are working. The return on the invested design effort is the opportunity for improved performance. INS aiding is possible by whichever satellites are available, even when the number available is less than four. The accuracy of each satellite measurement can be independently and accurately characterized. In addition, validity decisions can be made on a per satellite basis, before they effect the navigation solution.

If the GNSS receiver contains an internal navigation filter, that filter should have no effect on the pseudorange, Doppler, and carrier-phase measurements. The receiver does contain filters in the radio frequency stage to reduce noise and radio interference. The radio frequency filters have center frequencies and bandwidths that are sufficiently high that they do not adversely affect INS aiding. The receiver also contains filters within the receiver code tracking delay-lock-loop (DLL) and carrier tracking phase-lock-loops (PLLs). The tradeoffs – involving accuracy, loss-of-lock, and other issues – in selecting these bandwidths are intricate and

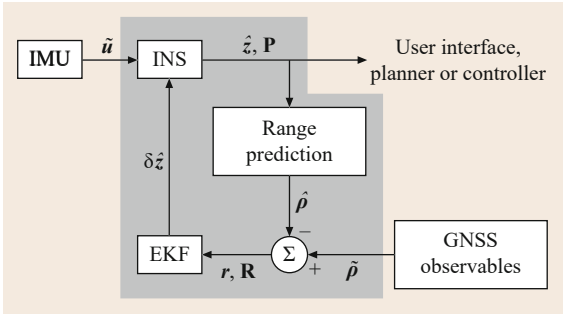

**Fig. 28.9** GNSS tightly coupled INS aiding block diagram

are determined by the receiver designers. The measurement errors introduced by the DLL and PLL are independent for each satellite; however, depending on the receiver, the time correlation may be significant enough that it needs to be taken into account in the INS error model.

At present, most available GNSS receivers, if provided with differential correction signals, will utilize the corrections in its computed position, but will not account for the corrections in the pseudorange, Doppler, and carrier-phase measurements that are output. The designer must account for the differential corrections in the residual formation process.

### 28.8.3 Ultra-Tight or Deep Coupling

Figure 28.10 shows an example block diagram for an ultratightly or deeply coupled approach. The INS uses its estimated state $\hat{\boldsymbol{z}}$ along with the satellite ephemeris data and equations describing the satellite orbits to predict the pseudorange $\hat{\boldsymbol{\rho}}$, Doppler $\hat{\boldsymbol{D}}$, and carrier-phase $\hat{\boldsymbol{\varphi}}$. These predictions are injected into the GNSS receiver carrier-phase and/or code tracking algorithms. The receiver carrier-phase and code tracking errors then serve directly as residuals for the EKF to estimate the error state $\delta\hat{\boldsymbol{z}}$, which is fed back into the INS to remove the estimated errors from the system [28.40, 41].

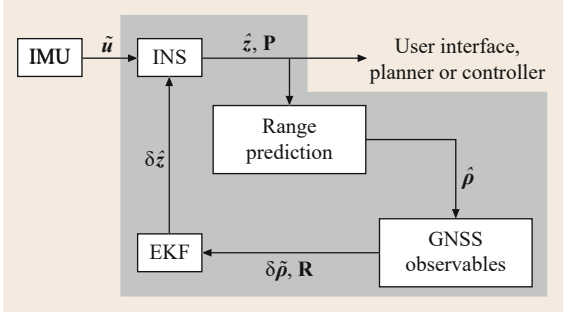

**Fig. 28.10** GNSS ultra or deeply coupled INS aiding INS block diagram

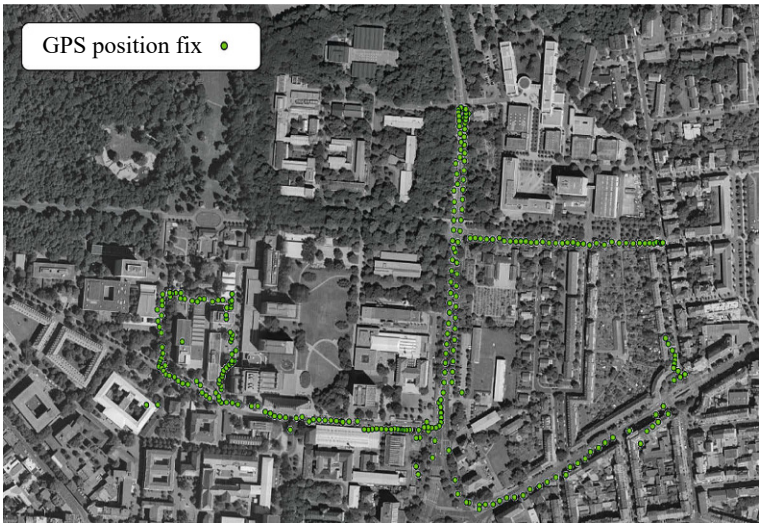

**Fig. 28.11** GPS position fixes obtained during a test drive (courtesy of Stadt Karlsruhe, Liegenschaftsamt)

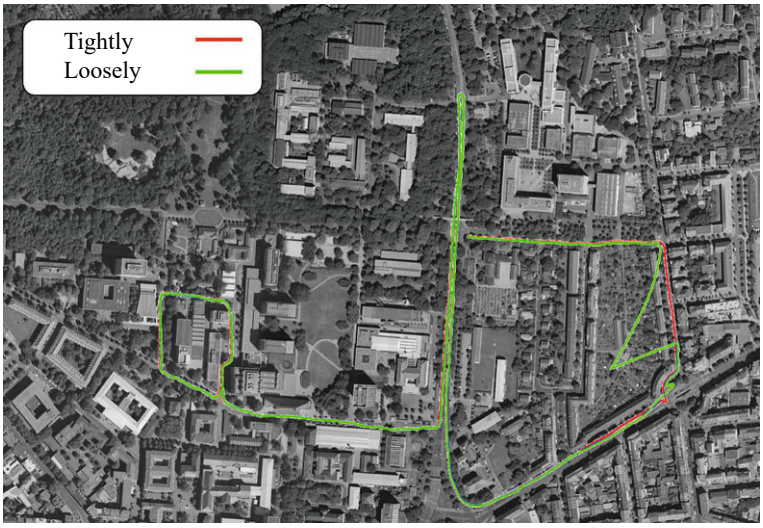

**Fig. 28.12** Navigation solutions of a loosely and tightly coupled GPS/INS system obtained by post-processing of recorded GPS and IMU data (courtesy of Stadt Karlsruhe, Liegenschaftsamt)

In contrast to the independent receiver tracking loops of the tightly and loosely coupled approaches, for the approaches depicted in Fig. 28.10, the code and carrier replica generation process within the receiver for all satellites is driven by the INS solution.

In each of Figs. 28.8, 28.9, and 28.10, the gray background indicates the portion of the system software that will be the concern of the INS designers. The gray background for Figs. 28.8 and 28.9 looks similar; however, the GPS processing portion of the software in the tightly coupled approach of Fig. 28.9 will be more involved than for the loosely coupled approach. The system software for the ultratightly coupled approach is significantly more involved and includes alteration of the GNSS internal receiver software (or firmware) that implements the carrier-phase and code tracking loops. Design of an ultratighlty or deeply coupled system typically requires collaboration between the INS and GNSS receiver design teams.

The advantages of the ultratightly coupled approach include the following. Accurate prediction of the satellite range and Doppler by the INS allows for faster and weaker signal acquisition. The INS allows the motion of the receiver antenna that is within the IMU bandwidth to be accounted for by the INS, outside the GPS receiver signal-tracking software; therefore, the bandwidth of the receiver tracking loops can be significantly decreased, which has benefits for noise reduction and lowering susceptibility to receiver jamming. Because the full vehicle bandwidth is within the bandwidth of the IMU, the approach also yields better satellite signal tracking during highly dynamic maneuvers. These factors generate en-

hanced accuracy, availability, and continuity at the expense of more advanced onboard processing.

### 28.8.4 Illustrative Comparison

To illustrate the performance differences between loosely and tightly coupled integration architectures, navigation solutions are compared that were obtained by a post-processing of GPS and MEMS IMU data that was recorded during a test drive. Post-processing assures that in both integration architectures, the identical sensor data was processed.

Figure 28.11 shows the position fixes provided by the GPS receiver during the test drive. On the right, a significant gap is visible between the position fixes. This was due to the fact that while driving along this street, the surrounding buildings blocked the view to some of the GPS satellites, so that the number of available satellites dropped below four.

Figure 28.12 shows the position solution using loose (green) and tight (red) integration architectures. Most of the time, architectures provide results that are indistinguishable at the scale of the image. However, during the aforementioned section of the test drive when less than four satellites are visible, the strapdown solution of the loosely coupled system remains unaided, as no GPS position fixes was available. Consequently, the position solution of the loosely coupled system drifts away from the true position (moving along the road). The error accumulation is smooth and its rate is determined by the quality of the IMU and the INS implementation. Once the GPS receiver is able to compute position again, the accumulated error is corrected and the state estimate snaps back to near the correct location. For the tightly coupled system, the pseudorange measurements from the two to three satellites that were still visible in this section of the test drive provided enough information to maintain an accurate position solution. Note that as the vehicle maneuvers, the actual satellites available at each epoch may change to correct the state in different directions.

## 28.9 Detailed Example

In the following, the design of a navigation filter for tight integration of GNSS and INS is sketched.

### 28.9.1 System Model

For the example design, the state vector

$$z = \left(\boldsymbol{p}^{\mathrm{n}}, \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}}, \mathrm{q}^{\mathrm{n}}_{\mathrm{b}}, \boldsymbol{b}_{\mathrm{a}}, \boldsymbol{b}_{\omega}, \boldsymbol{b}_{\mathrm{c}}\right)^{\top} \tag{28.55}$$

contains the rover position, velocity, attitude quaternion, accelerometer biases, gyroscope biases, and the receiver clock error vector $\boldsymbol{b}_{\mathrm{c}}$. The vector $\boldsymbol{b}_{\mathrm{c}}$ is composed of the receiver clock $ct_{\mathrm{r}}$ in meters and clock rate $c\dot{t_r}$ in m/s. This is a typical set of choices, which yields good performance for almost all applications and IMU grades. However, in some cases, it might be advantageous to add additional states to account for IMU SF and misalignment errors, time correlated errors such as those induced by vibrations, or time correlated GNSS ranging errors (e.g., code multipath).

The navigation system usually has two major components: the INS and the error estimator. The INS performs temporal updates by integrating the IMU data through the kinematic model to maintain the INS *total state vector* $\hat{z}$. As the INS integrates, for the various reasons already discussed, the uncertainty in the error between $z$ and $\hat{z}$ increases. The error estimator (Sects. 28.6 and 28.7) uses the aiding information to perform measurement updates that compute an estimate $\delta\hat{z}$ of the *error state vector*.

For this design example, the aiding information derives from GPS measurements and the error state vector is defined as

$$\delta z = \left(\delta\boldsymbol{p}^{\mathrm{n}}, \delta\boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}}, \boldsymbol{\psi}^{\hat{\mathrm{n}}}_{\mathrm{n}}, \delta\boldsymbol{b}_{\mathrm{a}}, \delta\boldsymbol{b}_{\omega}, \delta\boldsymbol{b}_{\mathrm{c}}\right)^{\top} .$$

In this definition, $\delta\boldsymbol{p}^{\mathrm{n}}$ are the position errors in the directions north, east, and down; $\delta\boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}}$ are the velocity errors in $n$-frame coordinates; $\boldsymbol{\psi}^{\hat{\mathrm{n}}}_{\mathrm{n}}$ is the three dimensional attitude error vector; $\delta\boldsymbol{b}_{\mathrm{a}}$ and $\delta\boldsymbol{b}_{\omega}$ are the errors of the accelerometer and gyroscope biases, respectively; and $\delta\boldsymbol{b}_{\mathrm{c}}$ is the vector composed of the receiver clock error $c\delta t_{\mathrm{r}}$ in meters and clock error drift rate $c\delta\dot{t}_{\mathrm{r}}$ in m/s.

The estimated error state $\delta\hat{z}$ is then used to correct the total system state $\hat{z}$. After this correction, the estimated error state vector is reset to zero. Such a configuration is known as error state feedback formulation, or error state closed loop formulation.

For the time propagation, the total system state is propagated by the SDA using IMU data. The error state time propagation is trivial. Having been set to zero after correcting the total states, the estimated error state remains zero when propagated forward in time. Therefore, the time propagation of the error state vector is not implemented. The error estimation algorithm does

propagate the error covariance matrix through time, by (28.11).

Note that the choice of reference frames for the various components of the total and error state vectors is completely independent. Similarly, the choice of attitude representations for the total and error state vectors is an independent choice. In this example, the attitude error vector is not a quaternion. The interpretation of the attitude error vector will be further discussed following (28.59).

The filter design requires a differential equation describing the dynamics of the error state. This differential equation is defined by differencing (28.1) and (28.6) and transforming to the appropriate reference frame. These equations are derived subsequently. To keep the derivations concise, terms which are not essential have been neglected. For example, for a system which processes GNSS measurements typically every second, but at least every few minutes, Coriolis error terms are small; velocity errors can be assumed to not be influenced by the position errors; and, the unit vector pointing from the GNSS antenna to a satellite can also be assumed to not be affected by position errors. All these simplifications have negligible impact on the filter performance. The neglected terms would become significant in the description of the long-term behavior of the navigation errors. Frequent updates from the GNSS measurements render these terms unnecessary.

### Position Error Differential Equation

The position error differential equations are derived from (28.44)–(28.46) for latitude, longitude and height, respectively. From these equations, it is obvious that the time derivative of the latitude depends on north velocity, height, and, via the radius of curvature in the north direction, also on latitude. Similar dependencies occur in longitude equation. However, following the reasoning of the previous section, the dependencies on position are weak and can be safely neglected. The resulting position error differential equation is

$$\delta\dot{\boldsymbol{p}}^{\mathrm{n}} = \delta\boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}} \,. \tag{28.56}$$

### Velocity Error Differential Equation

In the derivation of the velocity error differential equations, the Coriolis term in the velocity differential equation is neglected, leading to

$$\dot{\boldsymbol{v}}^{\mathrm{n}}_{\mathrm{eb}} \approx \mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} + \boldsymbol{g}^{\mathrm{n}} \,. \tag{28.57}$$

The equation for the estimated quantities can be similarly formulated as

$$\dot{\hat{\boldsymbol{v}}}^{\mathrm{n}}_{\mathrm{eb}} \approx \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} + \hat{\boldsymbol{g}}^{\mathrm{n}} \,. \tag{28.58}$$

We choose to model the relationship between the true and estimated attitude as

$$\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} = \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} \,. \tag{28.59}$$

Hereby, the attitude errors have been allocated to the navigation frame, the difference between true and estimated navigation frame is represented by the DCM $\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{n}}$. The attitude errors are assumed to be small; therefore, this DCM is expressed as

$$\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{n}} = (\mathbf{I} + [\boldsymbol{\psi}^{\hat{\mathrm{n}}}_{\mathrm{n}}\times]) = (\mathbf{I} + \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}}) \,, \tag{28.60}$$

where

$$\boldsymbol{\psi}^{\hat{\mathrm{n}}}_{\mathrm{n}} = (\alpha, \beta, \gamma)^{\top} \tag{28.61}$$

is the vector of attitude errors. This representation of the DCM is obtained by expressing the DCM as a sequence of small angle rotations and using the small angle approximations

$$\cos(\Delta) \approx 1 \text{ and } \sin(\Delta) \approx \Delta$$

in the DCM definition. Therefore, $\alpha$, $\beta$, and $\gamma$ can be interpreted as small angle errors around the navigation frame north, east, and down axes.

Substituting (28.60) into (28.59) leads to

$$\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} = (\mathbf{I} + \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}})\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} \,, \tag{28.62}$$

and

$$\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} = (\mathbf{I} - \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}})\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \,, \tag{28.63}$$

which follows from the orthonormality of the DCM and the fact that transposing a skew symmetric matrix changes the signs of the off-diagonal elements.

Defining the relationship between true and estimated specific force as

$$\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} = \boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} + \delta\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} \,, \tag{28.64}$$

the time derivative of the velocity errors is obtained by subtracting (28.57) from (28.58)

$$\begin{aligned}
\delta\dot{\boldsymbol{v}}^{\mathrm{n}}_{\mathrm{eb}} &= \dot{\hat{\boldsymbol{v}}}^{\mathrm{n}}_{\mathrm{eb}} - \dot{\boldsymbol{v}}^{\mathrm{n}}_{\mathrm{eb}} \\
&= \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} - (\mathbf{I} - \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}})\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\left(\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} - \delta\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}}\right) \\
&= \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} \\
&= -\left[\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}}\times\right]\boldsymbol{\psi}^{\hat{\mathrm{n}}}_{\mathrm{n}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} \,.
\end{aligned} \tag{28.65}$$

Now, the relationship between errors in specific force and quantities contained in the error state vector has to be established. The measured specific force is given by

$$\tilde{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} = \boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} + \boldsymbol{b}_{\mathrm{a}} + \boldsymbol{n}_{\mathrm{a}} \,, \tag{28.66}$$

where $\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}}$ is the true specific force, $\boldsymbol{b}_{\mathrm{a}}$ are the accelerometer biases, and $\boldsymbol{n}_{\mathrm{a}}$ is the noise corrupting the accelerometer measurements. If additional sensor errors like SFs or misalignments shall be estimated, this equation has to be augmented accordingly. An estimate of the specific force can be calculated from the measured specific force as follows

$$\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} = \tilde{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} - \hat{\boldsymbol{b}}_{\mathrm{a}} \,. \tag{28.67}$$

This leads to

$$\begin{aligned}
\delta\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} &= \hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} - \boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} \\
&= \left(\tilde{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} - \hat{\boldsymbol{b}}_{\mathrm{a}}\right) - \boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} \\
&= \left(\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} + \boldsymbol{b}_{\mathrm{a}} + \boldsymbol{n}_{\mathrm{a}} - \hat{\boldsymbol{b}}_{\mathrm{a}}\right) - \boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} \\
\delta\boldsymbol{f}^{\mathrm{b}}_{\mathrm{ib}} &= -\delta\boldsymbol{b}_{\mathrm{a}} + \boldsymbol{n}_{\mathrm{a}} \,,
\end{aligned} \tag{28.68}$$

and finally

$$\delta\dot{\boldsymbol{v}}^{\mathrm{n}}_{\mathrm{eb}} = \left[\hat{\boldsymbol{f}}^{\hat{\mathrm{n}}}_{\mathrm{ib}}\times\right]\boldsymbol{\psi}^{\hat{\mathrm{n}}}_{\mathrm{n}} - \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{b}_{\mathrm{a}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\boldsymbol{n}_{\mathrm{a}} \,, \tag{28.69}$$

where

$$\hat{\boldsymbol{f}}^{\hat{\mathrm{n}}}_{\mathrm{ib}} = \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{f}}^{\mathrm{b}}_{\mathrm{ib}} \,.$$

In this equation, the first two terms on the right hand side are time-varying linear functions of the error state vector. The last term shows how the (random) accelerometer measurement noise drives the error state. This will be discussed further in the summary portion of this section.

### Attitude Error Differential Equation

A simplified attitude error differential equation is obtained from an approximation of the DCM differential equation given by

$$\dot{\mathbf{C}}^{\mathrm{n}}_{\mathrm{b}} = \mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{nb}} \approx \mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{ib}} \,. \tag{28.70}$$

Again, a similar equation can be formulated for the estimated quantities

$$\dot{\mathbf{C}}^{\hat{\mathrm{n}}}_{\mathrm{b}} = \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{\Omega}}^{\mathrm{b}}_{\mathrm{nb}} \approx \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{\Omega}}^{\mathrm{b}}_{\mathrm{ib}} \,. \tag{28.71}$$

The time derivative of (28.59) is given by

$$\begin{aligned}
\dot{\mathbf{C}}^{\hat{\mathrm{n}}}_{\mathrm{b}} &= \frac{\mathrm{d}}{\mathrm{d}t}\left(\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\right) \\
&= \dot{\mathbf{C}}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{n}}\dot{\mathbf{C}}^{\mathrm{n}}_{\mathrm{b}} \\
&= \dot{\boldsymbol{\Psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{n}}\dot{\mathbf{C}}^{\mathrm{n}}_{\mathrm{b}} \,.
\end{aligned} \tag{28.72}$$

Inserting (28.71) yields

$$\begin{aligned}
\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{\Omega}}^{\mathrm{b}}_{\mathrm{ib}} &\approx \dot{\boldsymbol{\Psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{ib}} \,, \\
\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\hat{\boldsymbol{\Omega}}^{\mathrm{b}}_{\mathrm{ib}} &\approx \dot{\boldsymbol{\Psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{ib}} \,,
\end{aligned} \tag{28.73}$$

and finally (dropping second-order error terms)

$$\begin{aligned}
\dot{\boldsymbol{\Psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}}\mathbf{C}^{\mathrm{n}}_{\mathrm{b}} &\approx \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\left(\hat{\boldsymbol{\Omega}}^{\mathrm{b}}_{\mathrm{ib}} - \boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{ib}}\right), \\
\dot{\boldsymbol{\Psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}} &\approx \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{ib}}\left(\mathbf{C}^{\mathrm{n}}_{\mathrm{b}}\right)^{\top}, \\
\dot{\boldsymbol{\Psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}} &\approx \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{ib}}\left(\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\right)^{\top}\left(\mathbf{I} + \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}}\right), \\
\dot{\boldsymbol{\Psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}} &\approx \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{ib}}\left(\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\right)^{\top}.
\end{aligned} \tag{28.74}$$

This can be expressed without skew symmetric matrices

$$\dot{\boldsymbol{\psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}} \approx \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{\omega}^{\mathrm{b}}_{\mathrm{ib}} \,. \tag{28.75}$$

A derivation similar to that for (28.67) yields

$$\delta\boldsymbol{\omega}^{\mathrm{b}}_{\mathrm{ib}} = -\delta\boldsymbol{b}_{\omega} + \boldsymbol{n}_{\omega} \,, \tag{28.76}$$

which leads to the desired attitude error differential equation

$$\dot{\boldsymbol{\psi}}^{\hat{\mathrm{n}}}_{\mathrm{n}} \approx -\mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\delta\boldsymbol{b}_{\omega} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}}\boldsymbol{n}_{\omega} \,. \tag{28.77}$$

Similar to the velocity error differential equation, the first term is a time-varying linear functions of the error state vector. The last term shows how the (random) gyro measurement noise drives the error state. Such driving noise terms are referred to as *process noise*.

### Clock Error Differential Equation

A simple model for the receiver clock error is

$$\delta\dot{\boldsymbol{b}}_{\mathrm{c}} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}\delta\boldsymbol{b}_{\mathrm{c}} + \begin{pmatrix} \nu_{c\delta t} \\ \nu_{c\delta i} \end{pmatrix}, \tag{28.78}$$

where $\boldsymbol{\nu}_{\mathrm{cT}} = [\nu_{c\delta t}, \nu_{c\delta i}]^{\top}$ is a white Gaussian noise vector process [28.42].

#### Summary of Error Model

Summing up, the navigation filter system model in continuous time is given by

$$\dot{\delta z} = \mathbf{F}\delta z + \mathbf{G}\nu \,. \tag{28.79}$$

The system matrix is given by

$$\mathbf{F} = \begin{pmatrix} \mathbf{0} & \mathbf{I} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{F}_{23} & -\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & -\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{F}_{66} \end{pmatrix}, \tag{28.80}$$

where

$$\mathbf{F}_{23} = -\left[\hat{\boldsymbol{f}}_{\mathrm{ib}}^{\hat{\mathrm{n}}}\times\right] \text{ and } \mathbf{F}_{66} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}. \tag{28.81}$$

The process noise mapping matrix $\mathbf{G}$ is

$$\mathbf{G} = \begin{pmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ -\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I} \end{pmatrix}, \tag{28.82}$$

where the process noise vector is

$$\boldsymbol{\nu} = \left(\boldsymbol{n}_{\mathrm{a}}, \boldsymbol{n}_{\omega}, \boldsymbol{\nu}_{b_a}, \boldsymbol{\nu}_{b_\omega}, \nu_{\mathrm{cT}}\right)^{\top}. \tag{28.83}$$

In these equations, the inertial sensor biases are modeled as random walk processes with driving noise $\boldsymbol{\nu}_{b_a}$ and $\boldsymbol{\nu}_{b_\omega}$. Alternatively, the biases can be modeled by various other Gauss–Markov processes, the modification of the system matrix for this is straightforward.

Often, the error estimation filter is implemented via the Kalman filter. In addition to the above definitions of $\mathbf{F}$ and $\mathbf{G}$, the Kalman filter requires specification of the PSD matrix $\mathbf{Q}$ for the process noise vector $\boldsymbol{w}$. By (28.83) and the fact that the noise sources are independent, the matrix $\mathbf{Q}$ is block diagonal with five blocks. The four IMU blocks are determined from the Allan variance specifications for the IMU provided by its manufacturer. Specification of the block for the clock process noise is determined by the Allan variance parameters of the receiver clock. This is distinct from many other Kalman filter applications in which Kalman filter *tuning* is a time-consuming art.

### 28.9.2 Measurement Models

To complete this tightly coupled design example, models for GPS observables are required. We only include discussion of pseudorange and Doppler observables. Carrier-phase aiding can be achieved by similar methods, but is not discussed herein due to the complexities related to integer ambiguity resolution [28.43–46]. It should be noted that the measurements reported as Doppler measurements by many receivers are actually delta ranges computed over short time intervals. In such cases, more accurate estimation may be possible, especially during periods of acceleration, by more accurate models of the delta range observable; however, the resulting algorithms are more complicated to implement.

Because the IMU and GNSS antenna cannot be physically co-located, the position, velocity, and acceleration of these two items are distinct. Depending on the expected rover dynamics and the distance between the IMU and GPS antenna, it is sometimes necessary to consider this lever arm, $\boldsymbol{l}^{\mathrm{b}}$, in the aiding equations.

#### Influence of the Leverarm

The position of the GNSS antenna, $\boldsymbol{p}_{\mathrm{A}}^{\mathrm{n}}$, is related to the rover position, $\boldsymbol{p}_{\mathrm{U}}^{\mathrm{n}}$ (defined by the intersection of the sensitive axes of the inertial sensors), as follows

$$\boldsymbol{p}_{\mathrm{A}}^{\mathrm{n}} = \boldsymbol{p}_{\mathrm{U}}^{\mathrm{n}} + \mathbf{C}_{\mathrm{b}}^{\mathrm{n}}\boldsymbol{l}^{\mathrm{b}} \,. \tag{28.84}$$

With (28.63) this leads to

$$\boldsymbol{p}_{\mathrm{A}}^{\mathrm{n}} = \boldsymbol{p}_{\mathrm{U}}^{\mathrm{n}} + (\mathbf{I} - \boldsymbol{\Psi}_{\hat{\mathrm{n}}}^{\hat{\mathrm{n}}})\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}}\boldsymbol{l}^{\mathrm{b}} \,. \tag{28.85}$$

The estimated antenna position is

$$\hat{\boldsymbol{p}}_{\mathrm{A}}^{\mathrm{n}} = \hat{\boldsymbol{p}}_{\mathrm{U}}^{\mathrm{n}} + \mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}}\boldsymbol{l}^{\mathrm{b}} \,. \tag{28.86}$$

The error in rover position and rover attitude relate to the error in antenna position

$$\begin{aligned} \delta\boldsymbol{p}_{\mathrm{A}}^{\mathrm{n}} &= \hat{\boldsymbol{p}}_{\mathrm{A}}^{\mathrm{n}} - \boldsymbol{p}_{\mathrm{A}}^{\mathrm{n}} \\ &= \delta\hat{\boldsymbol{p}}_{\mathrm{U}}^{\mathrm{n}} + \boldsymbol{\Psi}_{\hat{\mathrm{n}}}^{\hat{\mathrm{n}}}\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}}\boldsymbol{l}^{\mathrm{b}} \\ &= \delta\hat{\boldsymbol{p}}_{\mathrm{U}}^{\mathrm{n}} - \left[\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}}\boldsymbol{l}^{\mathrm{b}}\times\right]\boldsymbol{\psi}_{\hat{\mathrm{n}}}^{\hat{\mathrm{n}}} \,. \end{aligned} \tag{28.87}$$

Equation (28.87) would also be the basis for processing position measurements in a loosely coupled system.

Similarly, the GNSS antenna velocity differs from the rover velocity depending on the length of the lever arm and the angular rate. With (28.63) and using the analog of the (28.67) for angular rates, the relationship between the velocity of the GNSS antenna and the rover can be expressed as

$$\begin{aligned} \boldsymbol{v}_{\mathrm{eA}}^{\mathrm{n}} &= \boldsymbol{v}_{\mathrm{eb}}^{\mathrm{n}} + \mathbf{C}_{\mathrm{b}}^{\mathrm{n}}(\boldsymbol{\omega}_{\mathrm{eb}}^{\mathrm{b}} \times \boldsymbol{l}^{\mathrm{b}}) \\ &= \boldsymbol{v}_{\mathrm{eb}}^{\mathrm{n}} + (\mathbf{I} - \boldsymbol{\Psi}_{\hat{\mathrm{n}}}^{\hat{\mathrm{n}}})\mathbf{C}_{\hat{\mathrm{b}}}^{\hat{\mathrm{n}}} \\ &\quad \left((\hat{\boldsymbol{\omega}}_{\mathrm{eb}}^{\mathrm{b}} - \delta\boldsymbol{\omega}_{\mathrm{eb}}^{\mathrm{b}}) \times \boldsymbol{l}^{\mathrm{b}}\right). \end{aligned} \tag{28.88}$$

An estimate of the GNSS antenna velocity is

$$\hat{\boldsymbol{v}}^{\mathrm{n}}_{\mathrm{eA}} = \hat{\boldsymbol{v}}^{\mathrm{n}}_{\mathrm{eb}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \left( \hat{\boldsymbol{\omega}}^{\mathrm{b}}_{\mathrm{eb}} \times \boldsymbol{l}^{\mathrm{b}} \right) , \tag{28.89}$$

leading to the following relationship between the errors in GNSS antenna velocity, rover velocity, rover attitude, and gyroscope biases

$$\begin{aligned} \delta \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eA}} &= \hat{\boldsymbol{v}}^{\mathrm{n}}_{\mathrm{eA}} - \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eA}} \\ &= \delta \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}} + \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}} \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \hat{\boldsymbol{\Omega}}^{\mathrm{b}}_{\mathrm{eb}} \boldsymbol{l}^{\mathrm{b}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \delta \boldsymbol{\Omega}^{\mathrm{b}}_{\mathrm{eb}} \boldsymbol{l}^{\mathrm{b}} \\ &= \delta \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}} - \left[ \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \hat{\boldsymbol{\Omega}}^{\mathrm{b}}_{\mathrm{eb}} \boldsymbol{l}^{\mathrm{b}} \times \right] \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}} - \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} [\boldsymbol{l}^{\mathrm{b}} \times] \delta \boldsymbol{\omega}^{\mathrm{b}}_{\mathrm{eb}} \\ &\approx \delta \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eb}} - \left[ \hat{\boldsymbol{\Omega}}^{\mathrm{n}}_{\mathrm{ib}} \boldsymbol{l}^{\mathrm{n}} \times \right] \boldsymbol{\Psi}^{\hat{\mathrm{n}}}_{\mathrm{n}} + \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} [\boldsymbol{l}^{\mathrm{b}} \times] \delta \boldsymbol{b}_{\omega} , \end{aligned} \tag{28.90}$$

where

$$\boldsymbol{l}^{\mathrm{n}} = \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \boldsymbol{l}^{\mathrm{b}} .$$

Equation (28.90) is also the basis for processing velocity measurements in a loosely coupled system.

With these provisions, the pseudorange and deltarange measurement models can be derived.

### Pseudorange Measurement

As described in Chap. 19, neglecting common mode errors (e.g., ephemeris, ionosphere, troposphere, and satellite clock), the measurement of the pseudorange $\rho_s$ to satellite $s$ can be modeled as

$$\tilde{\rho}_s = \left\| \boldsymbol{p}^{\mathrm{n}}_s - \boldsymbol{p}^{\mathrm{n}}_{\mathrm{A}} \right\| + c\delta t_r + v_\rho , \tag{28.91}$$

where $\boldsymbol{p}^{\mathrm{n}}_s$ denotes the satellite position in navigation frame coordinates and $v_\rho$ is the noise corrupting the pseudorange measurement. The total differential of (28.91) is

$$\delta \tilde{\rho}_s = \frac{\partial \rho_s}{\partial \boldsymbol{p}^{\mathrm{n}}_{\mathrm{A}}} \delta \boldsymbol{p}^{\mathrm{n}}_{\mathrm{A}} + \frac{\partial \rho_s}{\partial \boldsymbol{b}_{\mathrm{c}}} \delta \boldsymbol{b}_{\mathrm{c}} , \tag{28.92}$$

where $\delta \boldsymbol{b}_{\mathrm{c}}$ was defined in (28.55) and the derivatives evaluate to

$$\frac{\partial \tilde{\rho}_s}{\partial \boldsymbol{b}_{\mathrm{c}}} = [1\ 0] \quad \text{and} \quad \frac{\partial \tilde{\rho}_s}{\partial \boldsymbol{p}^{\mathrm{n}}_{\mathrm{A}}} = -\left[ \boldsymbol{e}^{\mathrm{n}}_s \right]^{\top} , \tag{28.93}$$

where $\boldsymbol{e}^{\mathrm{n}}_s$ is the unit line-of-sight vector between the antenna and satellite.

The measurement matrix $\mathbf{H}_\rho$ can be formulated using submatrices which describe the relationship between a pseudorange measurement and components of the filter state vector as

$$\mathbf{H}_\rho = \left( \mathbf{H}_{\rho,\boldsymbol{p}}, \mathbf{0}, \mathbf{H}_{\rho,\boldsymbol{\psi}}, \mathbf{0}, \mathbf{0}, \mathbf{H}_{\rho,\boldsymbol{ct_r}} \right) . \tag{28.94}$$

From (28.87) and (28.93), the submatrices of the pseudorange measurement matrix are

$$\mathbf{H}_{\rho,\boldsymbol{p}} = -\left[ \boldsymbol{e}^{\mathrm{n}}_s \right]^{\top} , \tag{28.95}$$

$$\mathbf{H}_{\rho,\boldsymbol{\psi}} = \left[ \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \boldsymbol{l}^{\mathrm{b}} \times \right] , \tag{28.96}$$

$$\mathbf{H}_{\rho,\boldsymbol{ct_r}} = [1\ 0]. \tag{28.97}$$

All other submatrices are zero vectors.

The residual measurement $\delta y$ processed in an error state space formulation is the difference between the actual measurement and the measurement prediction. For the pseudorange measurement, this evaluates to

$$\delta y_\rho = \tilde{\rho}_{\mathrm{i}} - \hat{\rho}_{\mathrm{i}} . \tag{28.98}$$

### Doppler Measurement

A Doppler measurement provides the relative velocity between GNSS antenna and satellite, projected onto the line-of-sight toward the satellite. As this is a measurement of the Doppler offset of the satellite signal, the frequency error of the receiver clock enters the deltarange measurement model

$$\dot{\rho}_s = \boldsymbol{e}^{\mathrm{n}}_s \cdot \left( \boldsymbol{v}^{\mathrm{n}}_{\mathrm{es}} - \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eA}} \right) + c\delta \dot{t}_r . \tag{28.99}$$

The total differential of (28.99) is

$$\delta \dot{\rho}_s = \frac{\partial \dot{\rho}_s}{\partial \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eA}}} \delta \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eA}} + \frac{\partial \dot{\rho}_s}{\partial \boldsymbol{b}_{\mathrm{c}}} \delta \boldsymbol{b}_{\mathrm{c}} , \tag{28.100}$$

where the derivatives evaluate to

$$\frac{\partial \dot{\rho}_s}{\partial \boldsymbol{v}^{\mathrm{n}}_{\mathrm{eA}}} = -\left( \boldsymbol{e}^{\mathrm{n}}_s \right)^{\top} , \tag{28.101}$$

and

$$\frac{\partial \dot{\rho}_s}{\partial \boldsymbol{b}_{\mathrm{c}}} = (0\ 1) . \tag{28.102}$$

Again, the Kalman filter measurement matrix can be formulated using submatrices as follows

$$\mathbf{H}_{\dot{\rho}} = \left( \mathbf{0}, \mathbf{H}_{\dot{\rho},\boldsymbol{v}}, \mathbf{H}_{\dot{\rho},\boldsymbol{\psi}}, \mathbf{0}, \mathbf{H}_{\dot{\rho},\boldsymbol{b}_\omega}, \mathbf{H}_{\dot{\rho},\boldsymbol{ct_r}} \right) . \tag{28.103}$$

From the derivatives in (28.101), (28.102), and (28.90), the submatrices are

$$\mathbf{H}_{\dot{\rho},\boldsymbol{v}} = -\left( \boldsymbol{e}^{\mathrm{n}}_s \right)^{\top} , \tag{28.104}$$

$$\mathbf{H}_{\dot{\rho},\boldsymbol{\psi}} = \left( \boldsymbol{e}^{\mathrm{n}}_s \right)^{\top} \left[ \hat{\boldsymbol{\Omega}}^{\mathrm{n}}_{\mathrm{ib}} \boldsymbol{l}^{\mathrm{n}} \times \right] , \tag{28.105}$$

$$\mathbf{H}_{\dot{\rho},\boldsymbol{b}_\omega} = -\left( \boldsymbol{e}^{\mathrm{n}}_s \right)^{\top} \mathbf{C}^{\hat{\mathrm{n}}}_{\mathrm{b}} \left[ \boldsymbol{l}^{\mathrm{b}} \times \right] , \tag{28.106}$$

$$\mathbf{H}_{\dot{\rho},\boldsymbol{ct_r}} = (0\ 1). \tag{28.107}$$

All other submatrices are zero. The residual measurement $\delta y$ processed in an error state space formulation for the Doppler measurement is

$$\delta y_{\dot{\rho}} = \tilde{\dot{\rho}}_{\mathrm{i}} - \boldsymbol{e}_s^{\mathrm{n}} \cdot \left( \boldsymbol{v}_{\mathrm{es}}^{\mathrm{n}} - \hat{\boldsymbol{v}}_{\mathrm{eA}}^{\mathrm{n}} \right) - c\delta\hat{\dot{t}}_r \,, \tag{28.108}$$

where $\hat{\boldsymbol{v}}_{\mathrm{eA}}^{\mathrm{n}}$ is given by (28.89) and $\tilde{\dot{\rho}}_{\mathrm{i}}$ represents the Doppler measurement.

### Navigation Correction

After processing the pseudorange and deltarange measurements available at the current epoch, the Kalman filter state vector contains estimated errors, which are used in closed-loop operation to correct the total quantities, thereby implementing *tight integration*.

Latitude, longitude, and height are corrected, respectively, using the following equations

$$\hat{\varphi}^{+} = \hat{\varphi}^{-} - \frac{\delta\hat{x}_{\mathrm{n}}^{+}}{R_{\mathrm{n}} - \hat{h}^{-}} \,, \tag{28.109}$$

$$\hat{\lambda}^{+} = \hat{\lambda}^{-} - \frac{\delta\hat{x}_{\mathrm{e}}^{+}}{(R_{\mathrm{e}} - \hat{h}^{-}) \cos\hat{\varphi}^{-}} \,, \tag{28.110}$$

$$\hat{h}^{+} = \hat{h}^{-} - \delta\hat{x}_{\mathrm{d}}^{+} \,. \tag{28.111}$$

The velocity is corrected using

$$\hat{\boldsymbol{v}}_{\mathrm{eb}}^{\mathrm{n},+} = \hat{\boldsymbol{v}}_{\mathrm{eb}}^{\mathrm{n},-} - \delta\hat{\boldsymbol{v}}_{\mathrm{eb}}^{\mathrm{n},+} \,. \tag{28.112}$$

From the estimated attitude error vector, a correction quaternion

$$\boldsymbol{\sigma}_{\mathrm{c}} = -\delta\hat{\boldsymbol{\psi}} \,, \tag{28.113}$$

$$\sigma_{\mathrm{c}} = \sqrt{\boldsymbol{\sigma}_{\mathrm{c}}^{\top}\boldsymbol{\sigma}_{\mathrm{c}}} \,, \tag{28.114}$$

$$\mathsf{q}_{\mathrm{c}} = \begin{pmatrix} \cos\frac{\sigma_{\mathrm{c}}}{2} \\ \frac{\boldsymbol{\sigma}_{\mathrm{c}}}{\sigma_{\mathrm{c}}} \sin\frac{\sigma_{\mathrm{c}}}{2} \end{pmatrix} \tag{28.115}$$

is calculated, which is used to correct the strapdown attitude quaternion

$$\hat{\mathsf{q}}_{\mathrm{b}}^{\mathrm{n},+} = \mathsf{q}_{\mathrm{c}} \cdot \hat{\mathsf{q}}_{\mathrm{b}}^{\mathrm{n},-} \,. \tag{28.116}$$

Finally, the biases and the receiver clock error estimates are corrected

$$\hat{\boldsymbol{b}}_{\mathrm{a}}^{+} = \hat{\boldsymbol{b}}_{\mathrm{a}}^{-} - \delta\hat{\boldsymbol{b}}_{\mathrm{a}}^{+} \,, \tag{28.117}$$

$$\hat{\boldsymbol{b}}_{\omega}^{+} = \hat{\boldsymbol{b}}_{\omega}^{-} - \delta\hat{\boldsymbol{b}}_{\omega}^{+} \,, \tag{28.118}$$

$$\boldsymbol{b}_{\mathrm{c}}^{+} = \hat{\boldsymbol{b}}_{\mathrm{c}}^{-} - \boldsymbol{c}\delta\dot{t}_{\mathrm{r}} \,. \tag{28.119}$$

As mentioned previously, after the estimated errors have been used to correct the total quantities, the error filter state vector is set to zero

$$\delta\boldsymbol{z}^{+} = \boldsymbol{0} \tag{28.120}$$

to avoid these estimated errors are being used again at the next measurement step.

### Implementation Aspects

When implementing an aided INS, some subtleties are important.

*Sequential Measurement Processing.* At each epoch, a varying number of pseudorange and deltarange measurements are available. For the Kalman filter processing of these measurements, two options exist. One option is to form a vector of all measurements, which is then processed in one single measurement update. The other option is to perform a scalar measurement update for each pseudorange and each deltarange measurement. The motivation for such sequential scalar measurement processing is that in the calculation of the Kalman gain matrix, using the standard EKF measurement update in (28.53) and (28.54), the matrix inversion reduces to a simple division. If all measurements are processed in one single step, a matrix with the number of rows equal to the number of available pseudoranges and deltaranges has to be inverted. This inversion is possible, but computationally more demanding. Alternatively, computation of the Kalman gain matrix can be avoided altogether by instead solving an appropriately weighted set of linear equations containing the prior and the measurement residuals [28.47, 48].

*Time of Measurement Validity.* The pseudorange and deltarange measurements are available for processing only after some delay (i. e., latency), typically between 50 and 200 ms. This delay is due to the time required for the receiver internal signal processing and the time required to transfer the data from the receiver to the navigation processor. Especially for high-speed or high-dynamics applications, this latency has to be considered. A very simple technique which usually delivers a close-to-optimal performance is to store the total navigation state at the time of validity of the measurements, and then to calculate the measurement residual for the Kalman filter when the measurements become available not based on the current rover state, but based on the rover state at the time of measurement validity. Denoting the current IMU epoch with the index $k$ and assuming that the measurements were valid $n$ IMU epochs in the past, the Kalman filter state vector update in the error state space formulation is given with this technique by

$$\delta\boldsymbol{z}_k^{+} = \delta\boldsymbol{z}_k^{-} + \mathbf{K}_k \left[ (\hat{\boldsymbol{y}}_{k-n} - \tilde{\boldsymbol{y}}_{k-n}) - \mathbf{H}_k \delta\boldsymbol{z}_k^{-} \right] . \tag{28.121}$$

Note that $\delta\boldsymbol{z}_k$ in this equation is really the correction valid at $(k-n)$. The time propagation of the error state vector from $(k-n)$ to $k$ has been neglected. For higher fidelity, this time propagation is easily accomplished using $n$ iterations of the error state transition matrix as defined in (28.10).

*Detection of Outliers.* It should be noted that prior to processing any type of measurement, a health check should be performed to identify and reject outliers (aiding measurements, IMU data, and model mismatch).

A simple but effective approach to detect outliers in the aiding measurements is to calculate the squared weighted norm of the residual vector $\boldsymbol{r}$ and compare it to a threshold. The observed measurement vector is then considered unlikely, and ignored, when

$$||\boldsymbol{r}||^2_{\mathbf{S}} = \boldsymbol{r}^\top \mathbf{S}^{-1} \boldsymbol{r} \geq \chi^2_\alpha(q, 0) \,, \tag{28.122}$$

where

$$\boldsymbol{r} = \tilde{\boldsymbol{y}} - \hat{\boldsymbol{y}} \,,$$

with covariance

$$\mathbf{S} = (\mathbf{H}\mathbf{P}\mathbf{H}^\top + \mathbf{R}) \,,$$

and $\chi^2_\alpha(q, 0)$ is the threshold computed from the central Chi-squared distribution with $q = \dim(\boldsymbol{r})$ degrees of freedom (Chap. 24).

Outlier detection using the squared Mahalanobis distance $||\boldsymbol{r}||^2_{\mathbf{S}}$ only works well when the covariance matrices $\mathbf{P}$ and $\mathbf{R}$ are accurate statistical representations for the actual errors of the state estimate and measurement errors. The Kalman filter designer should always check, in simulations, that performance is adequate under diverse conditions. A conservative filter tuning (i. e., $\mathbf{P}$ is larger than the covariances of the actual errors), is – within some range – usually not such a big problem, maybe some accuracy is lost; however, $\mathbf{P}$ being too small can cause the measurements to be weighted too little; the filter relies too much on its state estimate, and finally diverges. To check that a filter is implemented properly, especially, the quantities that are not measured directly (e.g., attitude and inertial sensor biases) need to be investigated. The position and velocity errors in a GNSS/INS system are largely dominated by the accuracy of the GNSS measurements, so flaws in the implemented system model might not be visible from these errors, whereas they clearly show in the attitude and bias estimates.

*Yaw Angle Observability.* A system is said to be observable, if it is possible to estimate the system state from the available measurements [28.19]. For example, consider a simple system where the system state contains position and velocity. If a series of position measurements is available, the system is observable, because position is measured directly and velocity can be inferred from the time history of position measurements. If only velocity measurements are available, the system is unobservable: velocity is measured directly, but it is not possible to obtain an estimate of position from velocity measurements only.

For GNSS/INS systems, observability depends on the trajectory characteristics. For a moment, to allow a straightforward discussion, assume that the accelerometer biases are zero. We also drop the additive noise, as it has no effect on observability. According to (28.69), the relationship between a change in velocity errors and the attitude errors is

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\delta v_\mathrm{n}\\ \delta v_\mathrm{e}\\ \delta v_\mathrm{d}\end{pmatrix} = \begin{pmatrix}0 & \hat{f}_\mathrm{d} & -\hat{f}_\mathrm{e}\\ -\hat{f}_\mathrm{d} & 0 & \hat{f}_\mathrm{n}\\ \hat{f}_\mathrm{e} & -\hat{f}_\mathrm{n} & 0\end{pmatrix}\begin{pmatrix}\alpha\\ \beta\\ \gamma\end{pmatrix}, \tag{28.123}$$

where $\hat{f}_\mathrm{n}$, $\hat{f}_\mathrm{e}$, and $\hat{f}_\mathrm{d}$ are the components of the specific force vector in the north, east, and down directions, respectively. Looking at the specific force skew symmetric matrix, it is found that a yaw error $\gamma$ can only affect the velocity error vector when the specific force in east or north directions is nonzero, respectively. The velocity errors are observable from position and/or velocity measurements, or from a sufficiently diverse set of pseudorange and/or deltarange measurements in the case of a tightly coupled system. However, when the horizontal specific force components $(f_\mathrm{n}, f_\mathrm{e})$ are zero, the yaw angle error cannot affect the velocity errors, and is therefore unobservable. As a consequence, for any GNSS/INS system that is at rest or in nonaccelerating motion (e.g., straight and level flight), the uncertainty in the yaw angle error will grow with time. If such a situation is expected, two options exist, either the accuracy of the gyros must be sufficient so that the growth in yaw error with time is not a problem for the expected duration without horizontal accelerations, or additional sensors have to be used which provide yaw angle observability, for example, a magnetometer or feature sensor.

Equation (28.123) would seem to imply that the tilt errors $(\alpha, \beta)$ are observable due to $\hat{f}_\mathrm{d}$ being nonzero because of gravity; however, this is not the case. It is only an artifact of the simplifying assumption stated to derive that equation. When the biases are not zero, analysis starting from the original equations shows that the tilt errors cannot be distinguished from the accelerometer bias errors, unless the specific force vector changes sufficiently (e.g., acceleration occurs). However, position or velocity measurements drive the linear combination of tilt and accelerometer bias errors to an unobservable space, on which they have no effect on those position and velocity measurements [28.20, 49, 50].

In free fall, the specific force is zero, so the attitude would be unobservable from position and velocity measurements. Similarly, for a satellite in orbit, the specific force is zero, so for a GNSS/INS system onboard a satellite, attitude would be completely unobservable. For satellites, start trackers are frequently used to achieve attitude observability.

## 28.10 Alternative Estimation Methods

This section briefly discusses various alternative GNSSs related state estimation approaches in comparison to the GNSS-aided INS approach that has been the main topic of this chapter.

### 28.10.1 Standalone GNSS

The topic of this section is state estimation based only upon GNSS, without IMU. This topic is thoroughly covered in Chap. 21 so this discussion only includes the detail necessary to allow comparison with GNSS-aided INS. The discussion will focus on pseudorange processing, but the ideas directly extend to carrier-phase and Doppler processing.

Any time at which the GNSS receiver has measured pseudorange $\tilde{\boldsymbol{\rho}} \in \mathbb{R}^{n_s}$ from at least $n_s \geq 4$ satellites, it can solve

$$\tilde{\boldsymbol{\rho}} = \boldsymbol{h}(\boldsymbol{x}) + \eta_{\boldsymbol{\rho}} \,, \tag{28.124}$$

for $\boldsymbol{x} = [\boldsymbol{p}, ct_r] \in \mathbb{R}^4$, where $\boldsymbol{p}$ is the GNSS receiver antenna position, $ct_r$ is the receiver clock bias, and $\eta_{\boldsymbol{\rho}} \sim N(\mathbf{0}, \mathbf{R})$.

Equation (28.124) is often solved using iterative weighted least squares (WLS). Starting with an estimate $\hat{\boldsymbol{x}}$, the receiver predicts

$$\hat{\boldsymbol{\rho}} = \boldsymbol{h}(\hat{\boldsymbol{x}})$$

and computes the residual measurement

$$\delta\boldsymbol{\rho} = \tilde{\boldsymbol{\rho}} - \hat{\boldsymbol{\rho}} \,.$$

The correction $\delta\boldsymbol{x}$ satisfies the normal equation

$$\mathbf{H}^\top \mathbf{R}^{-1} \mathbf{H} \delta\boldsymbol{x} = \mathbf{H}^\top \mathbf{R}^{-1} \delta\boldsymbol{\rho} \,, \tag{28.125}$$

where $\mathbf{H} \in \mathbb{R}^{n_s \times 4}$ is defined in (28.52). Given the solution $\delta\boldsymbol{x}$, the estimate is corrected as

$$\hat{\boldsymbol{x}} = \hat{\boldsymbol{x}} + \delta\boldsymbol{x} \,. \tag{28.126}$$

This process of measurement prediction and state correction repeats, using the same measurement, until $\delta\boldsymbol{x}$ is sufficiently small. This solution method fails when the rank of $\mathbf{H}$ is less than four.

Even though the noise on each of the individual pseudorange measurements is uncorrelated with the noise on other pseudorange measurements at a given time instant, the solution of (28.125) results in the estimated state vector having cross-correlated components. The error covariance of the solution is

$$\text{cov}(\hat{\boldsymbol{x}}) = \left(\mathbf{H}^\top \mathbf{R}^{-1} \mathbf{H}\right)^{-1} \,. \tag{28.127}$$

Most receivers do not output this matrix, especially the off-diagonal elements. Instead, receivers use certain portions of the diagonal of this matrix to compute HDOP, position dilution of precision (PDOP), vertical dilution of precision (VDOP), and so on. Lack of access to this matrix complicates the design of loosely coupled systems.

The pseudorange measurement error $\eta_{\boldsymbol{\rho}}$ accounts for various error sources. Depending on the application scenario, the error sources can include atmospheric delay, ephemeris model errors, multipath, and noise. Because the first three of these errors are time correlated, the position estimation error will also be time correlated. Equation (28.127) accounts only for the error at a single time instant, not the time correlation of the error. For a stationary receiver, the correlation time of the multipath error is significant over minutes. In such a scenario, faster sampling does not allow averaging to decrease the effects of such errors. For a moving receiver, the time correlation properties of the multipath effects are highly variable.

To enable the GNSS receiver to output a position estimate even when $n_s < 4$ and to filter noise, many GNSS receivers include a navigation filter. The filter time propagation equations are

$$\hat{\boldsymbol{x}}_{k+1}^- = \boldsymbol{\Phi} \hat{\boldsymbol{x}}_k^+ \,, \tag{28.128}$$

$$\hat{\mathbf{P}}_{k+1}^- = \boldsymbol{\Phi} \mathbf{P}_k^+ \boldsymbol{\Phi}^\top + \mathbf{Q}_\text{d} \,. \tag{28.129}$$

The filter measurement updates equations are

$$\hat{\mathbf{K}}_k = \hat{\mathbf{P}}_k^- \hat{\mathbf{H}}_k^\top \left(\hat{\mathbf{H}}_k \hat{\mathbf{P}}_k^- \hat{\mathbf{H}}_k^\top + \mathbf{R}_k\right)^{-1} \,, \tag{28.130}$$

$$\hat{\mathbf{P}}_k^+ = \left(\mathbf{I} - \hat{\mathbf{K}}_k \hat{\mathbf{H}}_k\right) \hat{\mathbf{P}}_k^- \,, \tag{28.131}$$

$$\hat{\boldsymbol{x}}_k^+ = \hat{\boldsymbol{x}}_k^- + \mathbf{K}_k \left(\tilde{\boldsymbol{\rho}}_k - \hat{\boldsymbol{\rho}}_k\right) \,. \tag{28.132}$$

These equations implement a Kalman filter. However, it is difficult to claim that this Kalman filter has any optimality properties relative to an actual system assumed to be modeled by

$$\boldsymbol{x}_{k+1} = \boldsymbol{\Phi} \boldsymbol{x}_k + \boldsymbol{v}_k \,, \tag{28.133}$$

because there is no physical basis for defining the filter parameters $\boldsymbol{\Phi}$ and $\mathbf{Q}_\text{d} = \text{cov}(\boldsymbol{v}_k)$ at the point in time when the receiver is designed. A typical method to address this issue is to allow the user some flexibility in the specification of $\boldsymbol{\Phi}$ and $\mathbf{Q}_\text{d}$. Three typical options are the P, PV, and PVA models.

### Position

In cases where the position (P) is modeled as a random walk

$$\mathbf{\Phi} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{\Phi}_c \end{bmatrix}, \tag{28.134}$$

$$\boldsymbol{x} = \left[\boldsymbol{p}^\top, \boldsymbol{x}_c^\top\right]^\top, \tag{28.135}$$

$$\mathbf{Q}_d = \mathrm{diag}([\mathbf{Q}_p, \mathbf{Q}_c]), \tag{28.136}$$

where the receiver manufacturer specifies the clock model parameters $\mathbf{\Phi}_c$ and $\mathbf{Q}_c$. This model assumes that the antenna velocity can be accurately modeled as a white random process with constant covariance $\mathbf{Q}_p$ for all times.

### Position–Velocity (PV)

When the receiver is in uniform motion (i. e., slowly varying velocity), performance is improved by including velocity states in the model

$$\mathbf{\Phi} = \begin{bmatrix} \mathbf{I} & T\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{\Phi}_c \end{bmatrix}, \tag{28.137}$$

$$\boldsymbol{x} = \left[\boldsymbol{p}^\top, \boldsymbol{v}^\top, \boldsymbol{x}_c^\top\right]^\top, \tag{28.138}$$

$$\mathbf{Q}_d = \mathrm{diag}([\mathbf{Q}_{pv}, \mathbf{Q}_c]), \tag{28.139}$$

where $T$ is the time step between GNSS measurements. This model assumes that the antenna acceleration can be accurately modeled as a white random process yielding a constant covariance $\mathbf{Q}_{pv}$ for all times. Ideally, $\mathbf{Q}_{pv}$ would be selected to accurately quantify the *random* variation in $\boldsymbol{v}$ over all times; however, this is not feasible given that in most applications this variation is not a stationary random process. Therefore, in reality, specification of the value of $\mathbf{Q}_{pv}$ is a tuning process for each specific application. Since a stationary stochastic model is being *fit* to a nonstationary process, a rigorous specification approach cannot be expected.

### Position–Velocity–Acceleration (PVA)

When the velocity cannot reasonably be modeled to be constant, then an acceleration state can be added in each of the three orthogonal directions. Instead of a pure random walk, the acceleration is usually modeled as a scalar Gauss–Markov process (i. e., low frequency, colored noise). This model is reasonable because accelerations are not usually constant, but are correlated over short time intervals. The resulting dynamic model has

$$\mathbf{\Phi} = \begin{bmatrix} \mathbf{I} & T\mathbf{I} & \mu_1\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} & \mu_2\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mu_3\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{\Phi}_c \end{bmatrix} \tag{28.140}$$

$$\boldsymbol{x} = \left[\boldsymbol{p}^\top, \boldsymbol{v}^\top, \boldsymbol{a}^\top, \boldsymbol{x}_c^\top\right]^\top \tag{28.141}$$

$$\mathbf{Q}_d = \mathrm{diag}([\mathbf{Q}_{pva}, \mathbf{Q}_c]) \tag{28.142}$$

where

$$\lambda > 0\,,$$
$$\mu_1 = \frac{(\mu_3 - 1 + \lambda T)}{\lambda^2}\,,$$
$$\mu_2 = \frac{(1 - \mu_3)}{\lambda}\,, \quad \text{and}$$
$$\mu_3 = \exp(-\lambda T)\,.$$

The process driving noise $\boldsymbol{v}_k$ accounts for the *random* variations in the acceleration. Ideally, $\mathbf{Q}_{pva}$ would be selected to accurately quantify the *random* variation in $\boldsymbol{a}$ over all times; however, as stated above for $\mathbf{Q}_{pv}$, this is not feasible due to the nonstationarity of the acceleration process. Instead, a value of $\mathbf{Q}_{pva}$ is selected that provides a reasonable (i. e., compromise) performance under the expected range of acceleration conditions.

### Comparison

The purpose of this section is to discuss a few points important in the design of GNSS-aided INS systems.

First, the Kalman filter in the GNSS receiver is designed by tuning the model choice (e.g., P, PV, and PVA) and parameters $\mathbf{Q}_d$ to yield a satisfactory performance tradeoff. In all cases, there is no rigorous method to select $\mathbf{Q}_p$, $\mathbf{Q}_{pv}$, or $\mathbf{Q}_{pva}$. The receiver may allow some user choices, such as high, medium, or low dynamics; however, there should be no misconception that this is an accurate model of the dynamic process over all times. The resulting receiver navigation filter is not optimal and has no stochastic interpretations. The filter gain $\mathbf{K}$ could just as well have been designed by other methods, such as pole-placement. In particular, the matrix $\mathbf{P}$ does not indicate the covariance of the estimation error.

Second, if $n_s < 4$, then the navigation filter can still incorporate the information from the available measurements using (28.130)–(28.132). This corrects the state in certain directions while allowing the uncertainty to increase in the other directions.

Third, over time intervals without GNSS measurements, the state trajectory can be estimated by iterating (28.128) and (28.129). However, this prediction should

be considered carefully. The P-model will predict the current position estimate forward in time, regardless of the actual antenna motion. The PV-model will make a linear prediction using the current position and velocity estimates, regardless of the actual antenna motion. The PVA-model will make a parabolic prediction using the current position, velocity, and acceleration estimates, regardless of the actual antenna motion.

Using the GNSS receiver's filtered output to aid an INS in such a situation is clearly inappropriate, because the IMU provides the INS with information unavailable to the GNSS receiver. Even when $n_s \geq 4$, the GNSS receiver's internal navigation filter is problematic for INS aiding applications: the GNSS navigation internal filter should be disabled. The INS computation of the vehicle trajectory, based on the IMU inputs using (28.7), will be much more responsive than the estimates of the GNSS receivers internal filter. The bandwidth of the INS trajectory estimation is determined by the bandwidth of the IMU and in a proper design is much higher than the bandwidth of the vehicle motion. The bandwidth of the GNSS receiver trajectory estimate is determined by the bandwidth of the receiver tracking loops, the receiver sample time, and the hypothesized receiver navigation filter parameters $\mathbf{\Phi}$ and $\mathbf{Q}_d$. The GNSS receiver bandwidth is typically much lower than the INS or vehicle bandwidth. Taking GNSS measurements at a higher rate does not alleviate the issues.

## 28.10.2 Advanced Bayesian Estimation

The MAP estimate of the trajectory

$$\mathbf{Z} = \{z(t) \text{ for } t = t_0, \ldots, t_K\}$$

maximizes the cost function [28.37, 51–53]

$$J(\mathbf{Z}) = \left(p_{z_0}(z(t_0)) p_{\eta_y}(\mathbf{Y} - \boldsymbol{h}(\mathbf{Z})) \right. \\ \left. p_{\nu_u}(\mathbf{Z}_+ - \boldsymbol{\phi}(\mathbf{Z}, \mathbf{U})|z_0)\right), \qquad (28.143)$$

where

$$z(t_0) \sim \mathrm{N}(z_0, \mathbf{P}_0)$$

is the prior distribution of the initial state,

$$\mathbf{Z}_+ = \{z(t) \text{ for } t = t_1, \ldots, t_K\} ,$$
$$\mathbf{Y} = \{\boldsymbol{y}(t) \text{ for } t = t_1, \ldots, t_M\}$$

is the set of all GNSS measurements from the initial to the present time, $\mathbf{U} = \{\boldsymbol{u}(t) \text{ for } t = \tau_1, \ldots, \tau_K\}$ is the set of IMU measurements from the initial to the present time, and the operator $\boldsymbol{\phi}$ is defined in (28.7). This formulation assumes that $\boldsymbol{x}(t_0)$, $\boldsymbol{\nu}_u$, $\boldsymbol{\nu}_{c_u}$, $\boldsymbol{\nu}_{c_y}$, and $\boldsymbol{\eta}_y$ are all mutually independent.

Direct maximization of (28.143) is complicated by various factors. First, each $\boldsymbol{x}(t_k) \in \mathbb{R}^n$ and $n \geq 15$. Second, the number of time instances $K$ grows without bound as the duration of an application increases. In addition, the IMU time $\tau$ is small, the total number of GNSS measurements $M$ increases with $K$, and the number of GNSS measurements per time step is time-varying. Third, the kinematic model $\boldsymbol{f}$ and the measurement models $\boldsymbol{h}$ are nonlinear. Fourth, in general the various probability density functions can be non-Gaussian and multimodal.

The EKF, which has been the focus of this chapter, is only one approximate solution of the nonlinear Bayesian estimation problem. The EKF is designed based on linearized error models and uses the assumption that the various noise sources are normally distributed. Normal noise distributions are reasonably valid for GPS and IMU sensors. Linearized error models are discussed further below.

### Particle and Unscented Filtering

The particle filter (PF) and unscented Kalman filter are two other approximate solutions that have become popular. The PF approximates the probability density function of the state estimate with a set of probability-weighted particles. Each particle is an instance of the state vector. Each particle is propagated through time using the kinematic model. The probabilistic weights are adjusted using the measurement model. Detailed descriptions of each of these steps are presented in [28.14, 38]. The PF is expected to be more accurate than the EKF when the EKF linearization and normal density assumptions are not valid. For example, if the density is multimodal or if the model second derivatives are significant relative to the uncertainty of the state estimate. The computational cost of the PF is related to the number of particles. The number of particles required for an accurate representation of the density function grows exponentially with the dimension of the state vector. Due to the INS state vector having dimension 15 or larger, the number of particles is large enough that PFs typically are not used.

Once the state is initialized, the state error covariance is typically small enough that the neglected second derivatives of the EKF approach have little impact; therefore, a main issue is getting past the initialization step. In particular, the accuracy of the attitude is important, especially yaw. Traditional means to initialize the state for military applications include in-flight alignment or gyro compassing. Lower cost and commercial applications typically use GNSS and an electronic compass, with the accelerometer serving as an inclinometer at initialization. Another approach is to use real-time smoothing as outlined in the next subsection.

### Realtime Nonlinear Bayesian Estimation

Recent advances in the field robotics literature for the real-time solution of the simultaneous location and mapping (SLAM) problem using a formulation similar to that of (28.143) have interesting utility in the GNSS-aided INS field.

The likelihood function corresponding to the cost function of (28.143) reduces to the nonlinear least squares function

$$\begin{aligned}\|\boldsymbol{v}\|^2_{\mathbf{W}} = &\|\boldsymbol{z}(t_0)-\boldsymbol{z}_0\|^2_{\mathbf{P}_0} \\ &+\sum_k \|\boldsymbol{\phi}\left(\boldsymbol{x}(t_k),\boldsymbol{U}_k\right)-\boldsymbol{x}(t_{k+1})\|^2_{\mathbf{Q}_k} \\ &+\sum_j \|\boldsymbol{h}\left(\boldsymbol{z}(t_j)\right)-\tilde{\boldsymbol{y}}(t_j)\|^2_{\mathbf{R}_{y_j}}\,, \end{aligned} \tag{28.144}$$

where the optimization variable is the portion of the system trajectory contained in Z. The vector $\boldsymbol{v}$ is the concatenation of each of the vectors summed in the right-hand side of (28.144) and $\mathbf{W}$ is the positive definite block diagonal matrix formed by the positive definite submatrices $\mathbf{P}_0$, $\mathbf{Q}_k$, and $\mathbf{R}_{y_j}$. The quantity

$$\|\boldsymbol{v}\|^2_{\mathbf{W}} = \boldsymbol{v}^\top \mathbf{W}^{-1}\boldsymbol{v}$$

is the squared Mahalanobis distance defined based on the matrix $\mathbf{W}$. The reduction of the cost function from (28.143) to (28.144) relies on the reasonable and standard assumptions that $\boldsymbol{\nu}_u \sim \mathrm{N}(\mathbf{0},\mathbf{Q}_d)$, $\boldsymbol{n}_y \sim \mathrm{N}(\mathbf{0},\mathbf{R}_y)$, and $\boldsymbol{x}(t_0) \sim \mathrm{N}(\boldsymbol{x}_0,\mathbf{P}_0)$.

Efficient algorithms for real-time solution of (28.144) are presented, for example, in [28.47, 48]. In the SLAM literature, accurate estimation of the entire rover trajectory is of interest, as it is necessary for the accurate estimation of the landmark feature map.

In GNSS-aided INS applications, the same techniques applied over short duration (e.g., 30 s) time windows containing recent measurements have utility for different objectives: detection of faulty or spoofed satellite signals, detection of multipath, detection of IMU faults, and INS initialization to name just a few. In such applications, the measurement sets $Z$, $Y$, and $U$ are defined to contain a recent window of measurement, that is, all measurements for $t_k \in [t-M, t]$. In this approach, all measurements prior to $t-M$ have been deemed valid (or discarded) by prior processing so that $\hat{\boldsymbol{z}}(t-M)$ is accurate with known error covariance. Realtime minimization of (28.144) provides the necessary state estimate, while also allowing comprehensive analysis of the residuals relative to the stated assumptions. Such methods have the ability to enhance the availability and continuity of solutions with high integrity. Related fault detection methods have a long history in the navigation literature [28.54], but mostly are applied at only the most recent point in time. Such present time approaches have the limitation that the effect of the fault on the navigation solution cannot be removed, if the fault is not detected at the time when it occurs. Alternatively, evaluation over a sliding window of recent measurements offers an enhanced ability to detect faults within the window as well as the capability to recompute a fault-free solution to the navigation problem when a fault is detected within the interior of the temporal window. This approach is applied in [28.55, 56] where compass-free initialization of a low cost INS is demonstrated. These methods have only recently become practical due to the increased performance and decreased cost of computation.

## 28.11 Looking Forward

This chapter began with the notion that the cost of sensors and computation was rapidly decreasing, whereas the capabilities of both were rapidly increasing. In addition, the number of independent GNSS's and their capabilities are rapidly increasing. GPS modernization is only one example of the increased number of signals and signal strength that is becoming available. These various factors taken together indicate a very bright future for the accuracy, integrity, and availability of navigation systems at cost points low enough for new and rapidly evolving commercial applications. Finally, there are several opportunities for aiding by non-GNSS sources: feature aiding via RADAR, light detection and ranging (LIDAR), or vision; digital communications-based ranging by DTV, digital radio, or cell phone (signals of opportunity (SOO)). In addition, some of these alternative signals, such as cell phones, are becoming reliable sources for communication of real-time GNSS differential corrections.

At the same time, recreational, commercial, sporting, and military users have all had a small sample of the interesting new applications possible from reliable and accurate real-time navigation solutions. Some of these applications – for example, autonomous vehicles, safety-augmentation systems, or manned safety-of-life systems – require high levels of integrity with predictive indicators of certain accuracy specification violations.

GNSS-aided inertial systems are the dominant technology with a bright future for such applications.

A current challenge for all existing approaches is the detection and mitigation of spoofing. This is one challenge that may be addressable by integration of information from various sources, including GNS, IMU, vision, radar, signals-of-opportunity, and so on.

# 29. Land and Maritime Applications

Allison Kealy, Terry Moore

This chapter presents an overview of applications of global navigation satellite systems (GNSS) relevant to the land and maritime environments. It focuses on the positioning performance requirements, technologies, developments, and trends for current and projected growth areas for GNSS in the land, rail, and maritime transport sectors. Representative applications including: personal navigation, location-based services, maritime, and land-based intelligent transport systems, railway logistics, and maritime operations are showcased as they encompass overlapping and related tasks such as fleet and asset monitoring, cooperative mobility, autonomous and precise navigation, vehicle and machinery control, and others.

Applications across the land and maritime domains have traditionally been classified as high end or low end, where these two classes are distinguished primarily by their accuracy requirements. High-end applications such as land and hydrographic surveying (Chap. 35) or geodesy and mapping (Chap. 36) have positioning accuracy requirements at the centimeter or subcentimeter level and low-end applications such as personal navigation (PN) and other mass-market (consumer-level) applications are satisfied with accuracies at the meter, submeter or even tens of meters level. The pervasiveness and convenience of global navigation satellite systems (GNSS), combined with an increasing recognition of the value of positioning accuracy, has created an unprecedented demand for better levels of GNSS performance, blurring the distinction between high- and low-end applications. Significantly, with the increasing ubiquity of GNSS and mounting concerns surrounding the vulnerability of GNSS, applications are now being classified as safety-liability-critical or nonsafety-liability-critical, where positioning needs have extended well beyond that of just accuracy. Parameters such as positioning integrity, reliability, continuity, and availability have emerged as the key performance metrics underpinning the technologies and techniques selected for individual applications. In this chapter, definitions for these parameters are adapted from [29.1]. Accuracy is defined as the degree of conformance of an estimated or measured position at a given time to a reference value. Reliability refers to the ability of the system to detect blunders in the measurements and to estimate the effects of undetected blunders on the position solution. Integrity refers to the probability (per operation or per unit of time) that the system generates an unacceptable error also without providing a timely and valid warning to users that the system must not be used for the intended operation. Availability is the percentage of time the system is able to provide solutions within specified accuracy, reliability, and integrity thresholds. Continuity refers to the probability that the system will stop providing position outputs of the specified quality during a given operation or time interval.

According to the GNSS market monitoring report published by the European GNSS Agency

(GSA) [29.2], by 2019 there will be on average, one GNSS receiver in use for every person on the planet. This trend is driven by the enhanced performance capabilities and competitive pricing of smartphones and tablets. With the increasing pervasiveness of mobile, location-enabled devices, new applications are continually being introduced as both consumers and industry sectors recognize the efficiencies that can be gained from knowing where things are. It would be unfeasible to provide a complete study of all of these applications in a single chapter. This chapter therefore focuses on current and projected growth areas in land-based and maritime applications of GNSS. It is divided into three sections.

In the first section, land-transport applications are presented. It introduces the state of the art in PN systems and the trends in location-based services (LBS) brought about by the increasing ubiquity of mobile devices including smartphones and tablets. Positioning technologies and techniques that address some of the vulnerabilities of GNSS for applications that leverage the location-aware capabilities of current generation smartphones are also presented. Following on from this, intelligent transport systems (ITS) are presented as a class of applications that combine both consumer- and enterprise-level LBS applications and cut across safety- and nonsafety-critical requirements of positioning performance.

Demands for positioning integrity have seen the rail sector lag significantly behind that of the land and maritime sectors in terms of the adoption of GNSS. In the second section, rail-transport applications are therefore treated as a distinct class of land applications. In this section, a range of safety- and nonsafety critical applications that mirror and complement the objectives for ITS in the road transport sector are described. Future GNSS is offering significant potential for integrity enhancement and is the subject of a number of investigative studies for the rail transport sector. The outcomes and recommendations of some of these studies are presented in this section.

In the third section, maritime applications of GNSS that support and contribute to the development of maritime ITS (MITS) are presented.

## 29.1 Land-Based Applications of GNSS

According to [29.2], the trend is for LBS and road segments to dominate GNSS cumulative revenue, with a combined total of more than 91% (Fig. 29.1). This is driven by the increasing capability for smartphones and tablets to replace dedicated, nomadic personal navigation GNSS devices (PND) such as in-car navigation systems, as well as increased uptake in location-aware applications and data services.

The expansion of GNSS use in the land transport sector will continue into the future given the expected growth and adoption of personal navigation applications (PNAs), LBS, and ITS. Offering the potential to significantly improve the safety and efficiency of road networks, these applications extend well beyond the traditional domains of vehicle navigation, commercial fleet management, public transport monitoring, passenger information, and emergency vehicle location and dispatch. GNSS now underpins the capabilities of safety-critical applications that operate under the ITS concept. A study undertaken by the Royal Academy of Engineering [29.3] provides a representative list of land, rail, and maritime GNSS applications. Table 29.1 shows the breadth of land transport applications relying on GNSS and the diverse positioning accuracy levels required.

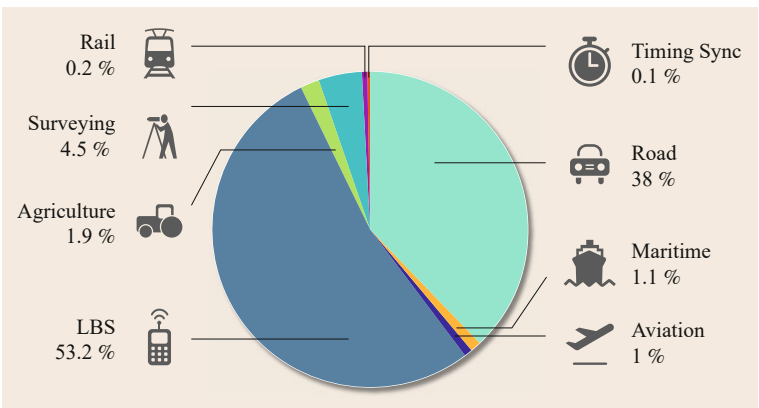

**Fig. 29.1** Cumulative core revenue by segment (cumulated revenue 2013–2023) (after [29.2], courtesy of European GNSS Agency, 2015)

**Table 29.1** Accuracy requirements for land transport applications. Road level accuracy: typically meter level positioning at 1 Hz. Lane level accuracy: typically submeter level positioning at 1 Hz. Where-in-lane level accuracy: typically decimeter–centimeter level positioning at 1 Hz (after [29.3])

| Application | Accuracy |
|---|---|
| In-car navigation | Road level |
| Fleet management | Road level |
| Urban traffic control | Lane level |
| Emergency calls | Road level |
| Dynamic route guidance | Road level |
| Selective vehicle priority | Road level |
| Collision avoidance | Where-in-lane level |
| Automated highway | Where-in-lane level |
| Road pricing | Lane level |
| Intelligent speed assistance | Where-in-lane level |
| Lane control | Where-in-lane level |
| Stolen vehicle recovery | Road level |
| Restraint deployment | Where-in-lane level |
| Trip travel information | Road level |

In this section, the GNSS positioning techniques underpinning land transport applications are presented and the use of augmentation infrastructure and assistance data to improve the accuracy and availability of the position solution are described. As these applications mature, and their use become more widespread, a range of topics are emerging as relevant and significant. Of particular focus to this chapter are the techniques, sensors, and signals that improve the robustness of the positioning solution for safety critical applications. This section therefore addresses important topics related to the fusion of GNSS and non-GNSS positioning technologies. While we acknowledge the need to take into account other factors that impact on the utility of location-aware devices including privacy, user behavior, context awareness, and so on, they are considered outside of the scope of this chapter.

### 29.1.1 Personal Devices

Personal devices including not only smartphones and tablets but also specific equipment such as tracking devices, digital cameras, portable computers, and fitness gear support a plethora of location-based applications. There are almost three billion mobile applications currently in use that rely on positioning information. Of these, PN is perhaps the most mature, with in-vehicle navigation systems the most popular example.

PN is defined as a means of determining an individual's location (positioning), selecting and providing guidance on the required route and mode of transport to a desired destination in *any* environment (outdoor or indoor), using geographic or spatial information, and information on location-based phenomena and services, [29.4]. These systems typically provide guidance information that assist a user in navigating from a point of origin to a destination. PN capabilities have resulted from the convergence of mobile computing, spatial/mapping information, and positioning technologies, with the first-generation PN devices (PNDs), dedicated units providing simple Global Positioning System (GPS) point positions to pinpoint the user's location, overlaid onto a base map.

Until recently, the proliferation of in-vehicle navigation systems established PNDs as the largest consumer market for GNSS-enabled devices. However, these capabilities have now been integrated into applications that enable any location aware smartphone to operate as a PND. The inherent synergy between location and mobile communication facilitated in smartphones has enabled the *services* characteristic of PN. Navigation applications that use a variety of positioning hardware built into smartphone, and the communication capabilities of the device, can access real-time traffic updates, weather information, and other relevant spatial and temporal information to improve the navigation instructions provided (Fig. 29.2).

**Fig. 29.2** **(a)** TomTom in-car navigation system as a personal navigation application for a smartphone and **(b)** TomTom in-car navigation system as a standalone PN device (courtesy of TomTom International BV)

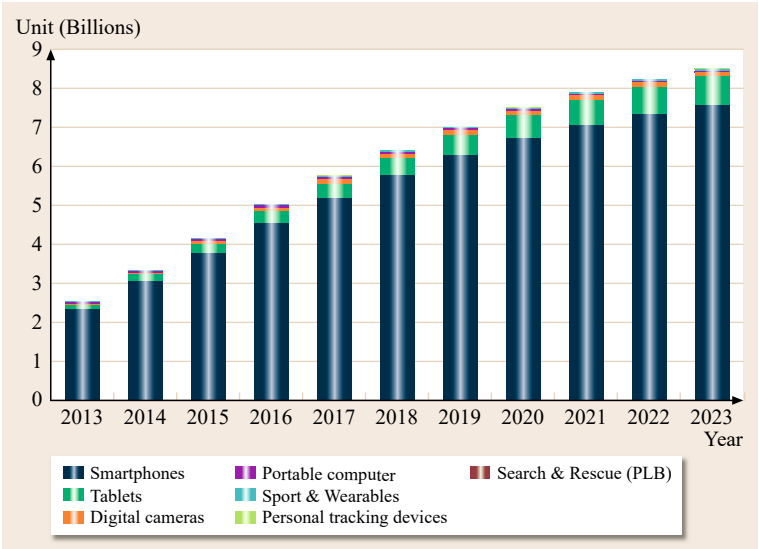

**Fig. 29.3** GNSS devices in use by application – LBS segment (after [29.2], courtesy of European GNSS Agency, 2015)

**Table 29.2** Classification of LBS by applications (after [29.5])

| Location-based services | Applications | Required quality of service (QOS) |
|---|---|---|
| Information/directory services | • Dynamic yellow pages that automatically informs consumer of location of nearest hospitals, restaurants, shopping malls and theatre, and ATM<br>• Nearest parking lot, drug store, or gas station | Location accuracy of a tens of meters<br>Response time of few seconds<br>Need for high reliability (98–99%) |
| Tracking and navigation services | • Tracking of children, locating lost pets<br>• Locating friends in a particular area<br>• Tracking stolen vehicles, asset tracking<br>• Dynamic navigational guidance<br>• Voice-enabled route description | Location accuracy of few meters<br>Response time of few seconds<br>Need for very high reliability (Goal should be 100%) |
| Emergency services | • Roadside assistance<br>• Search and rescue missions<br>• Police and fire response<br>• Emergency medical ambulance, E911 | Location accuracy of a tens of meter<br>Response time of few seconds or less<br>Need for very high reliability (Goal should be 100%) |
| Location-based advertising | • Wireless coupon presentation, targeted and customized ads<br>• Marketing promotions and alerts<br>• Customer notification and identification in the neighborhood store | Location accuracy of few meters<br>Response time of a minute<br>Need for high reliability (98–99%) |

The distinctions between PNAs that run on a smartphone and dedicated PNDs are often argued in terms of cost and usability – applications typically cost less and operate on a single mobile device and PNDs are more power efficient and simple to use. However, as the functionality and use of smartphones increases, the decline evident in the standalone PNDs market will continue. Figure 29.3 shows the number of GNSS-based devices predicted to be in use through to 2023. While niche personal devices such as personal trackers and wearable devices are expected to gain prominence, smartphones and tablets will continue to dominate the landscape for personal devices. In fact, smartphones or devices that emulate smartphone functionality (messaging, Internet search, social apps, navigation, video and picture capture, etc.) such as Google Glass and Apple iWatch support an increasing range of location aware applications and services, including [29.2]:

- *Geo marketing and advertising*: Consumer preferences are combined with positioning data to provide personalized offers to potential customers and create market opportunities for retailers.

- *Safety and emergency*: GNSS, in combination with network-based methods, provides accurate emergency caller location.
- *Enterprise applications*: Mobile workforce management and tracking solutions are implemented by companies to improve productivity.
- *Sports*: GNSS enables monitoring of users' performance through a variety of fitness applications, such as step counters and personal trainers.
- *Games and augmented reality*: Positioning and virtual information are combined to entertain the user and improve everyday life.
- *Social networking*: Friend locators provided by dedicated apps or embedded in social networks use GNSS to help keep in touch and share travel information.

### 29.1.2 Location-Based Services

LBS refer to an increasing range of mobile computing applications that provide information and functionality to users based on their geographical location [29.7]. According to [29.8], all location-based user needs can be characterized into five fundamental mobile actions: identifying the location of the user with respect to another person or place – *locating*; searching for persons, objects, or events – *searching*; requesting directions to a location – *navigating*; requesting specific attributes of a location – *identifying*; looking for events at or near a certain location – *checking*. A simple classification of LBS applications is presented in Table 29.2.

In many cases, it is the services aspect that differentiates LBS from the autonomous devices and applications. For example, a sports watch used by an athlete to monitor speed or distance, as well as health monitoring indicators such as heart rate and blood pressure, differs from the services aspect of an alerting system that automatically requests assistance from emergency services based on tracking information received from a location-based medical device used by an elderly person.

LBS can be classified into two types: push and pull. In a push type of service, the user receives information from the service provider without requesting it at that instant, although the user may have originally subscribed to the service at an earlier time. for example, send an SMS message advertising a sale at a nearby shopping mall or an accident up ahead. In a pull type, the user has to actively request for information. For example, where is the nearest restaurant or train schedules. More complex LBS that are emerging can *push* information in response to user preferences, based on their location, making the experience more personalized or *context-aware*. For example, *tell me when I'm near the library as I have a book to return*. Other types of LBS based on service distinctions can be found in Table 29.3.

The generalized architecture of LBS is shown in Fig. 29.4. At the core of these systems is the positioning information used to describe the location of the mobile handset. In the following sections, the typical positioning technologies used in current generation LBS are fully described.

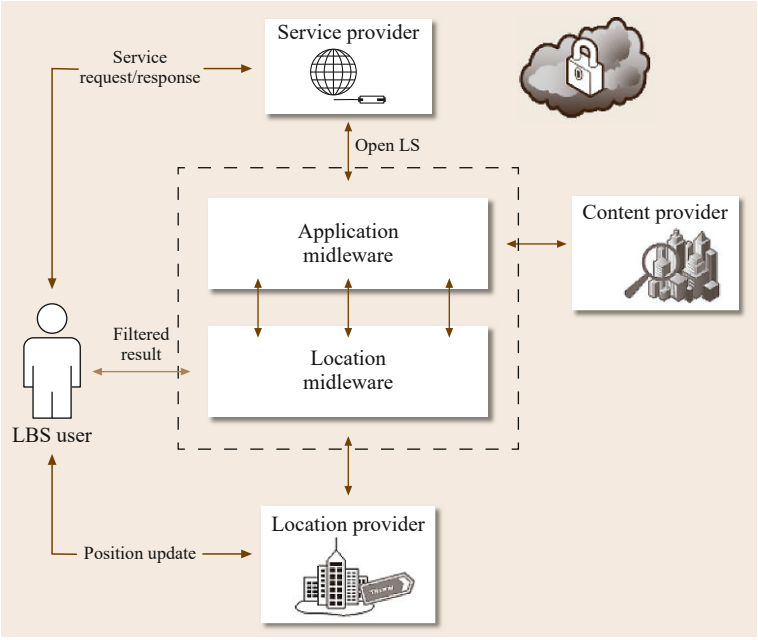

**Fig. 29.4** Components of an LBS (after [29.6])

**Table 29.3** Classification of LBS by applications (after [29.5])

| Types of LBS | Characteristics |
|---|---|
| Person-oriented LBS | • Consists of applications where a service is user based<br>• User usually controls how location information is collected and utilized |
| Device-oriented LBS | • Applications are external to user<br>• Person or the device located is not controlling the service |
| Push- versus pull-based applications | • Push based: information delivered to the mobile terminal (end user) automatically when certain event occurs<br>• Pull based: mobile terminal (end user) initiates the request |
| Direct versus indirect profile | • Based on how the user profile is collected: directly from the user during the set up phase, by tracking the user's behavior pattern or from third parties<br>• Security and privacy issues become critical to maintain user trust and to avoid fraudulent activities |
| Availability of profile information | • Profile information requested on the fly or already available to the LBS |
| Mobility and interaction | • Range of mobility scenarios exist based on combinations of mobility of users and network components<br>• The level and type of interactions depend on the mobility scenario |
| State of interaction | • Stateless interaction: each request is an independent transaction unrelated to previous request<br>• Stateful interaction: the LBS preserves the state across service requests (beneficial to for forecasting future transactions, requests, and behavior) |
| Static versus dynamic information source | • Static: data about historical buildings and landmarks, places of attraction, hotels and restaurants, and maps<br>• Dynamic: information that changes with time (weather, traffic, and road conditions) |
| Source of location information | • Location information provided by the user or the network infrastructure or by a third party |
| Accuracy of location information | • Depending on the positioning technology used in the network infrastructure, different accuracy for localization request of mobile terminals result |

### 29.1.3 Positioning Technologies and Techniques for PN and LBS

Since 2011, the GNSS positioning hardware integrated into smartphones has been based around multiple GNSS constellations – combining signals from both the GPS and GLONASS constellations. More recently, receiver chipsets that integrate signals from combinations of or all constellations have become available or an under evaluation (e.g., Broadcom's BCM47531, a GNSS chip that generates positioning data from five satellite constellations simultaneously (GPS, GLONASS, QZSS, SBAS, and BeiDou). Figure 29.5 shows the percentage of available receivers capable of tracking signals from one GNSS (i. e., GPS only), two GNSS (i. e., GPS + Galileo, GPS + GLONASS, GPS + BeiDou), three GNSS (i. e., GPS + Galileo + GLONASS, GPS + Galileo + BeiDou, GPS + GLONASS + BeiDou), or tracking signals from all constellations at the same time. It can be concluded that almost 60% of all available receivers, chipsets, and modules are supporting a minimum of two constellations.

These receivers typically deliver a solution commensurate with that of the GPS standard positioning service (SPS), and are among the lowest cost receivers on the market (consumer grade). Currently, SPS capabilities are provided by the coarse acquisition (C/A), pseudorandom noise code transmitted on the L1 frequency. This positioning accuracy is formally specified (for GPS) as better than 9 m, 95% horizontal error and 15 m, 95% vertical error. More recently, results of 3.286 m horizontal and 6.301 m vertical were recorded for the first quarter of 2014, by regular GPS SPS assessments undertaken by the US Federal Aviation Association at sites across the United States [29.9].

Over the last decade, the satellite positioning technology for an increasing range of location-aware devices has matured, offering much better performance in terms of sensitivity, power consumption, size, and cost than was previously possible. These receivers offer more channels, capable of tracking signals from GNSS constellations as well as regional satellite-based augmentation systems (SBAS) including the European Geostationary Navigation Overlay Service (EGNOS) which covers Western Europe and beyond, the Wide Area Augmentation System (WAAS) covering North and Central America, the multifunctional satellite augmentation system (MSAS) covering Japan and East

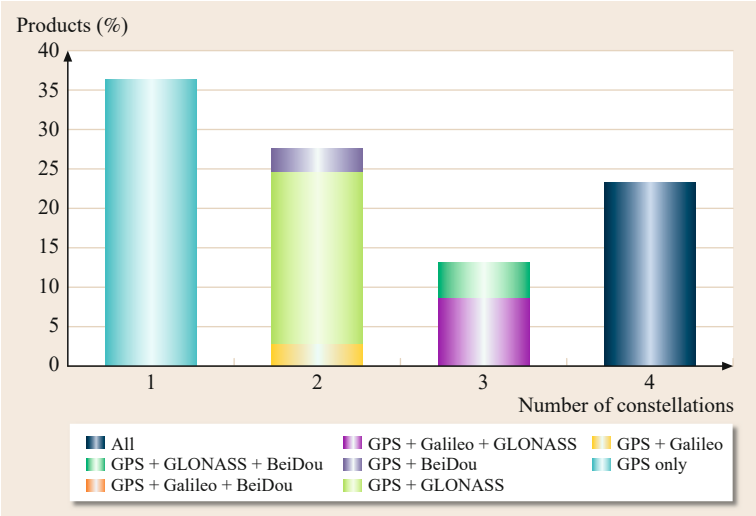

**Fig. 29.5** Supported constellations by receivers – LBS segment (after [29.2], courtesy of European GNSS Agency)

Asia, the GPS and GEO Augmented Navigation System (GAGAN) to cover the Indian subcontinent, and the system for differential corrections and monitoring (SDCM) as a component of GLONASS.

Figure 29.6 shows the u-blox EVA-7M chipset, typical of the hardware integrated into mobile devices. Table 29.4 provides a summary of the corresponding technical specifications for this receiver.

An increase in the number of signals being tracked is aimed at enhancing both the positioning availability and accuracy. In GNSS difficult operating environments, such as buildings, tunnels, and urban streetscapes, satellite visibility is completely or partially obscured or multipathing effects can dramatically degrade the measurement quality. As these conditions are increasingly characteristic of the environments in which PNAs are most commonly used, modern PNAs adopt a range of techniques to improve positioning accuracy and availability, these include the use of high sensitivity GNSS receivers (HSGNSS), Assisted GNSS (A-GNSS), SBAS corrections, and sensor/measurement fusion techniques.

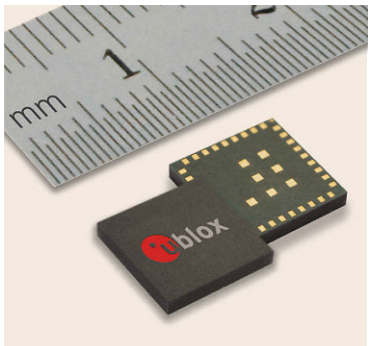

**Fig. 29.6** u-blox PN chipset (courtesy of u-blox)

### High Sensitivity GNSS

HSGNSS receivers have become the preferred choice for PND and LBS because of their ability to acquire and track the weak GNSS signals available in degraded

**Table 29.4** Technical specification for the u-blox EVA-7M chipset (after [29.10]). CEP (circular error probability) is defined as the radius of a circle centered on the true value that contains 50% of the actual measurements

| | | |
|---|---|---|
| Receiver type | 56-channel u-blox 7 engine,<br>GPS/QZSS L1 C/A,<br>GLONASS L1 frequency division multiple access (FDMA),<br>SBAS (WAAS, EGNOS, MSAS) | |
| Navigation | update rate up to 10 Hz | |
| Accuracy (GPS/GLONASS) | Position | 2.5 m/4.0 m CEP |
| | SBAS | 2.0 m/n.a. CEP |
| Acquisition (GPS/GLONASS) | Cold starts | 30 s/32 s |
| | Aided starts | 5 s/n.a. |
| | Reacquisition | 1 s/3 s |
| Sensitivity (GPS/GLONASS) | Tracking | −160/−158 dBm |
| | Cold starts | −147/−139 dBm |
| | Warm starts | −148/−145 dBm |

signal environments. For example, GPS signals transmitted some 20 000 km above the Earth are already very weak, typically −160 dBW when they arrive at a receiver on the surface of the Earth. In outdoor environments, GPS signals are around the −155 dBW level. According to [29.11], attenuation of the signal by trees, buildings, etc., can reach values of about 5 dB in cars, up to 20 dB in buildings and more that 25 dB in subterranean garages. Standard GNSS receivers are not sensitive enough to track these signals with low dBW values and are therefore unable to work in these environments. A high sensitivity receiver can acquire, track, and compute a position from a weak signal that is 1/1000 the strength of a typical outdoor signal.

To compute a position, a GNSS receiver has to perform two operations; the first is termed *acquisition* and the second *tracking*. A minimum of four satellites need be tracked in order for a three-dimensional position solution to be obtained. In the acquisition phase, the receiver first assumes that a satellite is visible and allocates a channel to this satellite. There are two search unknowns. One is the exact frequency of each satellite carrier – which needs to be tuned in response to the inherent uncertainty in the receiver reference oscillators and the Doppler uncertainty due to inaccuracies in the receiver location and velocity. The other is the alignment (correlation) of the received signal with a locally generated replica of the code. To acquire the signal, a GNSS receiver must therefore search the entire space of possible frequency offsets and code delays.

Conventional GNSS receivers integrate the code delays for each frequency offset for 1 ms, which is the duration of a complete C/A code cycle. To improve the acquisition of weak signals in GNSS difficult environments, high sensitivity receivers increase the integration time and the number of correlators available. Commercially available GNSS receivers typically have only 2–4 correlators per channel while high-sensitivity receivers, such as the u-blox positioning engine and SiRFstar chipsets from Qualcomm, have over two million correlators. By significantly increasing the number of correlators in the receiver, many frequency/delay searches can be conducted in parallel, with more correlations and integrations possible than with a standard receiver in the same amount of time. The end result is an increase in the sensitivity of the receiver, without increasing the acquisition time. To see this, let $n$ denote the number of correlators available for each satellite, $T$ denote the integration time, $A$ denote the acquisition time, and $B$ denote the number of code delay and Doppler bins. These quantities are related by

$$A = \frac{BT}{n} \,. \tag{29.1}$$

It is clear from (29.1) that, for a fixed acquisition time $A$ and number $B$ of search bins, increasing the number $n$ of correlators allows the integration time $T$ to be increased commensurately. The benefit of this is that increasing $T$ increases the output signal-to-noise ratio (SNR) of the correlators therefore allowing weaker input signals to be detected. It is wellknown that, as $T$ increases, the power $P$ at the output of the correlator is approximately proportional to $T$, i. e., $P = P_0GT$ where the quantity $P_0$ is the input power and $G$ is the power gain per second of integration time. After substituting $T = P/(P_0G)$, we can then rearrange (29.1) to find an expression for the power at the correlator output

$$P = \frac{AP_0Gn}{B} \,. \tag{29.2}$$

A conventional receiver has $B = 120 \cdot 10^3$ bins to search in $A = 60$ s using $n = 4$ correlators. If the signal arrives at the receiver with $P_0 = 10^{-16}$ W, then the correlator output power is

$$\begin{aligned} P &= 60 \cdot 10^{-16} \times 4G \,/\, 120 \cdot 10^3 \\ &= 2G \cdot 10^{-19} \,\mathrm{W} \,. \end{aligned} \tag{29.3}$$

A HSGPS receiver with $n = 1000$ correlators achieves the same output power for a received signal with power

$$\begin{aligned} P_0 &= \frac{BP}{AGn} \\ &= 120 \cdot 10^3 \times 2G \cdot 10^{-19} \,/\, (60G \cdot 10^3) \\ &= 4 \cdot 10^{-19} \,\mathrm{W} \approx -183.8 \,\mathrm{dBW} \,. \end{aligned} \tag{29.4}$$

Thus, increasing the number of correlators greatly increases the sensitivity of the receiver. Note that for integration times greater than 20 ms noncoherent integration must be performed.

If the attenuation is too large, the acquisition time can still be too long. This problem can only be solved if external information is available to reduce the search space for individual correlators. Once at least four satellites are being tracked, and their ephemeris is decoded, a receiver can perform the position, velocity, and time calculations. If it loses lock, then acquisition must be repeated, although the search space is now considerably smaller and therefore high sensitivities can be accommodated for tracking with little overhead in terms of computation and hardware.

### Assisted GNSS

Assisted GPS (A-GPS) or assisted GNSS (A-GNSS) is closely linked to HSGNSS but is particularly relevant to LBS, as it leverages the communication capabilities of mobile devices to enable more rapid acquisition

of the satellite signals and in particular weaker signals, significantly reducing the *time to first fix* (TTFF) for the GNSS receiver. A-GPS first gained prominence as the positioning technique underpinning the United States Federal Communications Commission's (FCC) Enhanced 911 (E911) program directive, which mandated that the accurate location of mobile phones had to be made available to emergency services. It is now a standard configuration for GNSS chipsets used for PN and LBS, offering more robust positioning capabilities in GNSS difficult environments.

A-GNSS capabilities are directed at the positioning hardware integrated into mobile handsets – the C/A code on the L1 frequency. As mentioned in the previous section, before the GNSS receiver can compute its own position, it needs to be able to acquire and track the GNSS signals. To achieve this, the receiver needs to know what satellites are visible and then be able to decode orbital information for these satellites from the navigation message. In particular, the satellite clock parameters (in subframe 1 of the navigation message) and ephemerides (in subframes 2 and 3) are essential to computing the position solution. The satellite receiver uses the satellite clock corrections to determine the precise time that the signal was sent, and the orbital parameters are used to calculate the satellite position in space at that time. If the signal level is below about −173 dBW, an unassisted receiver may not be able to achieve a valid fix at all because the signal is too weak for the receiver to decode the navigation data message. This situation is exacerbated by the inferior quality of the antenna available in smartphones compared to other standalone PNDs.

In GNSS difficult environments, the mobile phone network is used to assist the receiver in the mobile device to overcome the problems associated with TTFF and the low signal levels that are encountered. A-GNSS provides information to the receiver as to what satellites (frequencies) it can expect to see and then provides assistance in the form of the positions of the satellites. In this way, the TTFF is reduced from the order of 1 min to a few seconds [29.12]. Figure 29.7 shows the typical A-GNSS architecture.

There are two techniques used to provide A-GNSS assistance:

1. *Mobile station based (MSB)*: In MSB mode, the mobile station performs the calculation. The A-GNSS device receives ephemeris, reference location, reference time, and other optional assistance data from the A-GNSS server. The A-GNSS device can then use this information to receive signals from visible satellites and calculate the position. The device can report the position, velocity, and time solution back to the A-GNSS server if required.
2. *Mobile station assisted (MSA)*: In MSA mode, the A-GNSS server performs the calculation. The A-GNSS capable device receives acquisition assistance, reference time, and other optional assistance data from a mobile service provider. Using this information, it acquires the signals of the visible satellites, makes the pseudorange measurements,

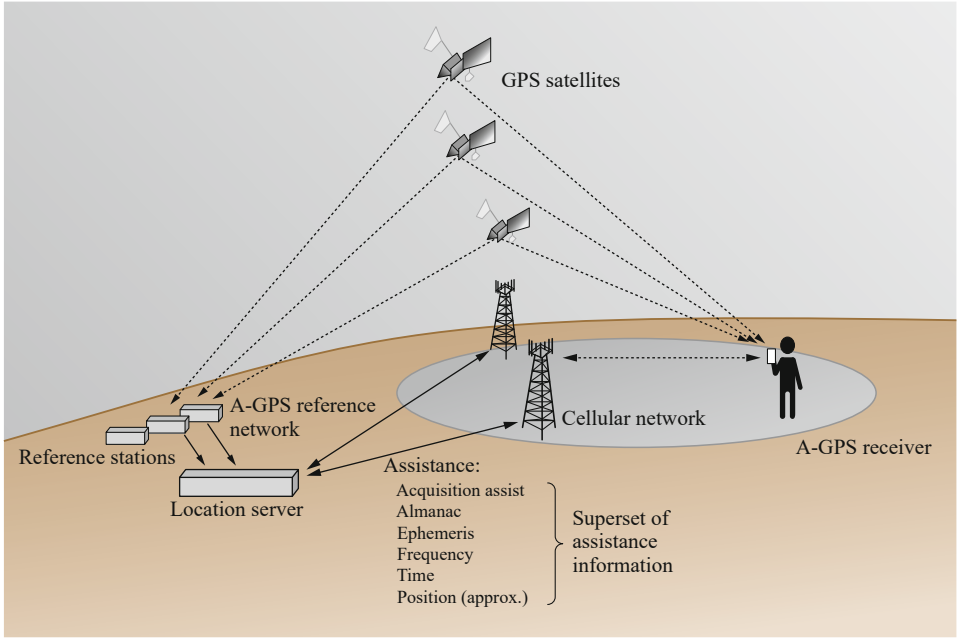

**Fig. 29.7** Representative A-GNSS Architecture. (after [29.12] with permission)

and then sends these measurements to the A-GNSS server. The mobile service provider continuously logs GNSS information (mainly the almanac) from the GNSS satellites using a A-GNSS server in its system. With the help of the above data (the data received from the mobile device and the data already present in A-GNSS server) the A-GNSS server calculates the position and optionally sends it back to the A-GNSS device.

Comprehensive technical details on A-GNSS implementations can be found in [29.12].

### Space-Based Augmentation Systems

Full details on space-based augmentation systems (SBAS) can be found in Chap. 12. Suffice to state here that SBAS capabilities augment the primary GNSS constellations providing ranging, integrity, and correction information. Primarily motivated by the integrity needs of the aviation sector, SBAS can significantly contribute to improving the accuracy, availability, and integrity of safety and liability critical applications such as tracking of the elderly and other vulnerable personnel, or collision avoidance systems.

The augmentation information provided by SBAS include corrections and integrity for satellite position errors, satellite clock errors, and ionospheric delays. These corrections are broadcast via geostationary satellites to suitably equipped satellite receivers. The accuracy improvements are at the levels of 1–3 m, 95% and are significant to many of the land transport applications in Table 29.1. While the integrity needs of the land transport sector are yet to be defined, their relevance and significance particularly in GNSS difficult environments have already been recognized.

### Alternatives to GNSS

The positioning requirements of LBS have driven the need for GNSS-like or enhanced GNSS performance in environments that completely or partially obscure GNSS signals. Smartphones attempt to address this problem by using available signals in the phone to maintain the availability of the positioning solution in indoor and outdoor environments, switching between GNSS and other positioning modes such as WiFi and cell-based systems. In most instances, these positioning capabilities are more than adequate for the current generation of PN applications. However, for other navigation and tracking applications, other sensors and signals are offering more robust capabilities albeit with additional cost, infrastructure, and computational overheads.

In this section, we acknowledge that the major focus for non-GNSS positioning capabilities (for LBS) centers around indoor and urban environments. First, we will look at the positioning technologies integrated into mobile phone handsets and second, a review of other signals and sensors being pursued as robust augmentations and alternatives to GNSS is provided. Figure 29.8 presents an overview of the accuracy and coverage characteristics of alternative/indoor positioning technologies [29.13].

*Positioning with Cellular Networks.* The full capabilities of LBS are delivered when the cellular networks and mobile handset work together to locate the user and then transfer the position data either upon request or continuously. Commercial examples range from low-accuracy positioning methods based on cell identity to high-accuracy methods combining wireless network information and satellite positioning (A-GNSS). The techniques can be classified as user centric – the position computation is performed by the user's device, or network centric – the user's position is determined by the tower or a hybrid solution. Table 29.5 provides a summary of the positioning techniques used by smartphones. Positioning methods include:

- The cell-of-origin (COO) method determines (at the mobile) which is the closest tower delivering the signal to the user. While this is an inexpensive method, the accuracy is limited to the density of towers or the size of the cell, which may range from 10–500 m for an indoor micro cell to an outdoor macro cell reaching several kilometers [29.14].
- Radiolocation techniques (similar to GNSS) uses characteristics of the radio signal that travels between the mobile use and the cellular towers to derive the handset position. By measuring the distance to at least three towers, positions of mobile users can be computed.
  - Time of arrival (TOA) is a network-centric approach that measures the time it takes for radio signals to arrive at multiple points.
  - Received signal strength (RSS) determines the distance from the measured signal strength. It performance significantly worse than any other cellular positioning technique as it is influenced by antenna direction and multipath effects.
  - Enhanced observed time difference (E-OTD) measures the difference between the time of arrival of the cellular signal at the handset and at a nearby fixed receiver. Time differences from at least three noncollinear towers are required to compute a position.The positioning accuracy of E-OTD is about 100–125 m.
- The location (multipath) pattern matching method uses the multipath signature in the vicinity of the mobile user to find its location. The user's termi-

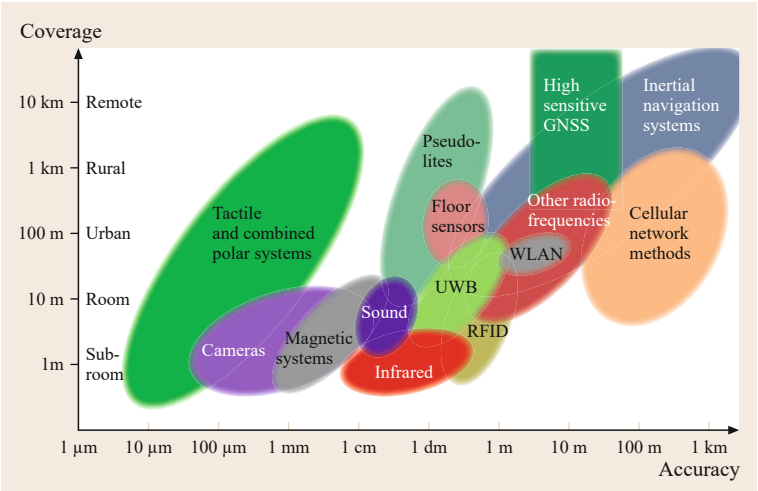

**Fig. 29.8** Relationship between coverage and accuracy for a range of indoor positioning technologies. (after [29.13])

**Table 29.5** Position determination techniques used in smartphones

| Technique | Range/operational availability | Accuracy | Services and content |
|---|---|---|---|
| COO | Globally (in principle) | 250 m–35 km | Traffic information, information services |
| E-OTD | Globally (in principle) | 100–500 m | Location-based billing, information services |
| TOA | Globally (significant capital investment) | 100–500 m | Location-based billing, information services |
| Fingerprint | In urban areas (significant capital investment) | < 150 m | Fleet management, advertisement, routing |
| GNSS | Globally | 5–10 m | Positioning and navigation |
| A-GNSS | Globally (after significant capital investment) | 5–10 m | Positioning and navigation |
| WLAN | Local (dependent on existing infrastructure) | 1–10 m | Information services |

nal creates a signal pattern (phase and amplitude characteristics) which can be measured and stored in a database. The cell tower receives a multipath signal form the mobile terminal and compares its signature with the multipath location database, which defines locations by their unique multipath characteristics.

*Positioning Using Wireless Local Area Networks (WLAN).* The widespread availability of WLAN (WiFi) networks present additional signals that can be used for positioning. The classic approach is trilateration, using ranges derived from the RSS measurements. However, the WiFi signals themselves are highly sensitive to interference and multipath caused by the operating environment (e.g., walls, people, equipment) and can result in incorrect positioning of the user. The method of fingerprinting (similar to pattern matching in cellular networks) is proving to be more successful but requires an additional workload to create the database containing the recorded signal strength data from various access points at known points spread across the environment in which positioning information is required. The Ekahau real-time location system (RTLS) uses a general propagation model for the WiFi signals, and parameterizes this model using a number of test measurements. The mobile user then sends its measurements of signal strengths to all surrounding access points to the positioning engine, which in turn calculates the position by solving a maximum likelihood problem.

*Ultrawideband Positioning.* It is expected that smartphone positioning will, out of necessity, encompass a hybrid solution, based on the fusion of multiple sensors. It can also be expected that additional sensors and signals will find their way into smartphones – where, at this stage their role has been toward higher end (enterprise or commercial) applications given their additional cost and infrastructure requirements. Table 29.6 provides a summary of the characteristics of a range of alternative positioning technologies. These technologies are however, now routinely integrated into a range of the so-called real-time location systems (RTLS) where robust positioning performance in indoor or GNSS difficult environments negates the additional infrastructure costs associated with these technologies. Ultrawideband (UWB) is one example of this.

The high bandwidth and accurate pulse timing offered by UWB signals make them ideal for positioning given their high multipath resistance, penetration, and accurate ranging capabilities. Commercial UWB positioning systems such as that offered by

**Table 29.6** Summary of the characteristics of alternative positioning technologies used in GNSS difficult environments

| Technology | Typical accuracy | Typical coverage (m) | Measuring principle | Application |
|---|---|---|---|---|
| Cameras | 0.1 mm–dm | 1–10 | Angles from images | Metrology, robot navigation |
| Infrared | cm–m | 1–5 | Thermal imaging, active beacons | People detection, tracking |
| Tactile & polar | μm–mm | 3–2000 | Mechanical, interferometry | Automotive, metrology |
| Sound | cm | 2–10 | Distance from time of arrival | Hospitals, tracking |
| RFiD | dm–m | 1–50 | Proximity detection and fingerprinting | Pedestrian, navigation |
| Ultrawideband | cm | 1–50 | Body reflection, time of arrival | Pedestrian, navigation |
| HSGNSS | 10 m | global | Parallel correlation, assisted GNSS | LBS |
| Pseudolites | cm–dm | 10–1000 | Carrier-phase ranging | Pit mines |
| Inertial navigation | 1% | 10–100 | Dead reckoning | Pedestrian, navigation |
| Magnetics systems | mm–cm | 1–20 | Fingerprinting and ranging | Hospitals, mines |
| Infrastructure systems | cm–m | building | Fingerprinting, capacitance | Ambient-assisted living |

Ubisense [29.15] and Time Domain [29.16] operate within restricted frequency bands (the FCC has restricted the frequency band for unlicensed UWB to 3.1–10.6 GHz while the European Communications Commission has restricted it to 6.0–8.5 GHz. UWB systems operate over short distances (typically ≈ 100 m depending on the operating environment and sensor configuration) and use TDoA, ToA, and signal travel time as measurement techniques to determine ranges between an UWB transmitter and receiver radios. UWB solutions are typically deployed as part of RTLS for efficient asset tracking, monitoring, and management. Other applications include relative positioning of vehicles and personnel tracking [29.17]. With positioning accuracies potentially at the levels of 0.2 m [29.18], UWB is becoming an important component of automotive, aerospace, and a variety of manufacturing processes.

*Radio Frequency Identification Positioning.* Similar to UWB, radio frequency identification (RFiD) positioning systems are primarily used to tag and track personnel and assets. They require the deployment of RFiD scanners across the operational environment. These scanners are then able to interrogate either active or passive tags attached to the object to be tracked. The range between the scanner and the tag is the most important relationship defining the positioning technique used (active tags enable a greater range than passive tags). COO and RSS ranging are the two most popular techniques used in RFiD positioning. For COO, the location of the reader is described by a cell identified by the maximum read range to a tag [29.19]. This technique offers relatively low accuracy and depends on the size of the distinguishable cells 10–20 m. A dense configuration of scanners across an area would improve the granularity of positioning but would incur a significantly higher cost. As a result, it is not practical to use RFiD for real-time tracking applications over large areas. To improve the achievable positioning accuracy, the deduction of ranges to the RFiD tags from received signal power levels is used (it can be converted to a distance). Calibration for the signal strength to range conversion is required. The position fix can be obtained using trilateration if range measurements to several tags are performed. To create a more general localization method than using trilateration, the RFiD location fingerprinting is used. The principle of operation of RFiD fingerprinting is similar to that used in WiFi and cellular positioning systems. Significant efforts into improving the positioning accuracy of RFiD has demonstrated results at the meter level [29.20]. Commercial RFiD tags are now widely used in a range of safety and security critical applications.

*Micro-Electro-Mechanical Systems (MEMS) Inertial Sensors.* MEMS inertial sensors like gyros and accelerometers are a key enabling technology for LBS. These low cost, low profile motion sensors are currently embedded as standard in most modern mobile devices providing very reliable information about rotation and acceleration rates and – after integration – about relative velocity and position over a certain period of time (i. e., a few minutes depending on sensor type and quality) with a high frequency (> 100 Hz). These data ideally complement the long-term stable, low-rate GNSS measurements. Moreover, inertial sensors are suitable to bridge bad GNSS signal reception conditions for a couple of minutes and guarantee a constant accuracy of the hybrid positioning solution. MEMS inertial sensors have already demonstrated significantly improved performance from their first-generation configurations, with MEMS accelerometers approaching performances close to those of tactical grade inertial measurement units (IMUs) [29.21]. The short-term relative positioning accuracy of MEMS IMUs is very high.

**Table 29.7** Performance specifications for different grades of inertial sensors

| IMU sensor grade | Sensor name and components | Characteristics ($1\sigma$ error coefficients) |
|---|---|---|
| Navigation grade | *Honeywell HG9900 IMU* | |
| | Honeywell GG1320AN digital laser gyroscope | • Bias: $< 0.003\,°/h$<br>• Random walk: $< 0.002\,°/\sqrt{h}$<br>• Scale factor: $< 5.0$ ppm |
| | Honeywell QA2000 accelerometer | • Bias: $< 25\,\mu g$<br>• Scale factor: $< 100$ ppm |
| Tactical grade | *Systron Donner SDI500* | |
| | MEMS quartz gyroscope | • Bias: $1\,°/h$<br>• Random walk: $< 0.02\,°/\sqrt{h}$<br>• Scale factor: $< 200$ ppm |
| | MEMS quartz accelerometer | • Bias: $100\,\mu g$<br>• Scale factor: $< 200$ ppm |
| Consumer grade | *Honeywell HG9000 IMU* | |
| | ADIS16334 iSensor MEMS accelerometer | • Bias: $3\,°/s$<br>• Random walk: $2\,°/\sqrt{h}$ |
| | ADIS16334 iSensor MEMS gyroscope | • Bias: 12 mg |

However, if unassisted, the errors and biases typical of these sensors accumulate rapidly, with positioning errors up to hundreds of meters [29.22]. Significant efforts in improving the performance of MEMS sensors through their integration with GNSS has resulted in much success commercially for land-based applications. In fact, for all of the alternative positioning technologies presented in this chapter, many successful commercial RTLS rely on a combination of multiple technologies to provide robust positioning capabilities in all environments. Table 29.7 lists the performance specifications for different grades of inertial sensors.

### 29.1.4 Intelligent Transport Systems

ITS can be defined as the application of advanced information and communication technology to surface transportation in order to achieve enhanced safety and mobility while reducing the environmental impact of transportation. Cooperative ITS (C-ITS) are an emerging capability that leverage wireless communication capabilities to enable vehicles and surrounding infrastructure to exchange information about the location, speed, and direction of other road users also using C-ITS [29.23]. Vehicle-to-infrastructure (V2I) and vehicle-to-vehicle (V2V) communications are supported by dedicated short range communication (DSRC) capabilities which enables two-way short-to-medium range wireless communications and permits very high data transmission – critical in communication-based active safety applications. The US FCC has allocated 75 MHz of spectrum in the 5.9 GHz band for use by C-ITS vehicle safety and mobility applications. DSRC offers significant opportunities for sharing of information between vehicles, pedestrians, and roadside infrastructure.

The positioning performance enhancements offered by multiconstellation GNSS, SBAS, and alternative positioning sensors, combined with the maturing of fundamental ITS technologies and the emergence of telematics driven C-ITS capabilities are facilitating applications well beyond those of traditional ITS including:

- Smart mobility applications improve the efficiency, effectiveness, and comfort of road transportation through [29.2]:
  - *Navigation*: The most widespread application, providing turn-by-turn indications to drivers through portable navigation devices and in-vehicle systems (IVS).
  - *Fleet management*: On-board units (OBUs) transmit GNSS positioning information through telematics to support transport operators in monitoring the performance of logistics activities.
  - Satellite road traffic monitoring services collect floating car location data from vehicles through PNDs, IVS, and mobile devices, processing this traffic information to be distributed to users and other interested parties.
- Safety-critical applications leverage precise and secure positioning in situations with potential harm to humans or damage to a system/environment:
  - While being connected vehicles GNSS positioning will be integrated with the information coming from other sensors and communication technologies in in-vehicle systems (IVS), enhancing the safety and comfort of the driver.
  - Dangerous goods tracking can be done by transmitting GNSS-based positioning data on the vehicles, carrying them along with other information about the status of the cargo.

**Table 29.8** Positioning accuracy levels for C-ITS (after [29.24])

| Type | Level | Accuracy requirement | | Research prototype | Communication latency (second) |
|---|---|---|---|---|---|
| | | 95% confidence level (m) | Root means square (order) | Root means square (order) | |
| V2I: absolute (V2I: Vehicle to infrastructure) | Road level | 5.0 | meter | Meter | 1–5 |
| | Lane level | 1.1 | Submeter | Submeter | 1.0 |
| | Where-in-lane-level | 0.7 | Decimeter | Decimeter | 0.1 |
| V2V: relative (V2V: Vehicle to vehicle) | Road level | 5.0 | Meter | Submeter | 0.1 |
| | Lane level | 1.5 | Submeter | Decimeter | 0.1 |
| | Where-in-lane-level | 1.0 | Decimeter | Centimeter | 0.01–0.1 |

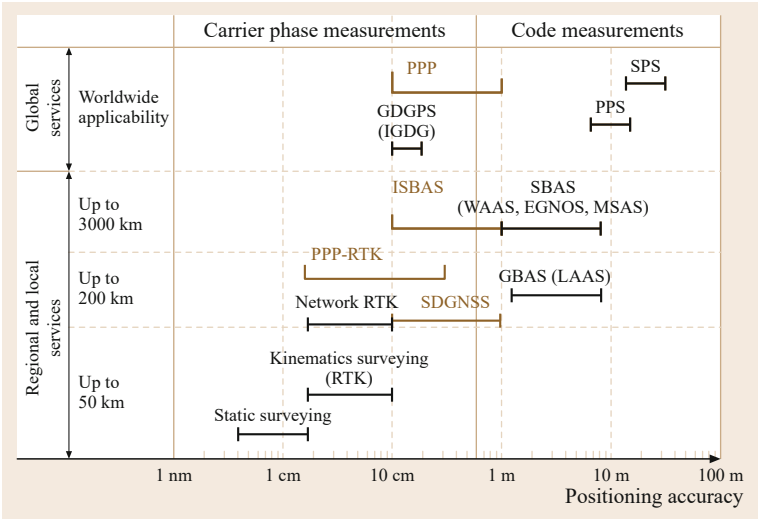

**Fig. 29.9** GNSS performance levels (after [29.24]). Definitions for the acronyms contained in this figure are as follows: GPS, global positioning system; PPP, precise point positioning; SPS, standard positioning services; GDGPS, global differential GPS; IGDG, Internet-based global differential GPS; PPS, precise positioning services; iSBAS, integrated SBAS; SBAS, space-based augmentation system; WAAS, wide area augmentation system; EGNOS, European Geostationary Navigation Overlay Service; MSAS, multifunctional satellite augmentation system; RTK, real-time kinematic; GBAS, ground-based augmentation system; LAAS, local area augmentation system; SDGNSS, satellite differential GNSS.

- *Liability applications*: The positioning data provided by liability applications are linked to legal and economic liabilities:
  - In road user charging (RUC), GNSS-OBUs support toll operators in charging based on the actual use of the roads and in managing congestion control.
  - Insurance telematics black boxes rely on GNSS data to increase the fairness of motor insurance for both insurers and subscribers.
- Regulated applications apply the transport policies introduced by national or international legislations:
  - The GNSS-enabled IVS are used in regulated applications, such as the European eCall or the ERA-GLONASS in Russia, which send an emergency call to 112 in the case of an accident, thus accelerating emergency assistance to drivers.
  - Enhanced digital tachographs leverage GNSS positioning to support road enforcers, recording the position of a given vehicle at different points during the working day.

In the following section, the positioning requirements of C-ITS applications are presented. Following this, the positioning techniques used to achieve these performance levels are also discussed followed by a discussion on the benefits of DSRC for C-ITS and how the position solution can be improved by using cooperative or collaborative positioning techniques.

### GNSS Performance Classification of C-ITS Applications

C-ITS applications cut across a range of GNSS performance parameters, with low-end applications such as vehicle tracking typically requiring low cost and low accuracy positioning information while high end applications such as lane control require high accuracy and high availability information. Increasingly, integrity for ITS applications is becoming more relevant as safety-critical applications gain prominence, for example, collision avoidance and autonomous vehicle navigation. The positioning accuracy requirements for C-ITS safety applications are typically classified into three levels: road-level (on which road the vehicle is placed); lane level (in which lane the vehicle

**Table 29.9** Summary of GNSS-based positioning techniques in terms of accuracy and their related C-ITS applications (after [29.24]). Definitions for the acronyms contained in this table are as follows: GPS, global positioning system; GNSS, global navigation satellite system; PPP, precise point positioning; PPS, precise positioning service; SBAS, space-based augmentation system; RTK, real-time kinematic; WADGPS, wide area differential GPS; DGPS, differential GPS

| Tier | Technique option | Status | | Accuracy range | Cost | C-ITS applications |
|---|---|---|---|---|---|---|
| | | Current | Future | | | |
| 1 | A | Standalone GPS (SPS) | Standalone multiple GNSS (use of Multi-GNSS in standalone mode is inherently more reliable than GPS alone) | 10–20 m | Low | Vehicle navigation, personal route guidance and LBS |
| 2 | A | Standalone GNSS (PPS). Code DGPS | Standalone multiple GNSS positioning | 1–10 m | Low | Vehicle navigation, LBS, road traffic management |
| 3 | B | Current WAAS Commercial WADGPS | Future SBAS design for multiple-GNSS | 0.1–1 m (utilizing SBAS and V2V relative positioning) | Low | C-ITS safety applications: lane-level positioning, lane-level traffic management, and where-in-lane-level applications |
| | C | Smoothed DGPS | Smoothed DGNSS | 0.1–1 m | Medium | |
| 4 | D<br>E | RTK<br>PPP | Combined PPP and RTK (seamless) | 0.01–0.1 m | Medium to high | Research prototype C-ITS safety systems, offering bench mark solutions for testing low-cost units |
| 5 | Advanced D and E | Static positioning | Subcentimeter RTK with multi-GNSS Signals | 0.001–0.01 m | High | Geosciences and geodynamic studies. Not recommended for C-ITS applications |

is in); where-in-lane-level (where the vehicle is in the lane). In Table 29.8, these levels have been quantified. From this, a classification of positioning accuracy levels for C-ITS can be represented as: 10–20 m; 1–10 m; 0.1–1 m; 0.01–0.1 m and 0.001–0.01 m. It is useful to note that the full positioning performance requirements for emerging C-ITS applications are yet to be specified and in many cases are still being fully defined.

Figure 29.9 presents the accuracy levels of existing and established GNSS positioning services. From this, the GNSS-based techniques that could be used for positioning in C-ITS applications are as follows:

- *Technique A*: Standalone (global navigation satellite system) GNSS absolute positioning and V2V relative positioning with low cost GNSS receivers.
- *Technique B*: Space-based augmentation system (SBAS) absolute positioning and/or V2V relative positioning with low cost GNSS receivers.
- *Technique C*: Smoothed differential GNSS (DGNSS) absolute positioning and/or V2V relative positioning with low cost GNSS receivers.
- *Technique D*: Real-time kinematic (RTK) positioning with dual-frequency receivers.
- *Technique E*: PPP and V2V relative positioning with high-end GNSS receivers.

Table 29.9 presents a summary of the five-tier GNSS positioning techniques and their relation to C-ITS applications.

### Cooperative Positioning and Sensor Fusion for C-ITS

As road transport applications become increasingly safety-liability-critical, the requirements for better positioning accuracy, availability, and integrity have motivated the trend toward the development of positioning systems that combine measurements from a range of traditional and nontraditional signals. Systems such as mobile phone devices simply switch between available alternatives when GNSS is unavailable. More robust techniques aim to determine the optimal solution based around the use of estimation techniques. Systems that combine GNSS measurements with low-cost inertial

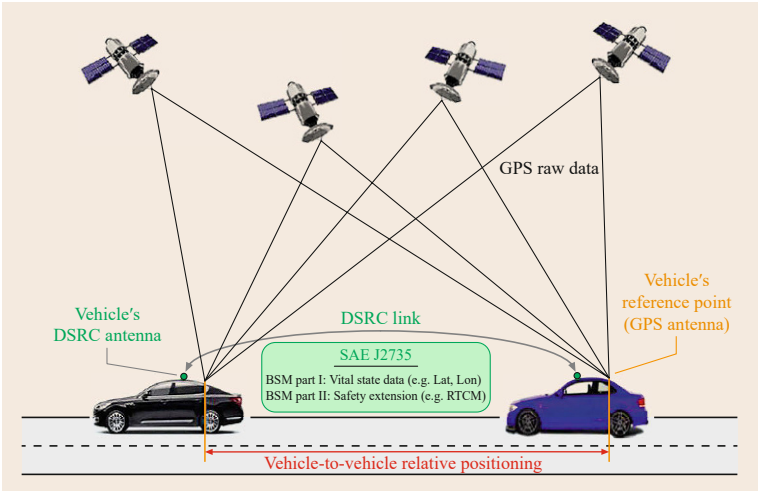

**Fig. 29.10** DSRC-enabled CP (after [29.24])

sensors are available with different levels of computational complexity. While many of these are aimed at high-end applications, the cost and size reductions in these sensors are seeing them embedded in mobile devices and consequently now routinely integrated in positioning and navigation applications.

Collaborative or cooperative positioning (CP) techniques have been adopted from the field of wireless sensor networks as an approach to improving the navigation and positioning performance for a range of human and land vehicle navigation applications. This is particularly relevant for those applications operating in GNSS-challenged environments where requirements for positioning availability cannot be met and/or which are safety-critical, requiring higher levels of reliability and integrity. CP techniques typically leverage an available communication infrastructure to share information between users operating within a defined neighborhood or so-called ad hoc network. This shared information can be integrated to deliver more robust positioning performance. Under certain conditions, the communication infrastructure itself can be used as a measurement source for positioning. Figure 29.10 shows the concept of relative positioning with GNSS raw data exchanged between vehicles using DSRC communications capabilities.

DSRC has the potential to provide a ranging measurement between vehicles in a vehicular ad hoc network (VANET). What is emerging as a significant consideration for CP are the benefits for positioning in terms of availability, integrity, reliability, and accuracy versus cost in terms of infrastructure, computational overheads, and the overall quantity and quality of information that needs to be shared to meet the positioning requirements of a specific application. CP algorithms typical use estimation and in particular decentralized filtering and tracking models to combine low-cost positioning sensors and signals, map matching, and DSRC.

Fusion of measurements from a number of sources can be approached in a Bayesian estimation framework. Here, the aim is to compute the distribution of an object state, which includes the object position and velocity, conditional on the measurements received from all sources. This is referred to as the posterior distribution. Because the relationship between the measurements and the object state is nonlinear, the posterior distribution cannot be found in the closed form. Many approximations have been proposed to address this problem. The most popular approximation is to linearize the measurement equation about the a priori expected value of the object state. This leads to the well-known extended Kalman filter (EKF; Chap. 22). This approximation is not always reliable but has been shown to provide good performance in many PN applications.

## 29.2 Rail Applications

The rail sector is recognized as a key contributor to realizing more efficient, safer, and sustainable mobility and ITS in the future. It is also widely accepted that knowledge about the position of each rail vehicle in the route network is compulsory for both safety and nonsafety relevant applications, and that the position and timing information provided by GNSS, when combined with other sensor systems, communication,

and information technology infrastructures, are critical to reducing accidents, delays, and operating costs while increasing track capacity, customer satisfaction and cost effectiveness [29.25]. However, despite the potential benefits offered by GNSS, liability, safety, and operational concerns surrounding current GNSS performance have resulted in a significant lag in railway ITS developments when compared to the land and maritime sectors [29.26].

Applications across the railway sector can be broadly classified according to the positioning performance required to support the individual application requirements, with safety-critical applications typically requiring higher levels of positioning availability, integrity and accuracy than non safety-critical applications. In [29.27], to investigate the performance and quality levels of GNSS positioning as required for railway applications, the European Rail Advisory Forum has proposed three main classes of applications, safety, operational, and professional. A summary of these applications and their positioning specifications is presented in Table 29.10. Within this classification, a description of relevant railway applications is presented in the following sections.

### 29.2.1 Signaling and Train Control

The principal motivation for train control is to prevent collisions when trains are traveling on the same track – either in the same direction (following each other) or traveling in opposite directions (toward each other). It is the safety critical part of train control, in which, automatic train control (ATC) systems continuously monitor all train movements and provide fail-safe signaling. For example, the ATC keeps tabs on a train's speed as it heads toward curves, automatically adjusting it if the driver fails to do so. The next generation of ATC technology is now referred to as communications-based train control (CBTC). A CBTC system is a [29.28]:

**Table 29.10** GNSS positioning requirements for different classes of railway applications (TBD: to be defined; ELM: European Land Mass)

| Application | Requirement | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Horizontal accuracy[a] (m) | Integrity alert limit[b] (m) | Integrity max. time to alarm[c] (s) | Availability[d] (%) | Service interrupt (s) | Continuity[e] (%) | Coverage[f] | Fix rate (s) |
| **Safety-related applications** | | | | | | | | |
| ATC on high density lines | 1 | 2.5 | < 1.0 | > 99.98 | < 5 | > 99.98 | ELM | 1 |
| Train control on medium density lines | 10 | 20 | < 1.0 | > 99.98 | < 5 | > 99.98 | ELM | 1 |
| Train control on low density lines | 25 | 50 | < 1.0 | > 99.98 | < 5 | > 99.98 | ELM | TBD |
| **Mass commercial/information and management – operational applications** | | | | | | | | |
| Tracking and tracking of vehicles | 50 | 125 | < 10 | 99.9 | TBD | TBD | ELM | TBD |
| Cargo monitoring | 100 | 250 | < 30 | 99.5 | TBD | TBD | ELM | TBD |
| Dispatching | 50 | 125 | < 5 | 99.9 | TBD | TBD | ELM | TBD |
| Passenger information | 100 | 250 | < 30 | 99.5 | TBD | TBD | ELM | TBD |
| **Infrastructure and civil engineering, professional application** | | | | | | | | |
| Positioning of machines | 0.01 | TBD | < 5 | 99.5 | TBD | TBD | Operating area | TBD |
| Infrastructure survey | 0.01 | $10^{-3}$ | < 10 | 99 | TBD | TBD | ELM | TBD |
| Fix point applications | 0.005 | TBD | < 30 | 99 | TBD | TBD | ELM | TBD |

[a] Accuracy is specified as the position error at 95% confidence level.
[b] Threshold value or alert limit – the maximum allowable error in the measured position before an alarm is triggered.
[c] Time-to-alarm – the maximum allowable time between an alarm condition occurring and the alarm being present at the output.
[d] Defined as intrinsic availability: This is the *Probability that a system or equipment is operating satisfactorily at any point in time when used under stated conditions, where the time considered is operating time and active repair time.*
[e] Continuity is defined as the probability that the location unit will be able to determine its position within the specified accuracy and is able to monitor the integrity of the determined position over the mission time, in all points of the route within the coverage area.
[f] The coverage is defined as the surface area or volume of space where the SIS service is sufficient to permit the user to determine its position with the specified accuracy and to monitor integrity of the determined position.

*continuous, automatic train control system utilizing high-resolution train location determination, independent of track circuits; continuous, high-capacity, bidirectional train-to-wayside data communications; trainborne and wayside processors capable of implementing automatic train protection (ATP) functions, as well as optional automatic train operation (ATO) and automatic train supervision (ATS) functions.*

CBTC includes three major components:

- Automatic train protection (ATP) assures that safety of trains by preventing collisions and derailments. It ensures that trains are separated by a safe distance, prevents overspeeding, and conflicting movements at junctions and crosses.
- Automatic train operation (ATO) controls the movement of the train specifically regulating speed, station stoppings, and opening and closing of doors.
- Automatic train supervision (ATS) assigns routes, monitors running trains, and provides data so that their service may be adjusted by controllers to minimize delays.

The primary functions of these subsystems can only be delivered through timely (real-time or near real-time), accurate, and continuous knowledge of where the train is on the track. The conventional technique for determining train location is through *block occupancy*. The conventional principle is that the track is divided into fixed *blocks* (a section of length equal to the distance needed for the train to come to a full stop under ordinary braking conditions and with a certain safety margin [29.29]). Only one train is allowed into a block at a time (Fig. 29.11).

Track circuits and axle counters are still widely used for ATP, to detect the presence of a train in a particular block. A track circuit is a simple electrical device used to detect the absence of a train on rail tracks. *Axle counters* refer to subsystems that are utilized for track vacancy detection on fixed-guide way transport systems such as railways. While the axle counter counts the vehicle axles entering and leaving a track section by means of the so-called rail contacts and indicates the track section as occupied when the number of axles counted at the exit differs from the number of axles counted at the entrance [29.30]. All ATC and ATP functions are based on this very coarse position determination.

To provide finer positioning resolution, the *moving block* system underpinning CBTC does not require traditional fixed-block track circuits for determining train position. Instead, it adapts to the current situation, taking into account its own accurate speed and position as well as that of any train ahead or behind. In this way, the minimum distance between two trains following each other is reduced to the braking distance of the second. Safety and reliability is therefore highly dependent on the accuracy and integrity of the position and speed measurements.

Railways provide a difficult operational environment for GNSS technologies. Tunnels, cuttings, and urban canyons are all problematic factors, potentially causing blockage of GNSS signals thus degrading GNSS availability and integrity. GNSS is currently unable to meet the specified integrity threshold for positioning for train control applications of $10^{-9}$ failures per hour. This is due to a failure risk of $10^{-4}$/h for any satellite under SPS [29.32]. Both of these contribute to the low uptake of GNSS for safety-critical rail systems. Figure 29.12 shows the applications requirements compared to the integrity levels available from GPS/Galileo/EGNOS.

To address the limitations of GNSS for rail applications, it is acknowledged that it must be hybridized with other sensors to determine a position sufficiently accurate for an use in safety applications. The Grail-2 (2007–2013) project funded by the GSA had the primary objective to develop a GNSS-based odometer, which would improve the ability of a train to determine its own position, integrating, and/or replacing the traditional odometric systems currently used in the ETCS (European Train Control System, a component of the European Railway Traffic Management System (ERTMS)) environment (tachometers, inertial navigation system (INS), Doppler radar, etc.) termed

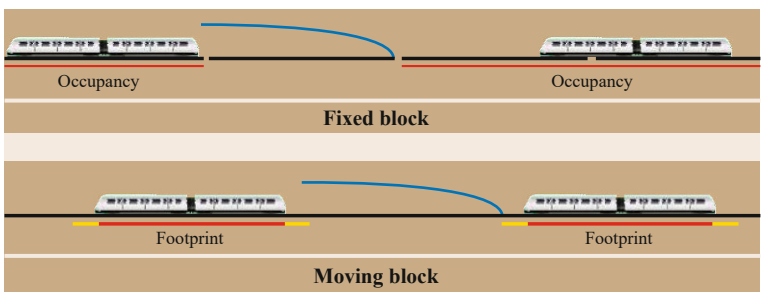

**Fig. 29.11** Block signaling for ATP. Image courtesy of Israel.abad/Wikimedia Commons distributed under the CC BY-SA 3.0 license

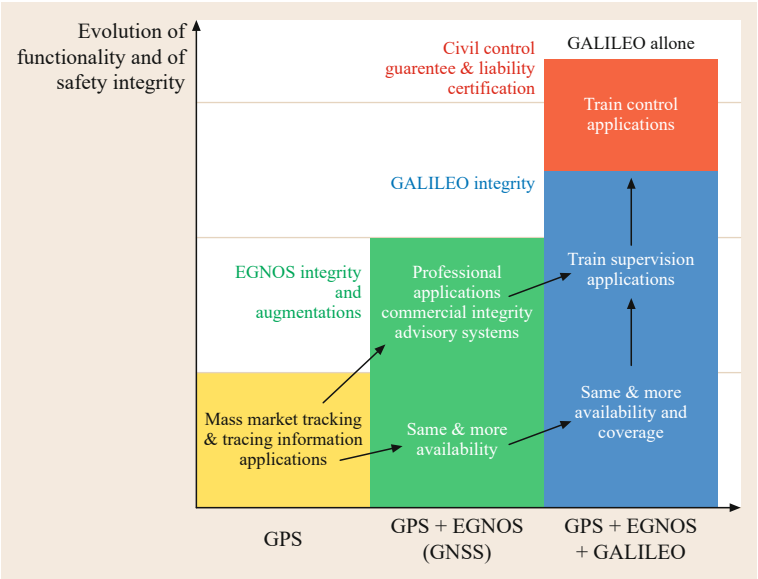

**Fig. 29.12** Satellite navigation systems and railway applications (after [29.31])

*enhanced odometry*, it integrated GNSS as an additional sensor to compensate for odometry problems in high-speed runs (slip and slide phenomena) [29.33]. Standard odometry approaches to estimating the train position within a block has relied on an on-board odometry subsystem that computes the distance traveled and therefore the updated position of the train – the so-called dead reckoning approach. Any errors in the distances due to wheel slip and slide can only be corrected with a reset from the next transponder that the train passes [29.34].

Under the GRAIL and GRAIL-2 projects, a dual frequency GNSS receiver augmented by EGNOS, was integrated with an IMU. The filtering and fusion of data coming from different sensors are performed by a Kalman filter – so-called data fusion filter (DFF), the GRAIL-2 implementation of the Kalman filter, is shown in Fig. 29.13, where

- PVA receives the GNSS position and velocity and the IMU measurements.
- DSA exploits the speed measure provided by the GNSS and the along track measured given by the IMU.
- RW receives measurements of angular rate by IMU and direction from two well-spaced GNSS antenna.

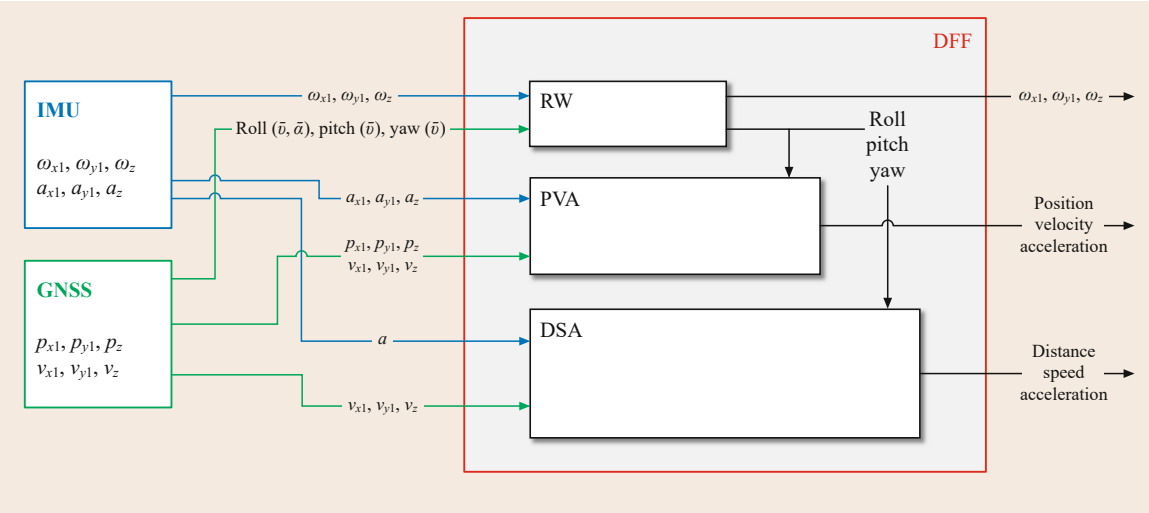

**Fig. 29.13** GRAIL-2 measurement fusion for enhanced odometry (after [29.33])

The InteGRail (for INTElligent inteGration of RAILway) (2005–2008) was another European project aimed at providing train position, velocity, and heading to the following specification: accuracy: 10 m along-track and 1 m cross-track ($2\sigma$) for discrimination of parallel tracks. The InteGRail prototype integrated measurements from an L1 GNSS/EGNOS receiver with an odometer, along-track acceleration sensor, fiber optical sensor for measuring the vertical rotation axis (i. e., the azimuth or heading angle), and digital route map [29.35]. More recently, the 3InSat (Train Integrated Safety Satellite System) (2012–2015) project funded by STS Ansaldo and the European Space Agency (ESA) aimed to develop, test and validate in a real set up a new satellite-based platform suitable for a train control and management system [29.36].

However, GNSS when combined with other systems, such as IMUs, does have the potential to provide high accuracy and integrity positioning for train control/rail management systems. Positive train control (PTC) initiatives in North America and many other countries, as well as steps toward a European Railway Traffic Management System (ERTMS) will result in significant growth in the uptake of GNSS across this sector. For positioning, the 3InSat project is aimed at designing and developing a multisensor location detection system (LDS) using multiconstellation GNSS.

The LDS multisensors/multiconstellation (GPS, GLONASS, Galileo, BeiDou) system which, through association of different SatNav receivers and on-board sensors (gyros, accelerometers, tachometer) will provide a safety compliant positioning solution able to reach high integrity values and improve the overall availability and resiliency. The LDS will make use of SBAS (e.g., EGNOS for Europe) in combination with GBAS for both differential corrections and integrity monitoring. Additionally, the LDS will have independent integrity monitoring on-board capability to further mitigate GNSS errors and autonomously assess the GNSS location integrity in the case of augmentation data unavailability (e.g., EGNOS SIS unavailability). A track area augmentation and integrity monitoring network is to be installed along the railways tracks. This element will be mainly used in regions out of the SBAS footprints.

Figure 29.14 shows the reference architecture for the 3InSat systems. The primary task of the space segment is to provide the reference satellite signals needed for train position computation as well as to distribute real-time corrections related to satellite ephemerides, clock offsets, propagation delays, and signal-in-space (SIS) integrity. The (track area) augmentation and integrity monitoring network plays a role similar to the EGNOS range and integrity monitoring subsystem and, in fact, it will be deployed only on those areas out of EGNOS footprint. The on-board unit trough the localization determination system (LDS) subsystem computes the train position by using the GNSS signal,

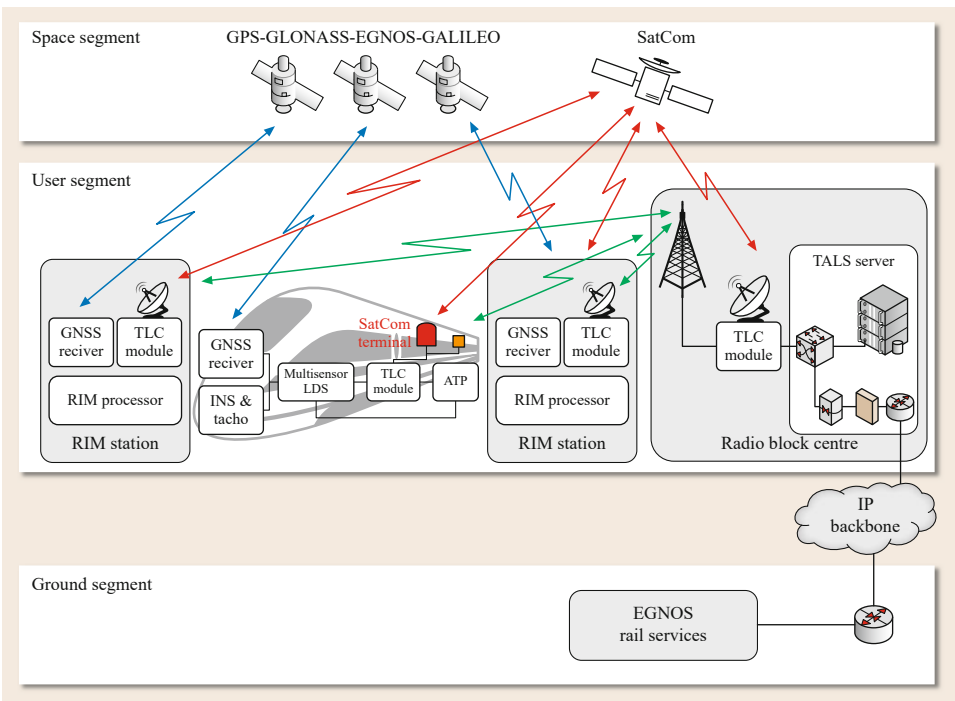

**Fig. 29.14** 3inSAT reference architecture (after [29.37])

the augmentation information for integrity monitoring, and the data from other sensors as inertial navigation systems (INS) and tachometers. The on-board bearer-independent telecommunication subsystem will take care of train control messages and other important system information [29.36].

### Infrastructure Data Collection

Train protection delivered through PTC in North America and the proposed European Train Control System (ETCS) monitors the train speed against the current permitted speed limit. The speed may be limited by line profile or signal indication, that is, the need to protect routes of other trains and track-related constraints. If the allowable speed is exceeded, a brake application is invoked until the speed is brought within the required limit or the train is stopped. Each block of the track is described by a fixed dataset related to its location, length, gradient and maximum speed limit, works on the line, etc., and communicates this to the train as it passes. Of many challenges that face railroads to implement this complex system is the need for a highly accurate base map and asset inventory database which must be compatible with all other PTC/ETCS systems. A solid base-map is the foundation upon which a PTC or ETCS implementation is built upon in order to properly control train movement based upon track slope, curvature, and speed zones.

Many commercial solutions exist for generation of the required spatial database for PTC/ETCS. Perhaps the most popular is the mobile mapping solution based around mobile Lidar, dual frequency, high precision GNSS, and on-board INS. These systems overcome limitations in GNSS-denied environments through the use of a hybrid positioning capability, offering better than 5 cm positioning accuracy and a resolution of up to 1 cm [29.38]. For example, in support of PTC/ETCS, the commercial Sanborn mobile mapping system can provide:

- Accurate knowledge of train location and GNSS for signal and braking control.
- Create a complete inventory of assets, obstructions, clearances, switches, frogs, crossings, etc.
- The complete environment of the crossing, including the condition of railway cross guards (if any), allowing for the maintenance of these guards; this data has potentially critical value to railroad, insurance, and forensics agencies if an accident occurs.

Every year, railway custodians globally spend millions of dollars to inspect the rails for internal and external flaws. Testing/inspection systems need to be synchronized with a positioning system, and here GNSS-based mobile mapping systems can provide more accurate data than traditional techniques. Secondly, recent developments in remote monitoring system (which are typically based on a combination of GNSS/GIS (geographic information system) technologies, wireless communications, signal processing, and embedded computing) have become compact and relatively inexpensive, and can therefore be used on almost any rail vehicle. These kinds of solutions that enable real-time performance monitoring contribute significantly to safety since they allow quicker detection of defects than traditional methods which are based on separate periodical track inspections.

The Alstrom TrainTracer is one example of a commercially available module that can be retrofitted to the train's control system, which remotely monitors changes in its major components and reports wirelessly to a ground-based server. By fitting the condition monitoring system with GNSS location tracking to each train, fault data can be processed and transmitted while the train is in service, rather than at scheduled maintenance times. Engineers can therefore remotely analyze and diagnose the on-board scenario facilitating more efficient detection of problems or troubleshooting failures. In addition, the Sanborn Automatic Track Inspection Program (ATRIP) provides the following key features:

- High relative accuracy between rails of 7 mm
- Meets positioning accuracy clearances
- Point cloud density is great enough to obtain all relevant information in one pass minimizing needed track time
- Mobile mapping data can be integrated with other data (ortho, LiDAR, etc.) to build a complete picture of rail right-of-way.

### Level Crossing Protection

All types of train protection systems are based on the desire to reduce or eliminate the possibility of driver error resulting in a train-movement-related accident by failing to obey a visually displayed line-side or in-cab signal instruction. Level crossing protection systems are actuated by knowing the position and speed of the train on the track. In a conventional automatic level crossing (ALX), the control system includes fixed sensors along the track which can detect a train approaching the crossing [29.39]. It senses not only the approach of the train but also the speed so that if a train is coming very slowly they will not activate until the train is close. When the traffic signals are activated, shortly after, the barriers are closed. Once the road traffic is stopped, the railway signal controlling the route over the crossing can be set to allow the train to proceed. The distances of the sen-

sor and signal from the crossing are determined by the highest speed at which trains are permitted to travel on the section of line in question. The distance from the sensor to the signal must be great enough for the ALX to fully operate before the train reaches the signal. If the ALX is not ready for the train to cross, the train must be able to stop in the distance between the signal and the crossing. Slower trains cause the crossing barriers to close unnecessarily early, increasing the waiting time for road traffic.

As a safety application for railway, much of the hybrid positioning capabilities proposed for ATC functions can be leveraged into triggering a warning on the approach to a level crossing, with a consistent time lapse regardless of the speed of the train. The EGNOS COntrolled RAILway equipment (ECORAIL) project is a demonstration of the capabilities of GNSS for ALX protection. This project developed an on-board unit that is able to determine the position of a train on the track with sufficient accuracy and reliability to be used for railway control purposes. A GNSS receiver augmented with EGNOS, odometer measurements, and a track database was used to demonstrate the control function of closing the barriers at the level crossing as a train approaches.

For the first part of the demonstration, the performance of ECORAIL was assessed as the on-board system computed the location of the train and determined the position on the track at which the crossing barriers should be closed. The closure commands were transmitted by radio link to a ground station, where their time-of-arrival was recorded. The ground equipment also recorded the times at which all the events in the conventional control equipment occurred. The positional accuracy achieved by ECORAIL was better than 3 m when compared with the fixed sensors. For the second phase of the demonstration, ECORAIL determined the timing of the barrier closure commands based on both the position and speed of the train, allowing the ALX operation to be optimized – slower moving trains are able to close the crossing when they are nearer to it, rather than relying on the fixed detectors.

Subsequent projects in a similar direction have identified significant performance benefits from a hybrid onboard system for position and speed determination. In almost all cases, these solutions represent the state of the art in positioning in difficult railway environments for safety critical applications.

### 29.2.2 Freight and Fleet Management

The ability to effectively track the location of goods and to estimate their delivery times is as important in the railway sector as in other modes of transportation. Similarly, accurate and timely information as to where a train is or has been is paramount to ensure efficient operation and service passenger information systems. A significant difference for the rail industry compared to other vehicular fleet management system is that [29.40]:

> *the state of the art in tracking and managing key rolling assets – railcars, tankers, and locomotives – lags far behind other highly capitalized, mission-critical industries.*

As with other positioning and tracking applications, the positioning capabilities of DGNSS – operating under ideal operating conditions can deliver the positioning performance required for robust tracking and monitoring functions. It is in difficult environments that positioning performance and consequently application service levels are compromised. As with many other similar applications, the use of hybrid solutions are an effective approach to providing a ubiquitous positioning capability. The hybrid positioning technologies used to position the train on the track is sufficient to meet the requirements for many freight and fleet management functions. Other technologies that are being deployed to help achieve the full benefits of a railway RTLS include: RFiD tags [29.41] and UWB. Ubisense has introduced an UWB RTLS that automates yard operations and improves efficiency and productivity. By precisely locating rolling stock in both indoor and outdoor areas, operators gain an unprecedented level of visibility into workflow which helps us to improve all areas of rail yard operations.

Benefits as documented by a commercial asset management company, RFTrax, include:

- Owners of large railcar fleets could use these data to significantly reduce the time spent in stations by being able to monitor the exact location of an entire railcar fleet, thus preventing *warehousing* of railcars and speeding up their reuse.
- Shippers could use these data to improve overall service delivery and efficiency by better managing railcar movements and use.
- The railroads themselves could significantly lower their costs and improve their margins by being able to understand the sources of problems such as truck hunting – the potentially destructive shifting of railcars and their loads in transit – as well as derailments and improve their maintenance of both their track and rolling assets.
- Integrating those data *upstairs* into the enterprise resource planning (ERP) systems can provide an even greater return on investment (ROI): Integrating rail-

car data with ERP data can significantly improve the rail freight industry's ability to be a key partner in initiatives such as just-in-time or lean manufacturing, vendor managed inventory, and other highly visibly efforts to improve supply chain responsiveness across the board.

### 29.2.3 Passenger Information Systems

An inevitable outcome of high accuracy Real Time Kinematic (RTK) positioning and monitoring of vehicle fleets has been the ability to provide current updates on arrival and departure schedules to passengers. Over the last decade, passenger information systems (PIS) have evolved from simple standalone audio and visual displays to multimodal integrated systems that keep passengers informed, safe, and entertained along their journey in public transit systems (metro trains, commuter rail, station platforms, buses, or bus shelters) [29.42]. PIS typically deliver real-time information seamlessly on-board vehicles, through web browsers and mobile devices, or physically at a station or transportation hub, while controlled and managed from a single control center. Many of the services provided by PIS, either pre-trip or on-trip, require the real-time position of the train to be monitored and reported continuously. Typical pre-trip information provided by a PIS includes the service provided by the next vehicle to arrive, the expected and timetabled arrival time of the next vehicle. On-trip information includes the name of the next station, the time of arrival there and advice on connecting services.

PIS tend to be multimodal with the most popular implementations connecting the primary forms of land transport (buses, trains, and trams) to ensure seamless travel across heavily trafficked routes. In all cases, an onboard system is required to determine and transmit the geographical location of the train. For buses, GNSS is primarily used for this task. In the rail industry, a number of leading electronics manufacturers are now offering PIS technology that can be retrofitted to existing railway vehicles. These systems either interface with GNSS directly or access positioning information from the train management system. PIS typically have low positioning accuracy requirements but in order to provide an enhanced user experience, this information needs to be available and reliable. The positioning information provided needs to be an order of magnitude higher than the underlying service. *Thus, if 99% of the trains run on time, the service information presented to users needs to be 99.9% accurate* [29.43]. In many cases where GNSS cannot satisfy this requirement, augmentation sensors and fusion techniques are necessary.

## 29.3 Maritime Applications

The maritime sector was an early adopter of GNSS for general navigation applications, with GNSS now a mandatory navigation aid for all ships regulated under the International Maritime Organization (IMO), International Convention for the Safety of Life at Sea (SOLAS) maritime safety treaty. The navigation requirements of non-SOLAS regulated vessels such as merchant, commercial, and recreational vessels, also depend heavily on GNSS. In addition, GNSS is used to ensure safe navigation in inland waterways (IWW) such as rivers, canals, lakes, and estuaries. The enhanced navigation performance from future multi-GNSS constellations is expected to deliver GNSS receivers that meet IMO performance standards for maritime operations. Specifically, GNSS capabilities are expected to underpin the IMO e-navigation initiative which aims to increase the safety and security of maritime navigation through the integration of all navigation tools into a comprehensive system that can collect, integrate, exchange, present, and analyze marine information on ships and at shore. Resilient position, navigation, and timing (PNT) has been identified as a core requirement for the successful implementation of the e-navigation concept [29.44].

IMO Resolution A.915(22) differentiates between the performance requirements of GNSS for navigation and positioning applications. Maritime positioning applications include vessel monitoring, traffic management, port operations, search and rescue (SAR), marine engineering, etc., and are representative of the increasing range of GNSS applications aimed at improving the safety and productivity of maritime operations. Figure 29.15 shows the expected growth (to 2023) in GNSS receiver shipments based on applications in the maritime sector. Much of this trend is being driven by the increased uptake in GNSS technology by the maritime consumer/recreation market, improved operational efficiency, portability, and durability of SAR technologies and policies that mandate capabilities for vessel monitoring systems (VMS) and automatic identification systems (AIS).

The increasing significance of GNSS to the maritime sector combined with concerns surrounding the integrity and vulnerability of positioning for safety and liability critical applications has established a vision for resilient maritime PNT. It is envisaged that GNSS or augmented GNSS will be the core PNT capability

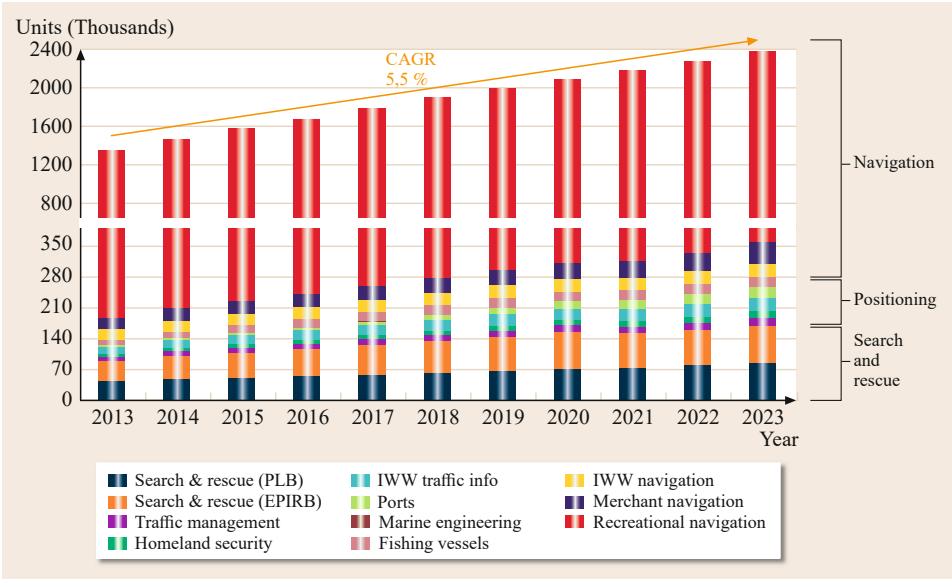

**Fig. 29.15** Maritime applications projected growth (2013–2023) (after [29.2], courtesy of European GNSS Agency)

underpinning maritime navigation and positioning applications in parallel with independent, dissimilar, and complementary positioning systems depending on the needs of the specific application.

In this section, GNSS performance capabilities for the maritime sector are presented. Augmentation systems that improve the fundamental performance are also discussed within the context of high-performance maritime applications including navigation systems, fishing vessel control, SAR, and port operations.

### 29.3.1 GNSS Performance Requirements for Maritime Applications

The requirements of maritime positioning and navigation applications are very diverse, but fundamentally rely on the output from an electronic position fixing system (EPFS), in order to effectively perform their required tasks. GNSS has become the primary means of providing EPFS information with GPS, GLONASS, and BeiDou endorsed as meeting IMO requirements as a World-Wide Radio Navigation System (WWRNS). IMO Resolution A.915(22) provides a benchmarking set of operational performance requirements (in terms of accuracy, coverage, availability, continuity, and integrity measures) for future GNSS to be endorsed as a WWRNS [29.45]. Table 29.11 shows the IMO GNSS performance requirements for general navigation.

In addition, IMO Resolution A.915(22) lists more than 30 different marine positioning applications and their proposed requirements – with accuracies ranging from 10 cm to 10 m. In [29.46] to facilitate a comprehensive analysis of the performance capabilities of future GNSS from this list, applications were grouped into sets defined through similar recommended navigation performance (RNP) parameters (Tables 29.12 and 29.13). This results in 12 groups of applications. The differentiators between groups are: whether two-dimensional or three-dimensional position fixes are needed; the accuracy needed and the associated integrity alert limit the coverage, in terms of global, regional (continental), or local whether or not continuity is specified as a requirement. All groups of applications have common requirements for availability (99.8%), integrity risk ($10^{-5}$/h) time-to-alarm (10 s), and update rate (1 Hz). To achieve these levels of positioning performance, for the most safety critical of applications, robust PNT information requires three complementary components: a core GNSS; augmentation of GNSS to ensure that GNSS performance is fit for purpose; and adequate backup in the event of GNSS system failure.

In [29.46] the NEMO (Navigation system analysis for European Maritime Operations) software suite was designed to analyze the performance of different GNSS constellations and combinations of different GNSS augmentations. The tool was designed with the specific objective to analyze performance using parameters, metrics, and definitions applied in the maritime sector. Table 29.14 summarizes the predicted capabilities of GNSS scenarios to meet the requirements of the 12 application groups.

**Table 29.11** IMO GNSS performance requirements for general navigation based on resolution A.915(22) (after [29.47])

| | System level parameters | | | | Service level parameters | | | |
|---|---|---|---|---|---|---|---|---|
| | Absolute accuracy | Integrity | | | Availability (% per 30 days) | Continuity (% over 3 h) | Coverage | Fix interval (s) |
| | Horizontal (m) | Alert limit (m) | Time to alarm[b] (s) | Integrity risk (per 3 h) | | | | |
| Ocean | 10 (100)[a] | 25 | 10 | $10^{-5}$ | 99.8 | N/A | Global | 1 |
| Coastal | 10 | 25 | 10 | $10^{-5}$ | 99.8 (99.5) | N/A (99.85) | Global | 1 |

### 29.3.2 Maritime Navigation

General navigation operations in the maritime sector as specified in Table 29.11 differentiates between five major phases: ocean and coastal waters, port approaches, restricted waters, and inland waterways. Safe and reliable navigation of vessels in each of these phases is based on GNSS and its augmentation systems. GNSS receivers used for navigation purposes vary significantly in terms of their positioning performance capabilities, robustness, and cost. GNSS receivers used for recreational and leisure navigation commonly use pseudorange measurements from both GPS and GLONASS satellites to determine the vessel position which drives many of the other features of the unit. Focusing primarily on plotting the position of the vessel on a basemap, features typically reflect those of in-car navigation systems such as route guidance and waypoint navigation as well as maritime specific details such as wind and tide information. More sophisticated models integrate other sensors such as 3-axis compass to provide heading information and a barometric altimeter to track pressure changes to determine elevation and to help monitor weather conditions.

**Fig. 29.16** Trimble SPS351 Marine DGNSS/SBAS Receiver (courtesy of Trimble)

Despite providing adequate positioning capabilities given the relatively low accuracy navigation or tracking requirements and the favorable satellite geometry conditions out on the open water, current generation GNSS faces a number of well-established shortcomings including a lack of basic integrity and limited accuracy without augmentation. Where higher levels of positioning accuracy and integrity are required, GNSS receivers like the Trimble SPS351 (Fig. 29.16), use the corrections and measurements provided by regional SBAS.

The beacon system of the International Association of Marine Aids to Navigation and Lighthouse Authorities (IALA) is the standard maritime GNSS augmentation system for many maritime applications. IALA GNSS beacons are used worldwide to provide DGNSS service for mariners [29.48]. For example, in the United States, the Coast Guard has successfully established a Nationwide Differential Global Positioning System (NDGPS) for maritime and land navigation. In Europe, beacons have been setup to provide DGNSS services across the European Maritime Area. Figure 29.17 is an

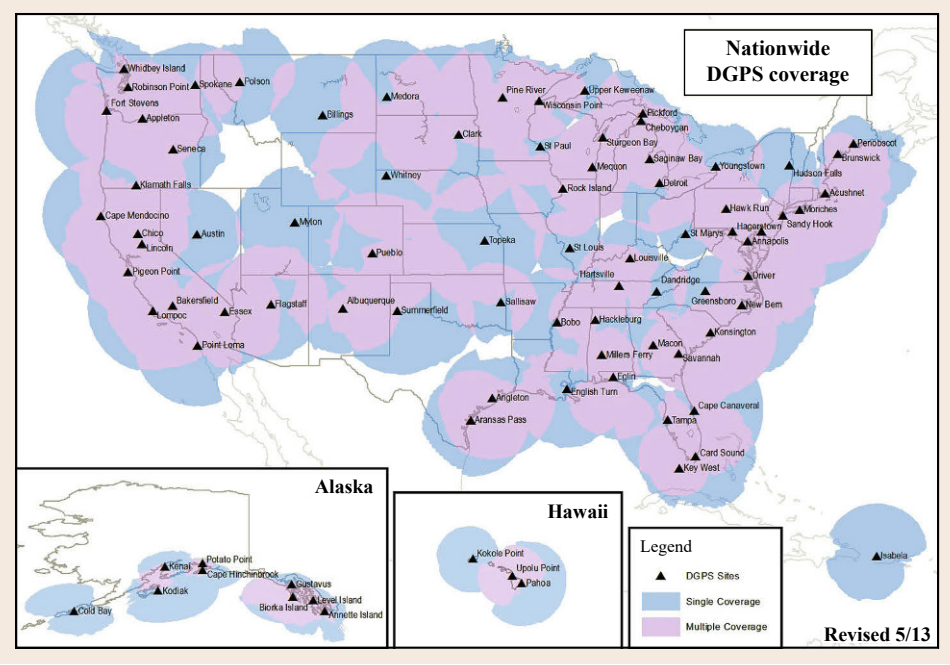

**Fig. 29.17** United States' Differential GPS coverage (courtesy of United States Coast Guard)

example of the coverage of the differential network for the United States.

In Australia, DGPS corrections are broadcast from beacons setup along the coastline. Each DGPS beacon comprises two independent GPS receivers (for redundancy) and a radio transmitter operating in the LF/FM band 285–325 kHz. Typical range of coverage is approximately 150 NM. The corrections are broadcast in the Radio Technical Commission for Maritime Services (RTCM) standard (Annex A.1.3). Typical accuracies achievable with DGPS range between 2–4 m, with accuracies decreasing with range. Since the range of corrections is limited, DGPS using LM/FM radio is restricted to applications that are relatively close to the coastline. For vessels that need DGPS corrections in the open oceans a different method of receiving corrections is required. Receivers such as the Kongsberg DPS112 combined GPS L1/L2, GLONASS L1/L2, and SBAS receiver offer an integrated IALA beacon capability.

In addition, receivers of this class integrate the submeter accuracy from Fugro's Seastar SGG network of globally distributed dual system reference stations. These data are centrally processed to produce a global solution, under which corrections are calculated for each navigation satellite. These corrections are applied to the satellite ephemeris (orbit) and time reference clock information – hence, the term orbit and clock solution. This service utilizes the GPS L1 and L2 frequencies, and the GLONASS L1 and L2 frequencies, thereby providing an accurate measurement of variations in thickness of the ionosphere. This enables signal delay to be calculated and consequently a more accurate range/position is obtained. SGG provides a high availability, high integrity, global solution to a horizontal accuracy of better than 1 m (95%), and vertical accuracy of better than 1 m (95%).

DGNSS receivers typically use code signals to achieve a real-time accuracy of 1 m, 95%. For maritime navigation and operations, PPP techniques deliver decimeter level positioning accuracies using dual frequency carrier-phase measurements in combinations with real-time orbit and satellite clock corrections. The International GNSS Service (IGS) provides free access to real-time orbit and clock products using its global network of IGS reference stations, however, paid subscription services from Fugro's Starfire G4 and Veripos Ultra, provides these corrections using privately managed global networks of reference stations to compute and deliver these corrections via satellite communications. Starfire's service extends beyond GPS and GLONASS to include the BeiDou satellites as well. Enhanced-RTK like capabilities are achievable using Starfire G2+ service, which promises centimeter level accuracies for GPS and GLONASS based on fixed integer ambiguities.

Furuno's SC-110 Satellite Compass (Fig. 29.18) determines a ship's heading by decoding the phase data in the GPS carrier frequency. In Fig. 29.19, a pair of antennas A1(ref) and A2(fore), each connected with an associated GPS engine and processor, are installed along the ship's fore-aft line. The GPS systems at A1 and A2 calculate the range and azimuth to the satellite. The difference in range between A1 and A2 is

$$\Delta\lambda + N\lambda\,,$$

where $\lambda$ is the wavelength of the GPS L1 signal of 19 cm and $N$ is the integer ambiguity resolved by the least-squares ambiguity decorrelation adjustment (LAMBDA) algorithm and automatically found during

**Fig. 29.18** Furuno SC110 Satellite Compass (courtesy of Furuno)

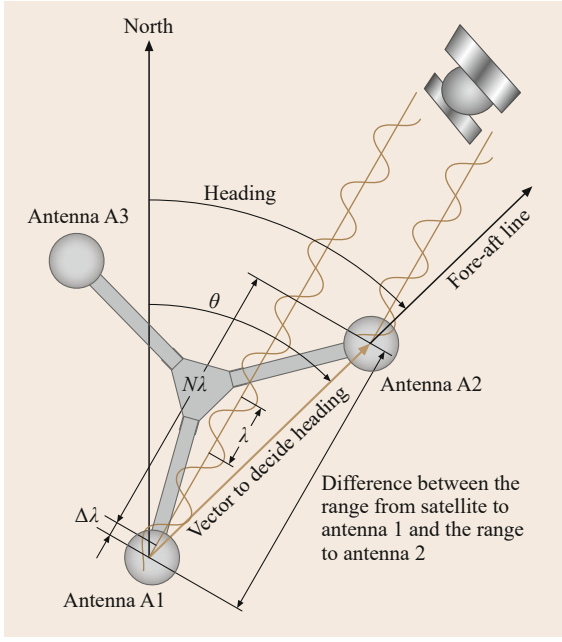

**Fig. 29.19** Furuno SC110 Satellite Compass Computation (courtesy of Furuno)

the initialization stage thus determining a vector (range and orientation) A1 to A2, i. e., heading of ship relative to north. In reality, a third antenna is added to reduce the influence of pitch, roll and yaw, and five satellites are used to process three-dimensional (3-D) data (by third sat), to reduce clock derived error (by fourth sat), and to calculate *N* in the initial stage (by fifth sat). If GPS signal is blocked by a tall building or the vessel is under a bridge, the 3-axis vibrating-gyro rate sensors in the processor unit take the place of the satellite until all five satellites are in view. The rate sensors also contribute to regulating the heading data against pitch, roll, and yaw together with the third antenna (A3 in Fig. 29.19).

### 29.3.3 eLoran

Enhanced long range navigation (eLoran) is an internationally standardized positioning, navigation, and timing (PNT) service for use by many modes of transport and in other applications. It is rapidly emerging as the primary GNSS backup for the IMO e-Navigation concept. eLoran is a low-frequency terrestrial navigation system based on a number of transmission stations, which emit precisely timed and shaped radio pulses centred at 100 kHz radio frequency. Each station emits a sequence of 8 pulses spaced 1000 ms apart. The stations are grouped into chains, which each consists of a single master station and two or more secondary stations. The master station transmits first, followed by successive transmissions from each of the secondary stations of the chain. The master/secondary transmission sequence is repeated periodically, with the period between repetitions called the Group Repetition Interval (GRI). eLoran is an independent, dissimilar complement to GNSS. As such, it will allow PNT users with demanding safety-critical or mission-critical applications to secure their safety, security, and economic benefits even when their satellite services are disrupted. eLoran is capable of meeting the accuracy, availability, integrity, and continuity performance requirements for [29.49]:

- Aviation nonprecision instrument approaches
- Maritime harbor entrance and approach maneuvers
- Land-mobile vehicle navigation
- LBS
- Precise time and frequency users.

The concerns about the vulnerability of GNSS have sparked a renewed interest in the Loran PNT system. Recently, considerable effort has been put globally into investigating whether eLoran can provide a viable backup to GNSS [29.50, 51].

### 29.3.4 Automatic Identification System

The automatic identification system (AIS) is a maritime vessel location and tracking system designed to facilitate the automatic exchange of information between ships and between ships and shore-based authorities (vessel traffic services). The primary function of AIS is to enhance collision avoidance capabilities by providing individual ships with a picture of the marine traffic in their area. Consequently, IMO SOLAS regulations currently mandates AIS be fitted aboard international voyaging ships with gross tonnage of 300 or more, and all passenger ships regardless of size (Fig. 29.20).

AIS integrates a standardized very high frequency (VHF) transceiver (channels 161.975 and

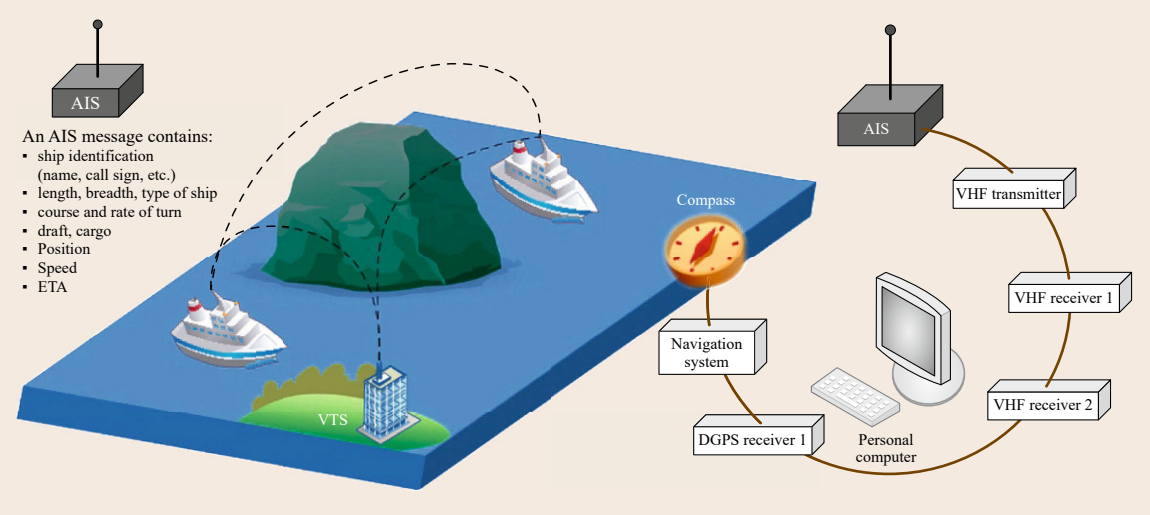

**Fig. 29.20** AIS Architecture (courtesy of Shine Micro and US Coast Gard)

**Table 29.15** Types and classes of AIS

| | |
|---|---|
| AIS Class A | Class A has been mandated by the International Maritime Organization (IMO) for vessels of 300 gross tonnage and upwards engaged on international voyages, cargo ships of 500 gross tonnage and upwards not engaged on international voyages, as well as passenger ships (more than 12 passengers), irrespective of size. |
| AIS Class B | Class B provides limited functionality and is intended for non-SOLAS vessels. It is not mandated by the International Maritime Organization (IMO) and has been developed for non-SOLAS commercial and recreational vessels. |
| AIS Base Station | Base Stations are provided by an aids to navigation authorities to enable the ship to shore/shore to ship transmission of information. Networked AIS Base Stations can assist in providing overall maritime domain awareness. |
| AIS aids to navigation (AtoN) | AIS AtoN provide an opportunity to transmit position and status of buoys and lights through the same VDL, which can then show up on an electronic chart, computer display or compatible radar. |
| AIS SART | Search and Rescue Transmitters using AIS can be used to assist in determining the location of a vessel in distress. |
| AIS on Search and Rescue (SAR) Aircraft | Search and Rescue Aircraft may use AIS to assist in their operations. |

162.025 MHz) with a positioning system such as a differential GNSS or LORAN-C receiver, and other electronic navigation sensors, such as a gyrocompass or rate of turn indicator. AIS transmits, automatically and at set intervals, dynamic information relating to the ship's position, course, speed, and heading; static information related to the ships name, length, breadth; and voyage-related details such as cargo information and status (underway, at anchor). This data is sent every 2–10 s depending on a vessel's speed while underway, and every 3 min while vessels are at anchor. AIS standard comprises several substandards called *types* that specify individual product types. The specification for each product type provides a detailed technical specification which ensures the overall integrity of the global AIS system within which all the product types must operate. The major product types described in the AIS system standards are: Class A and Class B, as well as different types of AIS used for shore stations (AIS Base Stations), aids to navigation (AIS AtoN), AIS on search-and-rescue (SAR) aircraft, and AIS SAR transmitters (AIS SART) (Table 29.15).

Vessels fitted with AIS transceivers and transponders can be tracked by AIS base stations located along coast lines or, when out of range of terrestrial networks, through a growing number of satellites that are fitted with special AIS receivers. Internet delivery of AIS information now provides the public with this information.

### Collision Avoidance

AIS was developed by the IMO technical committees as a technology to avoid collisions among large vessels at sea that are not within range of shore-based systems. The technology identifies every vessel individually, along with its specific position and movements, enabling a virtual picture to be created in real time. The AIS standards include a variety of automatic calculations based on these position reports such as Closest Point of Approach (CPA) and collision alarms. As AIS is not used by all vessels, AIS is usually used in conjunction with radar.

A vessel's text-only AIS display lists nearby vessels' range, bearings, and names. When a ship is navigating at sea, information about the movement and identity of other ships in the vicinity is critical for navigators to make decisions to avoid collision with other ships and dangers (shoal or rocks). Visual observation (e.g., unaided, binoculars, and night vision), audio exchanges (e.g., whistle, horns, and VHF radio), and radar or Automatic Radar Plotting Aid are historically used for this purpose. These preventative mechanisms, however, sometimes fail due to time delays, radar limitations, miscalculations, and display malfunctions and can result in a collision.

While the requirements of AIS are to display only very basic text information, the data obtained can be integrated with a graphical electronic chart or a radar display, providing consolidated navigational information on a single display.

### Fishing Fleet Monitoring and Control

There is an increasing interest in ensuring that fishing and aquaculture resources are environmentally, economically, and socially sustainable. Strategies such as the the EU common fisheries policy are aimed at achieving this outcomes [29.52]. GNSS will play a significant role in monitoring and enforcing many regulatory requirements of this policy. Examples include, proving where fishing vessels are and managing fishing quotas. In a broader sense, GNSS will be central to any effort aimed at efficiently managing the conflict-

ing uses of maritime areas. Real-time and postprocessed GNSS positions will support many of the diverse activities included in maritime spatial planning (MSP), defined as [29.53]:

> *a process of analyzing and allocating parts of three-dimensional marine spaces to specific uses, to achieve ecological, economic, and social objectives that are usually specified through the political process.*

AIS is widely used by national authorities to track and monitor the activities of their national fishing fleets. AIS enables authorities to reliably and cost effectively monitor fishing vessel activities along their coast line, typically out to a range of 60 miles (depending on location and quality of coast-based receivers/base stations) with supplementary data from satellite-based networks. The BDStar Navigation CDG-MF-08A BeiDou receiver (Fig. 29.21) is an advanced BeiDou receiver based on the technologies of positioning, communication, timing, and location-based information services of the BeiDou satellite. This receiver can manage a large amount of subordinated BeiDou subscriber machines in a wide range and monitor the ship position information and text message communication information of authorized subscribers in an area covered by the BeiDou system in real time, thereby protecting and convoying safety production in the marine fisheries.

### Vessel Traffic Services

In busy waters and harbors, a local vessel traffic service (VTS) may exist to manage ship traffic. Here, AIS provides additional traffic awareness and information about the configuration and movements of ships.

### Maritime Security

AIS enables authorities to identify specific vessels and their activity within or near a nation's Exclusive Economic Zone. When AIS data is fused with existing radar systems, authorities are able to differentiate between vessels more easily. AIS data can be automatically processed to create normalized activity patterns for individual vessels, which when breached, create an alert, thus highlighting potential threats for more efficient use of security assets. AIS improves maritime domain awareness and allows for heightened security and control. Additionally, AIS can be applied to freshwater river systems and lakes.

**Fig. 29.21** BDStar Navigation CDG-MF-08A Beidou Maritime Receiver (courtesy of BDStar)

### Aids to Navigation

The AIS Aids to Navigation (AtoN) product standard was developed with the ability to broadcast the positions and names of objects other than vessels, such as navigational aid and marker positions and dynamic data reflecting the marker's environment (e.g., currents and climatic conditions). These aids can be located on shore, such as in a lighthouse, or on water, platforms, or buoys. The US Coast Guard has suggested that AIS might replace racon (radar beacons) currently used for electronic navigation aids [29.54].

AtoN's enable authorities to remotely monitor the status of a buoy, such as the status of the lantern, as well as transmit live data from sensors (such as weather and sea state) located on the buoy back to vessels fitted with AIS transceivers or local authorities. An AtoN will broadcast its position and identity along with all the other information. The AtoN standard also permits the transmit of *Virtual AtoN* positions whereby a single device may transmit messages with a *false* position such that an AtoN marker appears on electronic charts, although a physical AtoN may not be present at that location.

### Search and Rescue

Deployed in 1982, the COSPAS-SARSAT is a worldwide satellite search-and-rescue (SAR) system that provides distress alert and location information to respective SAR authorities globally for maritime, aviation, and land users in distress [29.55]. SARSAT is an acronym for search and rescue satellite-aided tracking. COSPAS is an acronym for the Russian words *Cosmicheskaya Sistyema Poiska Avariynich Sudov*, which mean *Space System for the Search of Vessels in Distress*, indicative of the maritime origins of this distress alerting system.

The space segment for COSPAS-SARSAT consists of SAR payloads hosted by low-Earth orbiting (LEOSAR) and geostationary satellites (GEOSAR). To further improve the system performance, SAR capabilities will be hosted by the middle Earth orbits of the three GNSS constellations: GPS, Galileo, and GLONASS (MEOSAR). It is expected that by 2020 COSPAS-SARSAT will rely on a medium altitude Earth orbit MEO/GEO space segment, replacing the low Earth orbit LEO/GEO design [29.56]. With numerous

satellites, each with an Earth coverage or footprint significantly larger than the LEO satellites (about seven times larger), the MEOSAR constellations will enable an instantaneous and worldwide coverage. Distress beacons will be detected and located more quickly and accurately than today, in as little as one beacon burst, that is, about 50 s. The more efficient alert notices that result will directly contribute to the efficiency of rescue operations where time is critical. A COSPAS-SARSAT beacon operating on 406 MHz frequency is used to indicate distress. There are three types of beacons: emergency locator transmitter (ELT) for aviation use, emergency position indicating radio beacon (EPIRB) for maritime use, and personal locator beacon (PLB) for general land or rail use. These beacons allow for digitally coded unique identification information in the beacon message, including location of the distress site based on GNSS (for new generation beacon models). In addition, second-generation beacons have a higher requirement for independent location accuracy.

For coordinating on-scene resources of a marine SAR operation, it is imperative to have data on the position and navigation status of other ships in the vicinity. In such cases, AIS can provide additional information and enhance awareness of available resources, even if the AIS range is limited to VHF radio range. The AIS standard also envisioned the possible use on SAR aircraft, and included a message (AIS Message 9) for aircraft to report their position.

To aid SAR vessels and aircraft in locating people in distress, the specification (IEC 61097-14 Ed 1.0) for an AIS-based SAR transmitter (AIS-SART) was developed by the IEC's TC80 AIS work group. AIS-SART was added to Global Maritime Distress Safety System regulations effective January 1, 2010. AIS-SARTs have been available on the market since at least 2009.

Future GNSS will contribute to the international SAR service, enhancing the worldwide performance of the current COSPAR-SARSAT system. The positioning accuracy of today's system is very poor (typically a few kilometers) and the alert is not always issued in real time. The Galileo SAR service will drastically reduce the time to alert, and the position of the distress beacon will be determined to within a few meters [29.57].

### 29.3.5 Shipping Container Tracking

The role of GNSS in automating commercial maritime activities has gained prominence given the significant operating efficiencies achievable. In many areas, it is the tracking capabilities of GNSS that can realize these benefits. In this section, the focus is on shipping container tracking, identified as one of the major growth areas of maritime asset tracking, with millions of shipping containers flowing through ports all over the world on a daily basis [29.58]. This growth has been matched by developments in robust container tracking and tracing systems [29.59].

In [29.60] the Skema interactive knowledge based platform for transport and logistics highlight the use of GNSS for container tracking and tracing solutions. Differential and SBAS technologies for used for localization, combined with different telecommunication means (satellite and/or terrestrial) for communication. These combined GNSS-Telecommunication devices are installed on-board the containers/swap bodies/etc. Internationally, other forms of RTLS are used in ports. For example port of Singapore uses RFiD technology [29.61] with other proposed solutions based around wireless network technology and inertial sensors. In almost all cases, these solutions are integrated with the core GNSS capability [29.62].

While it is perhaps only necessary to locate an individual container to an accuracy of 10 m, operation in port areas and the task of placing containers onto cargo trucks and boats requires much finer levels of accuracy often at the millimeter level. Combined with associated problems of satellite visibility and multipath particularly in port areas, alternative positioning technologies have been readily integrated with GNSS as part of standard container tracking and gantry cranes.

Basic user requirements are for example [29.60]:

- Container tracking for the periodic real-time positioning of the swap body/container.
- Container integrity control.
- Geographical location related to automatic alerts and reports.
- Geofencing functions to raise a warning in case of deviation from a predefined route or in case of goods transiting into forbidden areas.
- Triggering of alarm with position data in case of tampering occurrence (e-seals anomalous data).
- Triggering of alarm in case the device does not show signs of life for a certain period of time indicating the possibility of tampering, removal, or destruction of the device.
- Times of departure, arrival, border crossing.
- Data management from inspections for statistical services.
- Operational history data logging and processing.
- Automatic and on-demand reports of the containers and their location and status.

## 29.4 Outlook

GNSS applications across the land, rail, and maritime sectors broadly reflect efforts to achieve multimodal C-ITS. As the whole of GNSS expands into these sectors, the challenges for meeting the performance requirements for safety and liability critical applications have necessitated the development of robust GNSS augmentation capabilities in terms of sensor fusion, measurement integration algorithms and innovative use of current and emerging signals of opportunity. This chapter has presented the current status of some of these augmentation technologies and techniques, but it is without question that the future will see more applications and more approaches to delivering GNSS-like performance in the most difficult environments.

# 30. Aviation Applications

Richard Farnworth

The Global Positioning System (GPS) has been available for civilian use for the past three decades and is now extensively used in aviation to support multiple applications.

This chapter describes how GNSS is used in aviation, the performance requirements that are being applied and the operational applications that have been enabled. It describes how conventional navigation has been gradually replaced by area navigation, the global introduction of Performance Based Navigation (PBN) and how the availability of GNSS has played a significant role in that evolution. The performance requirements for the different phases of flight are presented including the different methods by which the navigation integrity is ensured.

The goal of this chapter is to provide the reader with an overview of how GNSS has been adopted in aviation and explain how it has been integrated onto the aircraft alongside other navigation systems. The regulatory and certification process is also described to introduce the mechanisms by which aircraft operators can get approval to use GNSS in their daily operations.

## 30.1 Overview

The aviation community has embraced the use of GNSS as it provides a high performance global navigation capability meeting many of the requirements of aviation users. Furthermore, the cost, size and flexibility of GNSS receivers make it an attractive navigation solution for all airspace users. The global drive towards performance based navigation is creating an even stronger role for GNSS and together with external augmentation systems is enabling the introduction of new kinds of approach procedures which can improve safety and provide better access to airports. GNSS will be the cornerstone for many aviation applications in the future. However, there are still concerns with the single frequency, single constellation civil aviation uses today. The main issue is vulnerability linked to the robustness of the signals and the potential for electromagnetic interference; both unintentional and intentional. A multi-constellation/multi-frequency (MC/MF) environment should alleviate the majority of these issues but will introduce additional complexity. In order to explain its role and the way aviation uses GNSS this chapter will describe the evolution from conventional navigation to today's PBN environment and show how the different aviation applications have benefitted from the introduction of GNSS.

### 30.1.1 Conventional Navigation

Instrument navigation evolved from simple radio direction finding. By the 1920s aviation specific navigation systems had been developed such as radio ranging otherwise called A/N transmitters. This was based on a network of radio transmitters broadcasting the Morse code letters *A* and *N*. The pilot would listen to the broadcast tones and when the aircraft was on course he would hear a steady tone. When left of track he would hear the Morse code letter *A* and when right of track he would hear *N*. This system, which by the 1930s had defined a series of air routes across the continental US (CONUS), was the forerunner of the Non Directional Beacon (NDB). Today, the NDB is considered the most basic navigation aid; a simple radio transmitter which radiates a single frequency omnidirectional signal. Although the system is over seventy years old new NDB transmitters are still being installed today. In the aircraft, the receiving antenna was originally manually adjusted to find the signal bearing but very quickly became automated and is today called Automatic Direction Finding (ADF). This navigation capability allows the pilot to identify the relative bearing to the beacon. One of the challenges for the aircrew using NDB was that to *home-in* to a station the pilot had to correct for wind, so flying a specific bearing to/from the station required some skill. The introduction of VHF Omnidirectional Range (VOR) in the 1950s provided a specific bearing, or radial, to the ground aid but with significantly enhanced accuracy compared to the NDB. Figure 30.1 illustrates an aircraft flying on a radial towards a VOR station marked by the small hexagon symbol. It also illustrates a position *fix* at the intersection of radials from two VOR stations. Aircraft navigation was further enhanced in the 1960s by the introduction of Distance Measuring Equipment (DME) which, as the name suggests, provides range information. DMEs are often co-located with VOR stations to provide the pilot not only a radial but also a distance to the navigation aid.

As air transport grew in the 1930s and 40s the recognition that formal coordination of traffic flows and the management of the airspace was necessary. From the late 1940s until the late 1990s the structure of the airspace and the Air Traffic Services (ATS) routes was designed around the location of ground-based navigation aids. The ATS routes were point-to-point connecting one ground aid to another. When

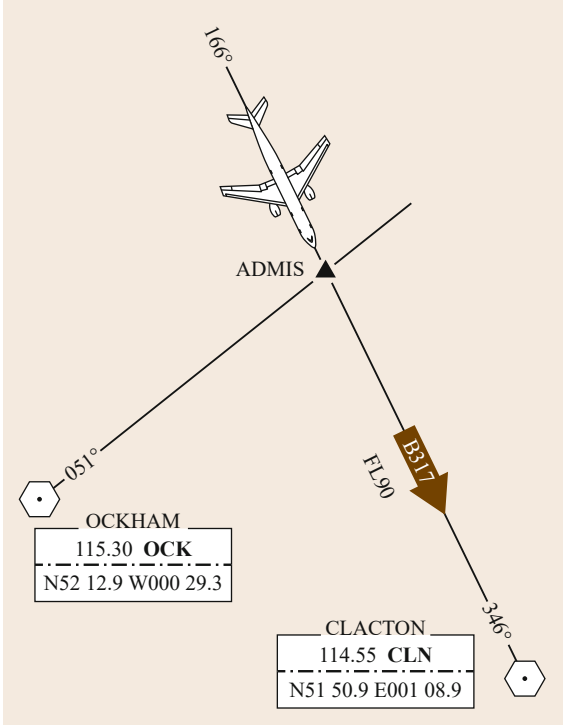

**Fig. 30.1** Conventional navigation: the aircraft is approaching a position fix, ADMIS, identified by the intersection of two VOR radials

new ATS routes were required additional navigation aids had to be installed to support them. If location or cost did not permit a new navigation aid then a *fix* could be defined provided the supporting navigation aids were within range. A *fix* is the point defined by the intersection of two radials or a range and bearing from a collocated VOR/DME. Where airports did not have precision instrument landing systems these same navigation aids were used to provide guidance for Non-Precision Approach (NPA) procedures. The location of the navigation aids was often therefore a compromise between the en-route and approach navigation requirements.

As the continental ATS route structure was defined by tracks to and from the ground navigation aids the pilots normally flew them by manually selecting aircraft heading, observing the bearing and distance to the aid and correcting the track to take account of the wind. The resulting navigation accuracy achieved was around 5 nmi (nautical miles). This is the 2-sigma value indicating that aircraft will be within 5 nmi of the desired track for at least 95% of the flight time. However, performance is not uniform as the precision of the VOR improves the closer to the station the aircraft is. The safety and protection requirements of the ATS routes were based on this expected performance. One major disadvantage of conventional navigation was that as the traffic increased and more ATS routes were implemented to manage the aircraft, more and more routes were starting or terminating at each navigation aid. Bottlenecks were appearing in the system. In the 1990s traffic saturation started to appear in certain places of the European network and this was the driver for action.

## 30.1.2 Area Navigation – RNAV

In the late 1970s the first digital avionics started appearing on civil aircraft. The Lockheed L1011 Tristar is credited as the first commercial aircraft with a navigation computer. The computer was called Carousel and it allowed pilots to manually enter coordinates and then use inertial navigation to guide the aircraft to that position. The pilots started using these early computers to fly the conventional ATS routes by inserting the coordinates of the ground based aids into the computer and allowing the navigation system to provide the guidance along the required inbound radial. These early computers were the forerunner of the modern, complex Flight Management System (FMS) which looks after the navigation, guidance and many other features of the aircraft. The ability to fly to a coordinate rather than to the overhead of a navigation aid provided flexibility and led to the development of Area Navigation (RNAV) which is defined as follows [30.1]:

> *A method of navigation which permits aircraft operations on any desired flight path within the coverage of ground or space-based navigation aids or within the limits of the capability of self-contained aids, or a combination of these.*

Figure 30.2 illustrates an RNAV route between a series of waypoints superimposed on a conventional route which passes over the groundbased navigation aids. The onboard computer used the same navigation aids to compute its position but the pilot was no longer obliged to fly from one aid to the next.

The evolution of on-board navigation computers which provided an area navigation capability enabled aircraft to be operated on any track between two geographic points-in-space independent of the location of the ground navigation aids. Aircraft now had the ability to fly to waypoints as well as tracking bearings between ground aids. This, theoretically at least, allowed new routes to be designed anywhere without requiring additional navigation aids to be installed. RNAV was available in the 1970s and 80s using VOR and DME inputs.

Despite these advances the route structure in air traffic systems remained firmly based on the location of the ground navigation aids. With only a partial equipage of the aircraft fleet the route structure could not be adapted. Handling a mix of aircraft, some with RNAV capability and some without, and the assignment by ATC of RNAV or conventional routes depending on aircraft capability proved to be unworkable. To overcome this problem in Europe a mandate for the carriage of *Basic-RNAV* equipment [30.2] finally came into force

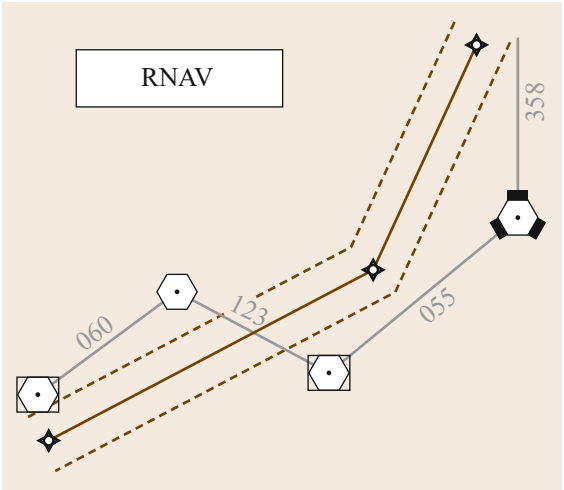

**Fig. 30.2** Conventional and area navigation between waypoints independent from the location of the ground based aids

in April 1998 more than twenty years after commercial aircraft with an area navigation capability had started rolling off the production line.

### 30.1.3 The Arrival of GNSS

At the same time as the aviation community was realising the potential of area navigation and addressing how to gain benefit from the capability of RNAV systems, the American Navstar Global Positioning System (GPS) was evolving. GPS could support RNAV systems globally so coverage of navigation aids would no longer be an issue. The GPS programme had been initiated in 1973 and by 1978 the first satellite was in orbit. During the 1980s the majority of the constellation was deployed and although it was not fully operational, GPS played an important role in the first Gulf War. Following the loss of flight KAL007, a Korean Airlines Boeing 747, which was shot down by the Soviets in 1983, President Reagan authorised that civilians should be given access to GPS. However, when the civilians were granted access to the GPS signal, the US military did not want their positioning system to be used against them and so they deliberately degraded the performance of the Standard Positioning Service (SPS) by a slight jittering of the atomic clock and a slight corruption of the navigation message. This deliberate degradation in performance on the primary frequency, L1, was called Selective Availability (SA) [30.3, 4]. Even with this known degraded performance, the aviation community could see the potential of this positioning system which provided global coverage and a position accuracy that was far better than any existing conventional ground-based navigation aid [30.5].

However, aviation is a highly regulated industry and if GPS was to be used on-board aircraft there was a need to develop international global standards. The avionics industry, the Radio Technical Commission for Aeronautics (RTCA), produced the first industry standard for GPS receivers in 1991 [30.6] and it was entitled *Minimum Operational Performance Standards for Airborne Supplemental Navigation Equipment Using Global Positioning System* (RTCA DO-208). This standard was soon followed by a European equivalent (ED-72-A) issued by Eurocae, the European Organisation for Civil Aviation Equipment and the US Federal Aviation Administration (FAA) Technical Standard Order, TSO C-129 [30.7], which provided the means by which GPS equipment could be installed and integrated on-board commercial aircraft and certified for operational use. It should be noted from the title that DO-208 and its European equivalent ED-72A allowed only for *supplemental* use of GPS at that time. This meant that the GPS equipment did not replace the conventional navigation equipment on the aircraft but was carried in addition and that the ground-based navigation aids needed to be kept operational in case of problems with GPS. This requirement is clearly demonstrated in the Joint Aviation Authorities (JAA) certification document for basic area navigation [30.8] which allowed the use of GPS as a RNAV sensor but with limitations.

The introduction of GPS as a navigation system was relatively clear cut for the aircraft manufactures, avionics manufacturers and even to the aircraft operators. A GPS receiver was another navigation box that had to be integrated and certified like any other on-board system. However, for the wider aviation community the GPS signal-in-space (SIS) was an enormous change and this was particularly true for the national air navigation service providers who provided Air Traffic Control and the enabling communications, navigation and surveillance services.

#### International Standardisation

International standards for civil aviation are governed by the International Civil Aviation Organisation (ICAO), a United Nations agency, and laid down in the Convention on International Civil Aviation, also known as the Chicago Convention, which was signed in 1944 by the initial 52 contracting States. Over the last 60 years, the ICAO family has grown and today has 191 signatory States. ICAO develops global Standards and Recommended Practices (SARPS) which are binding on the Member States unless they file for non-compliance and Procedures and Air Navigation Services (PANS) which may or may not be applied in each Member State.

Under Article 28 of the convention Contracting States are required to:

> *undertake, so far as it may find practicable, to provide, in their territory [...] air navigation facilities to facilitate international air navigation, in accordance with the standards and practices recommended or established from time to time, pursuant with the Convention.*

Until the advent of global positioning systems, every State had always provided their own navigation facilities within their territories. The arrival of global positioning systems brought a dilemma for some States. Here was a system providing global coverage but under single State control and in the hands of the military as well! The natural question that arose was *What responsibilities would a State be assuming by allowing the use of such a system for air navigation within its airspace?* [30.9]: It has taken some States a long time to overcome this institutional hurdle, there has been much debate and not all of them have yet succeeded

in allowing GPS to be used for anything other than supplemental navigation. The lack of control over core constellations GPS and GLONASS, both under military control, and the unwillingness to become dependent on signals provided by a single foreign State has been partly the driver for the development of the new and evolving satellite positioning systems such as Europe's Galileo, the Chinese BeiDou (also known as Compass) and the Indian Regional Navigation Satellite System (IRNSS/NavIC).

In 1994 the US Government offered, in a letter from the FAA Administrator to ICAO, that the:

> *GPS standard positioning service was to be made available on a continuous worldwide basis and free of direct user fees for the foreseeable future. At least 6 years notice prior to termination.*

A similar offer concerning GLONASS was made in 1996 by the Russian Federation.

#### A common Geodetic Reference System

The introduction of area navigation, which is based on the ability of the aircraft's computer to fly between coordinates, highlighted the need for the entire aviation community to move towards a common geodetic reference system rather than the national systems historically used. The introduction of GPS with its own global reference system reinforced the need for a uniformly coordinated reference system and the aviation community accepted this change. The ICAO Assembly agreed in 1989 to adopt WGS-84 [30.10], the latest evolution of the militarily developed World Geodetic System, as the standard geodetic system to be applied globally. With every State using their own national reference system, each developed separately for national needs and in the majority of cases not being compatible with each other; a coordinate given in one system did not bring the user to the same position in a neighbouring States coordinate system. As all reference systems are mathematical models, conversion from one model to another is possible. However, with the global implementation of WGS-84 in the 1990s it became very apparent that transformation from the national datum to WGS-84 was not a simple task [30.11] as in many cases the original survey data was either not available or of insufficient accuracy to support the precision needed for the aviation RNAV requirements. Therefore, the WGS-84 implementation programme took many years and even today some States have filed *non compliance* against this ICAO standard.

## 30.2 Standardising GNSS for Aviation

In 1993, ICAO established the GNSS Panel and tasked it with the objective to develop Standards and Recommended Practices (SARPs) for the use of GNSS in aviation. GNSS was given the following broad definition [30.12]:

> *A worldwide position and time determination system that includes one or more satellite constellations, aircraft receivers and system integrity monitoring, augmented as necessary to support the required navigation performance for the intended operation.*

The way GNSS was standardised in ICAO was a significant departure from the way standardisation had been done for other, traditional ground-based navigation systems. The purpose of standardising a conventional navigation aid such as a DME was to ensure interoperability. A DME transponder (the ground station) could be produced by a variety of global manufacturers and each manufacturer's transponder would need to behave exactly the same way in response to an airborne DME interrogator. With GPS the constellation was already global and the signals were defined by the US military in the Interface Control Document (ICD) 200 series and even though other GNSS systems would be developed later there would not be one constellation or augmentation with exactly the same signal characteristics as the other. The purpose of developing the SARPs for GNSS was to ensure that the aviation community had a common understanding of the parameters of the signal that could be assumed by the manufacturers of aviation receivers. Some States argued that the GPS signal was already defined in the ICD and the Standard Positioning Service (SPS) Performance Standard published by the US government [30.13]. These States felt it was not beneficial to reproduce all or part of the two documents in an ICAO standard. Eventually, it was decided to develop the ICAO GNSS standards [30.14] and they were published in Annex 10 [30.12] in 1999 and became globally applicable in 2001.

For civil aviation, whilst the accuracy of the position estimation is important, the confidence that the estimation is not corrupted is equally as important. This level of confidence is called *integrity* [30.15] and civil aviation has set a $10^{-7}$ requirement on the positioning system to alert the crew if there is a problem; that equals one missed detection in 10 000 000. Although the US DoD had considered a unique integrity channel when

GPS was being developed in the 1970/80s, it was never implemented due to cost. Therefore, for civil aviation integrity needed to be *added* to make the signal acceptable and this addition is referred to as augmentation.

ICAO has standardised three different types of augmentation system for GNSS as follows:

- Aircraft Based Augmentation System – ABAS
- Satellite Based Augmentation System – SBAS
- Ground Based Augmentation System – GBAS.

These systems are shortly described below. For detailed information on SBAS and GBAS, readers are referred to Chaps. 12 and 31, respectively.

### 30.2.1 Aircraft Based Augmentation Systems

This type of augmentation is the simplest form of integrity monitoring and can be segregated into two techniques. The first is to integrate the GPS receiver with inputs from other on-board sensors such as accurate clocks, altimetry systems or inertial platforms. This form of ABAS was termed Aircraft Autonomous Integrity Monitoring (AAIM). The second technique, which is the most widely applied form of ABAS used with GPS, is Receiver Autonomous Integrity Monitoring (RAIM). RAIM is an algorithm within the GPS receiver which makes use of redundant signals from the satellite constellation due to the availability of more than the minimum set of satellites needed to compute a position. A receiver requires four satellite measurements to compute a 3-dimensional position solution and its time. As the constellation was originally designed with 24 satellites and the actual number of satellites in the constellation has been consistently above that, more than the minimum number are generally visible to the user receiver. With those extra satellites available the algorithm in the user receiver can check the relative consistency of the different measurements and identify if a faulty satellite exists. This is called fault detection and a warning can be issued to the pilot if the receiver detects a fault. A warning is also given if the number of satellites is not sufficient to perform the RAIM check. If six or more satellites are visible some RAIM algorithms are capable of not only detecting the fault but also identifying which is the erroneous ranging source. This enables the receiver to exclude the faulty satellite and continue to provide a position with integrity; this functionality is called Fault Detection and Exclusion (FDE). As the ICAO standards are intended to define the Signal-in-Space and RAIM is a function implemented in the user equipment, the aviation specifications for RAIM can be found in the avionics equipment standards developed by organisations such as the RTCA and Eurocae [30.6].

### 30.2.2 Satellite Based Augmentation Systems

SBAS uses a regional network of ground monitoring stations to assess the core constellation and provide a navigation message to users through Geostationary Satellites. The SBAS system architecture is shown in Fig. 30.3. The navigation message created by the SBAS master control station provides range corrections and integrity information for each satellite in view of the ground monitoring network. If a GPS satellite correction becomes too large, then a *Do-Not-Use* flag will be sent for that satellite. These corrections are applied in the user equipment and provide both improved positioning accuracy and integrity.

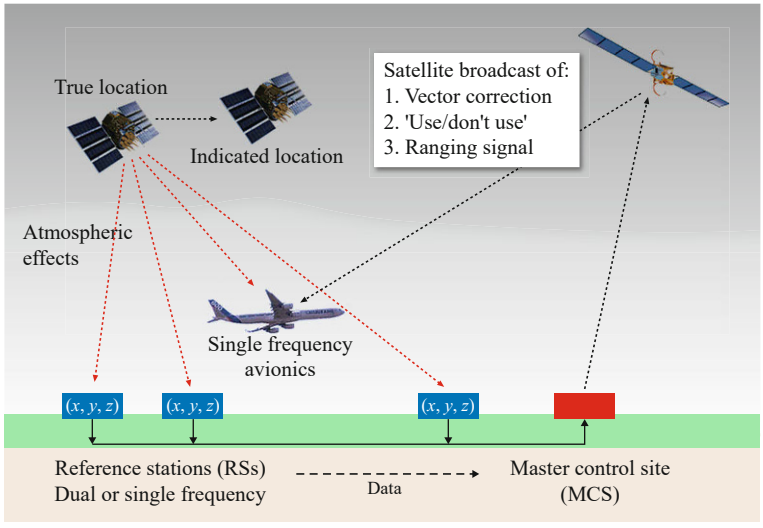

**Fig. 30.3** SBAS system architecture. Correction messages are broadcast to the user through a geostationary satellite

Several SBAS systems have been implemented or are under development in different regions of the world beginning with the US Wide Area Augmentation System (WAAS) [30.16], and followed by the European Geostationary Navigation Overlay Service (EGNOS) [30.17], the Japanese Multi-functional Satellite Augmentation Service (MSAS) [30.18], the Indian GPS Aided Geo Augmented Navigation (GAGAN) [30.19] and the emerging Russian System for Differential Corrections and Monitoring (SDCM) [30.20]. The reader should note that currently only SDCM provides monitoring of GPS and GLONASS. All the other SBAS systems only augment GPS. SBAS can provide older and less capable aircraft with a high end navigation capability with relatively little investment.

### 30.2.3 Ground Based Augmentation Systems

This augmentation system provides local monitoring of the core constellation and works on the principle that the error at the location of the ground station is the same as that of the aircraft. Whilst this is true when the aircraft is close to the ground station, the differences increase when the aircraft is further away. The GBAS system architecture is shown in Fig. 30.4. GBAS uses a series of very accurately located antennas on or around an aerodrome which feed the received signals to the processing unit allowing the system to calculate the time delay on each signal in view of the station. The processing unit generates a series of navigation messages which are transmitted to approaching aircraft using a VHF data broadcast (VDB) transmitter. The system also holds a series of unique approach paths in the approach database and upon selection by the ground station operator, the GBAS will transmit the desired final approach segment (FAS) for the aircraft to follow.

GBAS systems are intended to support precision approach and landing operations and ultimately replace the conventional Instrument Landing System (ILS).

A major benefit of GBAS over traditional precision approach and landing systems (ILS and MLS) is that a single station can support multiple runway ends and in theory, at least, can support multiple aerodromes which are in close proximity to each other. For ILS and MLS each runway requires a dedicated system and antenna installed close to the runway to support precision approach and landing operations. Therefore, GBAS has the potential to offer service providers with a cost effective solution to support multiple runway ends. Furthermore, as GBAS does not have to be located at the runway end, airports which previously could not support a precision approach due to geographical limitations and antenna siting issues may now be able to provide that capability. Another important benefit of GBAS over ILS is the potential to increase runway throughput during low visibility operations. When Low Visibility Procedures are implemented the ILS systems require a greater protection of critical and sensitive areas to ensure the radio signals emitted from the ground transmitters located close to the runway are not interfered with by any moving object such as an aircraft. Therefore, in low visibility conditions extra spacing between aircraft on approach is required. This can have a significant impact on the runway throughput. As GBAS does not have the same critical and sensitive areas as ILS the spacing between aircraft can be maintained in all weather conditions.

There are three different categories of ILS which support three different categories of approach and landing operations. These approaches bring aircraft to a Decision Height (DH) above the runway where the pilot must have sufficient visual references to be able to complete the landing or initiate a missed approach

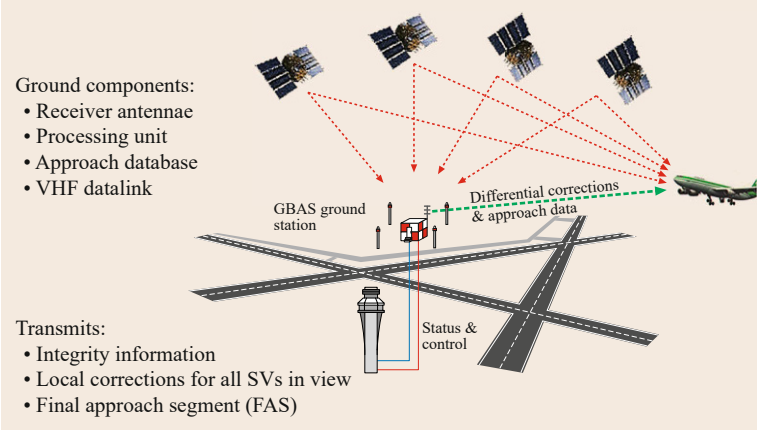

**Fig. 30.4** GBAS system architecture

procedure:

- Category I: Minimum DH = 200 ft
- Category II: Minimum DH = 100 ft
- Category III: No DH.

GBAS Category I systems are already operational in the US, Europe, Australia and Russia and development is ongoing to enable these systems to evolve to support Category II and III operations in the future.

## 30.3 Evolution of the Flight Deck

Up until the 1970s, flight crews played an active role in the generation of the position solution and the utilisation of the navigation information to meet the airspace requirements. The pilot followed information provided on printed charts showing the routes and the location of the ground based navigation aids. Pilots manually tuned the required navigation aids, identified the station and then used the signal to locate the aircraft on the ATS routes. With the advent of digital avionics this role started to change. From as early as the 1980s Flight Management Systems (FMS) started to include the ability to perform automatic navigation. Even with added automation the flight crew were still required to monitor the aircraft trajectories with reference to conventional navigation aids as the FMS was only approved for what was called supplemental navigation as mentioned earlier. In the 1990s along with the arrival of GPS the systems became more integrated and a monitoring function was added where the actual navigation performance being achieved was displayed to the pilot and could be checked against the required navigation performance for the route. This led to a more hands-off approach for the flight crew as the routes were programmed into the FMS and workload was considerably reduced.

Commercial aircraft use multi-function displays such as can be seen in Fig. 30.5. The displays are fed by the flight management computer and the various avionics equipment that are located in the avionics bay with all the other boxes that are Line Replaceable Units (LRUs) with a standardised form and interface. A typical GNSS avionics receiver used in commercial aircraft is shown in Fig. 30.6.

However, flight management systems became extremely complex and their development was not harmonised. Systems evolved in different ways as the different FMS manufacturers implemented a wide range of functionalities [30.21]. Issues became apparent due to the different performance of various aircraft with different FMS types or even different software versions of the same manufacturers FMS. The published ATS routes were not flown in exactly the same way, the aircraft did not always turn at the same point and the accuracy of the trajectory was not harmonised. This issue of mixed performance, commonly referred to as *mixed mode* operations, had to be addressed. The computer systems relied on input data which was formalised in an industry standard document published by Aeronautical Radio Incorporated, ARINC 424 [30.22], describing the navigation system database which became the reference document for interchange of data between different airborne systems. As navigation was becoming more automated and the navigation performance relied on high quality data, the responsibility of the providers of the navigation database increased and detailed processes were needed to ensure that data integrity could be guaranteed.

### 30.3.1 The Navigation Data Chain

Each country is required by ICAO to provide an Aeronautical Information Publication (AIP) which contains all the details of regulations, procedures and other information necessary for flying in that country's airspace. Data houses use the information published in the AIPs to create the source navigation data in ARINC 424 format that will be used by the FMS suppliers to create the on-board navigation databases.

Because of the importance in the correctness of the navigation data the whole process is regulated by a number of standards beginning with the ICAO Annex 15 which establishes global standards for aeronautical information services (AIS). Industry standards covering data source providers and FMS database providers [30.23, 24] have been developed to establish clear processes to make sure that the navigation data quality is assured throughout the data chain. Today the data suppliers are audited against the industry standards for the processing of aeronautical data by the regulatory authorities in an effort to ensure high quality data.

Changes are continuously being made in the aviation environment due to the introduction of new routes, navigation aids and procedures. Therefore a fixed 28 day amendment cycle for the on-board navigation database has been defined within ICAO Annex 15 and this is called the Aeronautical Information Regulation and Control (AIRAC) cycle. The AIRAC cycle, first adopted in 1964, requires that the aeronautical databases are always up to date. It is essential, for both efficiency and safety, that Pilots, Air Traffic Controllers, Air Traffic Flow Managers, Flight Management Systems and Aviation Charts all have the same data set. The AIRAC cycle defines effective dates which are globally harmonised to ensure that every stakeholder in the system applies changes at the same time.

### 30.3.2 General Aviation

Due to their cost and complexity flight management systems were originally only available on large commercial air transport type aircraft. Pioneers in the development of General Aviation RNAV systems began to appear in the 1980s based on Loran-C positioning inputs. These units provided the basic RNAV functions to provide guidance along a route between a series of waypoints. When GPS started becoming available at the beginning of the 1990s these same RNAV functionalities were re-engineered around a GPS navigation engine which replaced the Loran-C element for providing the position information. Garmin, the market leader in general aviation GNSS navigation units has built on this experience to create equipment available for general aviation aircraft that has almost all of the same navigation functionalities as the FMS used in commercial airliners [30.25]. A typical in general aviation navigation unit is shown in Fig. 30.7. This is a stand-alone unit installed in the cockpit instrument panel.

One of the issues that arose in the early days was the need for appropriate pilot training. General aviation pilots now had an on-board computer with hundreds of different functions and it was essential that they knew how to use and monitor these functions correctly.

### 30.3.3 Helicopters

Helicopter operations are often performed in challenging environments such as mountainous areas for emergency medical services, flights to offshore oil platforms and at low level in built up urban environments. When visibility is poor their operations are severely limited. The use of GNSS technology has enabled new procedures to be introduced that enhance safety and allow flights in conditions where visibility is limited and there is no surveillance available. Operations to offshore oil platforms are often outside the coverage of ground based navigation aids and in bad weather the use of

**Fig. 30.7** A typical general aviation GNSS navigation unit (courtesy of Garmin)

weather radar was very common as a means of navigating towards the platforms and avoiding obstacles. The weather radar was never designed for this purpose and safety concerns were raised by regulatory authorities. The introduction of GNSS based RNAV procedures has significantly contributed to safety improvements for helicopter operations. Dedicated instrument flight procedures for helicopters allow for Point-in-Space (PinS) designs and support approaches to hospital landing platforms. SBAS LPV procedures have allowed operations to lower operational minima than was ever possible previously.

## 30.4 From the RNP Concept to PBN

The early use of area navigation systems had simply automated the following of the conventional route structure and terminal procedures. GPS was not introducing new applications but providing an alternative means of doing what had been done before, albeit with much greater accuracy.

In the early 1990s ICAO published the RNP Concept which told the world what lateral navigation performance was required to fly on a particular route but did not prescribe how to achieve it. As the decade progressed the increased traffic demand and the pressure for greater efficiency led to area navigation being used more broadly and new routes were introduced that could only be flown by RNAV capable aircraft. However, due to the lack of harmonized standards different RNAV solutions led to different area navigation applications being implemented in different regions of the world [30.26]. Operators needed to get approval against different specifications and provide specific crew training to perform basically the same operation and this was becoming unnecessarily complex and costly. With the proliferation of different terminology there was also a lot of room for confusion.

To address this ICAO established the Required Navigation Performance and Special Operational Requirements Study Group (RNPSORSG) in 2004 with the aim of harmonising the use of area navigation globally and to standardise the terminology being used. This led to the development of the Performance Based Navigation (PBN) concept which was published in the ICAO PBN Manual [30.1] in 2007.

### 30.4.1 Performance Based Navigation (PBN)

The PBN concept, which superseded the RNP concept, builds on the older concept by not only stipulating the required performance but also how it can be achieved. PBN has three components as illustrated in Fig. 30.8:

- A Navigation Infrastructure
- A Navigation Specification

which together support a

- Navigation Application.

The PBN manual [30.1] specifies RNAV system performance requirements independently from the navigation sensor. It also includes the functionalities needed for particular applications. It provides this information in a series of 11 navigation specifications that are defined at a sufficient level of detail to facilitate global harmonization [30.27].

PBN takes account of the fact that RNAV systems have developed over a 40 year period and as a result there are a large variety of implementations (Fig. 30.9). Identifying navigation requirements, rather than the means of meeting the requirements, allows the use of all RNAV systems meeting these requirements irrespective of the means by which they are met. Technologies can evolve over time without requiring the operation itself to be revisited, as long as the requisite performance is provided by the RNAV system.

### 30.4.2 Navigation Specifications

A Navigation Specification is a set of aircraft and air crew requirements needed to support a navigation application within a defined airspace concept. The Navigation Specification defines the performance required of the RNAV system as well as any functional requirements such as the ability to conduct curved path procedures or to fly parallel offset routes. The Air Nav-

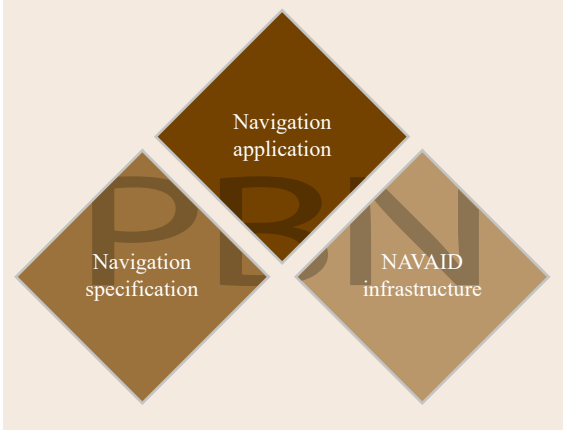

**Fig. 30.8** The three components of the PBN concept

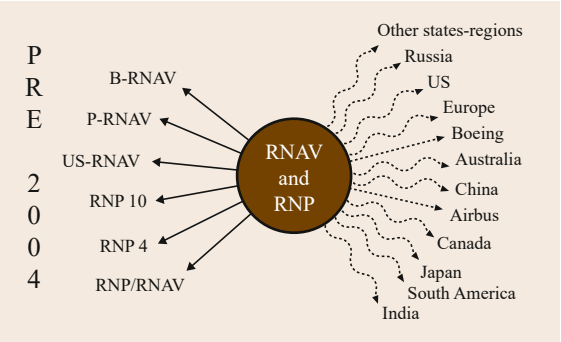

**Fig. 30.9** The proliferation of navigation standards around the world

igation Service Provider (ANSP) must also ensure that the available navigation aid infrastructure (both ground and/or space based) can support the users in meeting the requirements.

PBN assumes that future navigation (with the exception of Precision Approach which is not addressed in the PBN Manual) will be undertaken by the use of an Area Navigation system, either standalone or, incorporated into a flight management system which provides performance management capability (3D and ultimately 4D navigation). It was identified that with this greater reliance on the RNAV system a higher level of integrity would be needed as the pilot will no longer be in a position to cross check the navigation performance using conventional aids. To provide such increased integrity there would need to be an indicator to the pilot of the achieved performance so that he can confirm that the requirements for the airspace are continuously being met. The PBN concept therefore includes navigation specifications that have a requirement for on-board performance monitoring and alerting (OPMA). Navigation specifications that include a requirement for OPMA are *RNP specifications* and those not requiring OPMA are *RNAV specifications*. The RNAV specifications are the legacy operations. All the new navigation specifications have RNP in the title as they require OPMA.

GNSS, which includes OPMA by default with its integrity monitoring on the position solution is an ideal contributor to the achievement of RNP, although additional means are required on the aircraft to monitor the flight technical error. This effectively results in all RNP specifications requiring GPS as the positioning sensor.

Table 30.1 summarises the specifications included in the ICAO PBN manual [30.1]. The title of the navigation specification generally begins with either RNAV or RNP followed by a number which is the navigation accuracy requirement. This is the total system accuracy required to be met by the aircraft including both the error of the navigation system and the error linked to the ability of the pilot to accurately follow the desired path. The Advanced RNP specification does not include a number in the title as it is an umbrella specification including a variety of navigation accuracy requirements supporting different phases of flight. The specifications supporting the approach phase of flight are named RNP APCH and RNP AR APCH where AR is an abbreviation for *Approval Required* indicating that operators need specific operation approvals in order to fly such procedures.

To support these different specifications, the accuracy of the position estimation is key. Table 30.2 identifies which navigation sensors support which specification in the PBN manual. It can be seen that GNSS is a sensor that supports all of the specifications. The table also identifies which specifications require the aircraft to have an Automatic Flight Control System (AFCS) which may be Autopilot (AP) or Flight Director (FD).

**Table 30.1** PBN navigation specifications by phase of flight. The numbers in each column represent the 95% accuracy requirement in nautical miles for the phase of flight. Where there is no number it means that the navigation specification is not suitable for this phase of flight

| Navigation specification | Flight phase | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | En route oceanic/remote | En route continental | Arrival | Approach | | | | Departure |
| | | | | Initial | Intermediate | Final | Missed | |
| RNAV 10 | 10 | | | | | | | |
| RNAV 5 | | 5 | 5 | | | | | |
| RNAV 2 | | 2 | 2 | | | | | 2 |
| RNAV 1 | | 1 | 1 | 1 | 1 | | 1 | 1 |
| RNP 4 | 4 | | | | | | | |
| RNP 2 | 2 | 2 | | | | | | |
| RNP 1 | | | 1 | 1 | 1 | | 1 | 1 |
| Advanced RNP | 2 | 2 or 1 | 1 | 1 | 1 | 0.3 | 1 | 1 |
| RNP APCH | | | | 1 | 1 | 0.3 | 1 | |
| RNP AR APCH | | | | 1–0.1 | 1–0.1 | 0.3–0.1 | 1–0.1 | |
| RNP 0.3 | | 0.3 | 0.3 | 0.3 | 0.3 | | 0.3 | 0.3 |

**Table 30.2** Navigation sensors and AFCS requirements by navigation specification

| | Permitted sensors | | | | | AFCS requirement |
|---|---|---|---|---|---|---|
| | GNSS | IRU | DME/DME | DME/DME/IRU | DME/VOR | AP/FD |
| RNAV 10 | ✓ | ✓ | | | | FTE may be manually controlled by the pilot remaining within 1/2 full scale deflection of CDI with correct scaling for phase of flight |
| RNAV 5 | ✓ | ✓ | ✓ | ✓ | ✓ | |
| RNAV 1/2 | ✓ | | ✓ | ✓ | | |
| RNP 4 | ✓ | | | | | |
| RNP 2 | ✓ | | | | | |
| RNP 1 | ✓ | | ✓ | | | |
| A-RNP | ✓ | | ✓ | | | ✓ |
| RNP 0.3 | ✓ | | | | | ✓ |
| RNP APCH | ✓ | | ✓[a] | ✓[a] | | |
| RNP AR APCH | ✓ | | | | | ✓ |

[a] For the initial and intermediate phases only

Most specifications do not require AP/FD and it is expected that flying manually the pilot will remain within half of the full scale deflection of the Course Deviation indicator (CDI).

It should be noted that although DME/DME can support the accuracy required for some RNP navigation specification this is highly dependent on the availability and the geometry of the DME ground stations. In addition, due to different aircraft architectures some aircraft cannot provide On-board Performance Monitoring and Alerting (OPMA) with DME/DME.

## 30.5 GNSS Performance Requirements

ICAO requirements for GNSS signals-in-space are contained in Annex 10 to the convention on Civil Aviation [30.12]. The table of requirements from this ICAO Annex is reproduced in Table 30.3. There are different requirements depending on the operation to be performed but they all use the same four parameters of Accuracy, Integrity, Continuity of Service and Availability. Note the use of the term GNSS which indicates that these are the navigation system performance requirements for any GNSS system, not just GPS.

The requirements are presented as signal-in-space requirements. However, some of the parameters, such as positioning accuracy, cannot be applied as signal-in-space requirements without defining the user receiver. A GNSS position solution requires the combination of signals from several satellites. As a result, ICAO developed the concept of a fault-free receiver with a defined performance to be used to measure the signal-in-space. The accuracy and time-to-alert requirements are applicable to the navigation system performance at the output of the user receiver. The integrity risk, continuity and availability are applicable to the signal-in-space.

### 30.5.1 Description of the Relevant Parameters

*Accuracy* is a measure of the position error, which is the difference between the estimated position and the true position, that will be experienced by a user with a certain probability at any instant in time. In general, the probability used for the accuracy requirements in Table 30.3 is 95%. For example the en-route horizontal accuracy requirement of 3.7 km means that under nominal circumstances there is a 95% probability that the horizontal position error is $< 3.7$ km.

*Integrity* is a measure of the trust that can be placed in the correctness of the position solution. Integrity includes the ability of a system to provide timely and valid warnings (alerts) to the user. More specifically the integrity risk is defined as the probability that a user will experience a horizontal position error larger than the horizontal alert limit (HAL) or a vertical position error larger than the vertical alert limit (VAL) without an alert being raised within the specified Time-to-alert (TTA) at any instant in time. Integrity is the important parameter that provides monitoring of the position solution and is a safety driver for aviation users. The integrity mechanism uses alert limits which are set at a certain probability level. The alert limit for GNSS systems used in aviation is generally set to a probability of $10^{-7}$. That means that the probability of a position error exceeding the alert limit without a warning to the user is $10^{-7}$. In Table 30.3 the integrity requirement is written as $1-10^{-7}$ which means that the probabil-

**Table 30.3** The ICAO GNSS Signal-in-Space Performance Requirements (after [30.12], courtesy of ICAO)

| Typical operation | Accuracy horizontal[a,c] | Accuracy vertical[a,c] | Integrity[b] | Time-to-alert[c] | Continuity[d] | Availability[e] |
|---|---|---|---|---|---|---|
| En-route | 3.7 km | N/A | $1-1\cdot10^{-7}$/h | 5 min | $1-1\cdot10^{-4}$ to $1-1\cdot10^{-8}$/h | 0.99–0.99999 |
| Terminal | 0.74 km | N/A | $1-1\cdot10^{-7}$/h | 15 s | $1-1\cdot10^{-4}$ to $1-1\cdot10^{-8}$/h | 0.99–0.99999 |
| Non-precision approach (NPA) | 220 m | N/A | $1-1\cdot10^{-7}$/h | 10 s | $1-1\cdot10^{-4}$ to $1-1\cdot10^{-8}$/h | 0.99–0.99999 |
| APV-I[h] | 16 m | 20 m | $1-2\cdot10^{-7}$ in any approach | 10 s | $1-8\cdot10^{-6}$ per 15 s | 0.99–0.99999 |
| APV-II[h] | 16 m | 8 m | $1-2\cdot10^{-7}$ in any approach | 6 s | $1-8\cdot10^{-6}$ per 15 s | 0.99–0.99999 |
| Category 1 precision approach[g] | 16 m | 6–4 m[f] | $1-2\cdot10^{-7}$ in any approach | 6 s | $1-8\cdot10^{-6}$ per 15 s | 0.99–0.99999 |

[a] The 95th percentile values for GNSS position errors are those required for the intended operation at the lowest height above threshold (HAT), if applicable.

[b] The definition of the integrity requirement includes an alert limit against which the requirement can be assessed. For Category 1 precision approach, a vertical alert limit (VAL) greater than 10 m for a specific system design may only be used if a system-specific safety analysis has been completed. The alert limits are:

| Typical operation | Horizontal alert limit | Vertical alert limit |
|---|---|---|
| En-route (oceanic/continental low density) | 7.4 km (4 nmi) | N/A |
| En-route (continental) | 3.7 km (2 nmi) | N/A |
| En-route (terminal) | 1.85 km (1 nmi) | N/A |
| NPA | 556 m (0.3 nmi) | N/A |
| APV-I | 40 m (130 ft) | 50 m (164 ft) |
| APV-II | 40 m (130 ft) | 20 m (66 ft) |
| Category I precision approach | 40 m (130 ft) | 35–10 m (115–33 ft) |

[c] Accuracy and time-to alert requirements include the nominal performance of a fault-free receiver.

[d] Ranges of values are given for the continuity requirement for en-route, terminal, initial approach, NPA and departure operations, as this requirement is dependent on several factors including the intended operation, traffic density, complexity of airspace and availability of alternative navigation aids. The lower value given is the minimum requirement for areas with low traffic density and airspace complexity. The higher value given is appropriate for areas with high traffic density and airspace complexity. Continuity requirements for Approaches with Vertical Guidance (APVs) and Category I operations apply to the average risk (over time) of loss of service, normalized to a 15 s exposure time.

[e] A range of values is given for the availability requirements as these requirements are dependent upon the operational need which is based upon several factors including the frequency of operations, weather environments, the size and duration of the outages, availability of alternate navigation aids, radar coverage, traffic density and reversionary operational procedures. The lower values given are the minimum availabilities for which a system is considered to be practical but are not adequate to replace non-GNSS navigation aids. For en-route navigation, the higher values given are adequate for GNSS to be the only navigation aid provided in an area. For approach and departure, the higher values given are based upon the availability requirements at airports with a large amount of traffic assuming that operations to or from multiple runways are affected but reversionary operational procedures ensure the safety of the operation.

[f] A range of values is specified for Category I precision approach. The 4.0 m (13 ft) requirement is based upon ILS specifications and represents a conservative derivation from these specifications.

[g] GNSS performance requirements for Category II and III precision approach operations are under review and will be included at a later date.

[h] The terms APV-I and APV-II refer to two levels of GNSS approach and landing operations with vertical guidance (APV) and these terms are not necessarily intended to be used operationally.

ity of the position error being smaller than the alert limit is 99.99999%.

Figure 30.10 illustrates the accuracy requirement, given at the 95% or $2\sigma$ level and the alert limit, assuming a Normal distribution of errors set at $5.3\sigma$. Algorithms in the user equipment compute a protection level each time a position solution is calculated. If the protection level exceeds the required alert limit for the operation then an alert is raised within the time-to-alert.

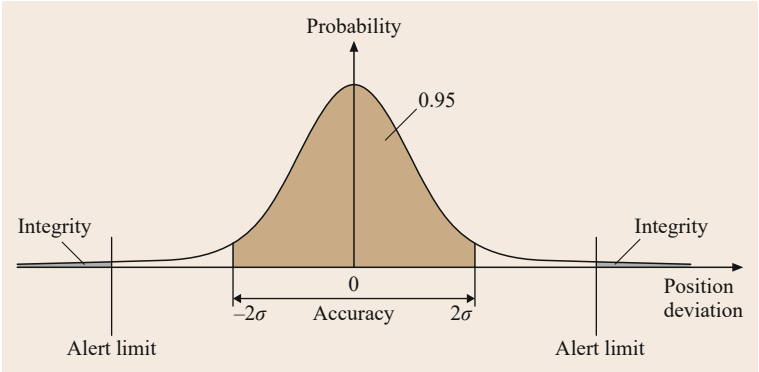

**Fig. 30.10** Integrity, alert limits and accuracy

*Continuity* is defined as the probability that a user is able to determine its position with the specified accuracy and is able to monitor the integrity of its determined position over the time interval applicable for the corresponding phase of flight [30.28]. Assuming the service is available at the start of an operation this is the probability of it becoming unavailable over a specified time interval that is linked to the duration of the operation. Taking, for example, the en-route continuity requirement and choosing the lower value from the range of $1–10^{-4}$/h. If the service is available at the start of the hour then the probability of losing the service in the following hour is $10^{-4}$. For approach operations which are short in duration the time period over which the continuity requirement is specified is 15 s.

*Availability* is defined as the probability that a user is able to determine its position with the specified accuracy and is able to monitor the integrity of its determined position at the initiation of the intended operation. Again there is a range of values in the ICAO table and a particular value of requirement needs to be selected for a particular operation depending on various factors described in table note [e] to the Table [30.29]. Assuming the lower value is taken of 0.99 this means that when a user expects to start an operation then the probability of them having a position meeting the accuracy requirement with integrity is 99%.

## 30.5.2 GNSS Integrity Concepts

### Receiver Autonomous Integrity Monitoring (RAIM)

The basic integrity mechanism applied in aviation GNSS user equipment is RAIM [30.30–33]. RAIM uses redundant information from the GNSS constellation itself to verify integrity. As previously stated there needs to be more than the minimum number of satellites needed to compute a position so that the receiver can check the consistency between the signals from different satellites. The basic RAIM algorithms only perform fault detection. When a fault is detected the GNSS system can no longer be used for navigation. More advanced RAIM algorithms perform Fault Detection and Exclusion (FDE) where a faulty satellite can be removed and a position solution with integrity can still be provided to the user. Multiple satellite failures will probably not be detected by such RAIM algorithms.

### Satellite Based Augmentation Systems (SBAS)

The integrity algorithms used in an SBAS receiver make use of signals derived from a network of ground monitoring stations that provide error correction and quality information for each of the satellite signals. The navigation message containing this information is broadcast to users over a wide area using geostationary satellites. The signal is broadcast on the GPS L1 frequency and can also be used as an additional ranging source. The receiver applies integrity algorithms that have been standardized in [30.34] to compute the vertical and horizontal protection levels. The SBAS integrity concept is described in detail in Chap. 12. SBAS enables approach procedures with minima equivalent to ILS category I.

### GBAS

The integrity concept for GBAS is more complex but applies the same principles to provide a series of parameters, based on local ground measurements, to be applied by the user equipment to compute the protection levels. The GBAS navigation message is broadcast to the aircraft using a VHF data-link. The GBAS integrity concept is described in detail in Chap. 31.

GBAS is intended as a precision approach and landing aid to replace today's ILS for all categories of approach and landing up to Category III.

## 30.6 Linking the PBN Requirements and the GNSS Requirements

The navigation specifications in the ICAO PBN Manual [30.1] define the performance and functionalities required to support different aviation applications. The GNSS requirements in ICAO Annex 10 [30.12] are applicable only to the navigation system. The difference is most apparent in the accuracy requirements as illustrated in Fig. 30.11.

The RNP lateral accuracy defined within the navigation specification is the Total System Error (TSE), to which the aircraft's performance will be certified. The TSE is made up of three error components (Fig. 30.11):

- Path Definition Error (PDE) – is the difference between the desired path that the designer wishes the aircraft to fly over the ground and the path that is calculated by the navigation computer. The PDE is assumed to be very small (almost negligible) and is tightly controlled by the oversight of the navigation data chain.
- Navigation System Error (NSE) – is the difference between the true position and the estimated position. This error is influence by which navigation sensor is providing the position estimation.
- Flight Technical Error (FTE) – is the difference between the estimated position and the defined path. It is a measure of how well the pilot or the avionics can following the guidance information provided by the navigation system.

When using GNSS as a position sensor the accuracy is well within the requirements for most phases of flight and the TSE, which is the difference between the track the aircraft should be following and the one it is actually following will be dominated by the FTE.

### 30.6.1 Phases of Flight

The navigation requirements vary with the different phases of flight. Table 30.1 shows the navigation specifications applicable to each phase of flight. The first column in the GNSS requirements, Table 30.3, lists typical operations and there is not a direct correlation between the two. This can lead to confusion.

#### En route – Oceanic and Remote

In Oceanic and remote areas where terrestrial navigation aids cannot be installed the route separation was originally based on inertial navigation systems and their specified drift rates which are measured in nautical miles per hour. This is the phase of flight where GNSS had the first significant impacts in aviation. FAA notice 8110.57, issued in 1995 authorised the use of GPS equipment meeting specific requirements to be used as a primary means of navigation for oceanic operations. This effectively allowed aircraft that were not fitted with inertial navigation systems to fly the routes over the ocean using GPS equipment. There had to be a dual receiver installation with RAIM FDE and a RAIM Availability prediction was required to be performed as part of the flight preparation.

It can be seen from Table 30.1 that several different navigation specifications can be applied in oceanic airspace. The typical one in use today is RNAV-10 but future plans are to apply RNP 4 or RNP 2 in some oceanic regions and therefore allow route spacing to be reduced. The minimum spacing between routes in RNAV-10 airspace is 50 nmi. When using GNSS as the navigation sensor in oceanic regions it must meet the requirements of the first line of Table 30.3. Positioning accuracy of 3.7 km (2 nmi) is easily achievable and is far better than the total system accuracy requirement of 10 nmi 95%. This leaves plenty of margin to accommodate the FTE performance.

The continuity requirement in the RNAV-10 navigation specification is set at $10^{-5}$ /h with an alert limit for integrity set at 20 nmi. Alert limits in GNSS receivers are generally set to the value of 4 or 2 nmi. miles which are sufficiently large to ensure availability requirements are met. The continuity requirement is driven by failure rates of hardware and this figure tends

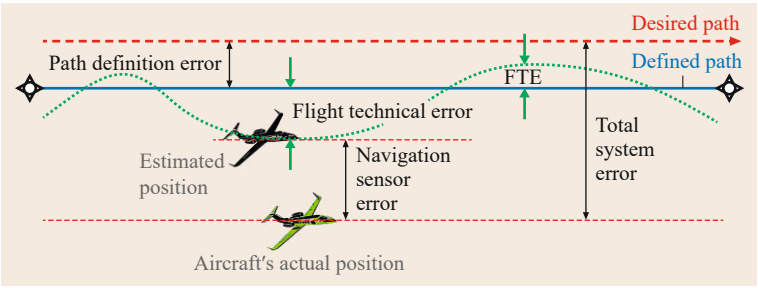

**Fig. 30.11** Total system error components

to lead to a requirement for dual equipment to ensure redundancy.

In this phase of flight there is generally no surveillance and Air Traffic Control is based on procedural separation rules with pilots sending position reports every 10° of longitude to the ATC centre via an HF radio link. The ability to automatically provide position reports through a satellite data link is becoming more the norm in oceanic regions enabling lower lateral and longitudinal separation minima to be applied. A more advanced system of Space-based Automatic Dependent Surveillance Broadcast (ADS-B) using satellite communication services is now under development for use in oceanic airspace (Sect. 30.10.1).

### En-route – Continental

The en-route phase is between the end of a departure procedure and the beginning of an arrival procedure. This is most of the core continental airspace where in busy regions of the world there is full coverage of surveillance radar and ground based navigation aids such as VOR and DME. Aircraft navigate along predefined routes which require a certain navigation performance from the aircraft. The European route network has a mandate for RNAV5 capability with a lateral accuracy requirement for the Total System Error (TSE) of ±5 nmi. Other regions have similar requirements although the accuracy requirement varies between 1 nmi and 5 nmi. The route spacing in an RNAV 5 environment can be between 18 and 10 nmi depending on the ATC intervention capability.

GNSS is not the only sensor that can be used to support RNAV-5 and the requirements on continuity, integrity and availability in the navigation specification are applicable to all possible sensors. For GNSS the requirements are in the first line of Table 30.3. A 2 nmi alert limit is used even though the performance required from the navigation sensor is 2 nmi 95%.

### Terminal Area – Arrivals and Departures

Around busy airports the terminal area is where the transition takes place between the en-route network and the approaches and departures to and from the airport. This is the most complex part of the airspace with climbing and descending traffic that needs to be separated safely. Navigation Accuracy requirements of ±1 nmi are typically required for this phase of flight.

### Approach

The approach is the final and most demanding part of the flight which delivers the aircraft to a point where the flight crew can take over visually and perform a safe landing.

Instrument Approaches used to be divided into just two categories:

- Non-Precision Approach (NPA), using the conventional navigation infrastructure such as VOR, DME or NDB to provide lateral guidance and delivering the aircraft to a point aligned to the runway centreline where the pilot could then perform a visual landing. Should the runway, or its lights, not be seen by the Missed Approach Point (MAPt) the pilot is to *go around*.
- Precision Approach (PA), based on an Instrument Landing System installed on the airport which provides both lateral and vertical guidance on a stable continuous descent path to the runway threshold. Because there is a vertical path for the pilot to follow, the minima for a PA is often much lower than for a NPA. The pilot will be head down following the instruments until decision height (or altitude) at which point he/she will look up and make a visual decision to land if the lights and/or runway is visible or, if not, fly a missed approach.
  GNSS is currently only approved for use up to Category I precision approach meeting the requirements provided in the last row of Table 30.3. Work is ongoing to develop the Category II and III requirements for GNSS systems and an additional row for these applications will be added to the Table.

GNSS has enabled the introduction of a third type of approach called an RNAV approach which can include guidance in both the lateral and vertical dimensions. RNAV approaches are divided into those with only lateral guidance that are called non-precision approaches (NPA) and those with both lateral and vertical guidance that are called APV. These APV operations are neither NPA nor PA but lie in between the two existing categories. In Table 30.3 the requirements for these approaches are indicated in two rows called APV-I and APV-II. RNAV Approaches have had a significant impact, particularly on general aviation users that often fly to airfields not equipped with precision approach and landing systems.

The vertical profile of a typical approach is illustrated in Fig. 30.12. The approach is divided into four segments, Initial, Intermediate, Final and Missed approach. As already stated, in a NPA the pilot descends to a Minima Descent Altitude or Height which has been calculated by the procedure designer to ensure obstacle clearance. If at that height, the pilot has the necessary visual references to safely land the aircraft the approach is completed visually. If not, he continues to the MAPt where the go-around is to be initiated. In a precision approach or an Approach with Vertical Guidance (APV)

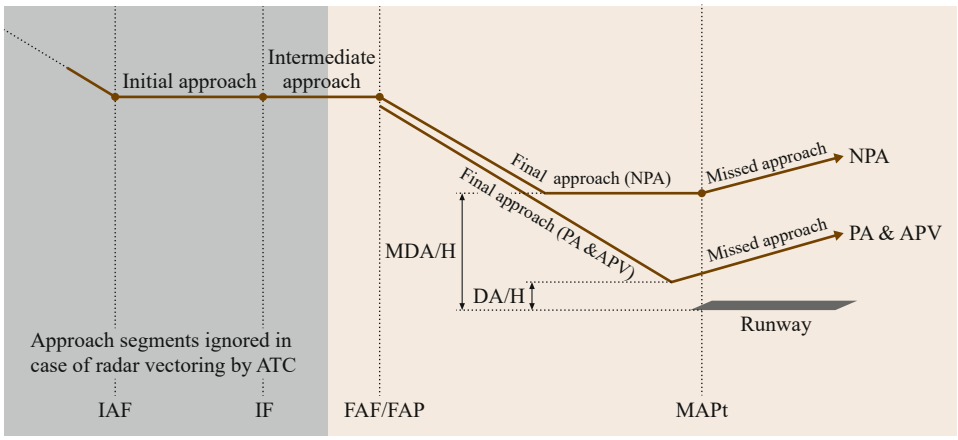

**Fig. 30.12** Vertical Profile of different types of approach showing the Decision Altitude/Height for approaches with vertical guidance and, the Minimum Descent Altitude/Height for a NPA and the Missed Approach Point. The procedure is made up of a series of points from the Initial Approach Fix (IAF), the Intermediate Fix (IF), Final Approach Fix (FAF) or Final Approach Point (FAP) and the Missed Approach Point (MAPt)

the procedure designer has calculated not only a lateral path to the runway but also a vertical path. This means that the pilot has a lateral and vertical guided path providing a much higher level of accuracy on the approach and allowing the pilot to be instrument flying until he/she arrives at the Decision Height which is the point that the pilot is required to take over the landing visually or initiate a missed approach.

## 30.6.2 RNAV Approaches

Controlled Flight into Terrain (CFIT) occurs when a normally functioning aircraft under the complete control of the pilot is inadvertently flown into an obstacle. The pilots are generally unaware of the danger until it is too late. RNAV approaches improve safety by providing the pilot with better situational awareness, reducing the risk of CFIT and providing lower approach minima to runways not equipped with a precision approach and landing system.

All RNAV Approaches require the use of GNSS and this is reflected in the name of the procedure which is of the form: $\text{RNAV}_{(\text{GNSS})}$ RWY 27. The number at the end indicating the runway heading rounded to the nearest ten degrees which in this case would be 270°.

The different types of RNAV approach, the associated terminology and the number of acronyms used is rather complex. In the ICAO PBN concept these approaches are RNP approaches because they require on-board performance monitoring and alerting. However, by the time ICAO had defined them as RNP approaches many procedures had already been published with the title RNAV and it was impossible to go back. A transition to using the RNP terminology in the approach chart title is now planned by ICAO and should be complete in 2023.

### Different Types of RNAV Approach

There are four types of RNP approach (RNP APCH) specified in the ICAO PBN manual (Fig. 30.13). For LNAV and LNAV/VNAV procedures the lateral position and integrity is provided using GPS with RAIM. The LP and LPV procedures require the use of GPS augmented by a Satellite Based Augmentation System (SBAS).

The terms LNAV, LNAV/VNAV, LP and LPV are the labels used on the minima lines that are published on the approach chart. An example of a typical RNP approach chart is shown in Fig. 30.14. The procedure includes three minima lines for different types of aircraft capabilities. The main part of the chart is the plan view showing the waypoints, the tracks between them and some speed restrictions. Below that is the vertical profile of the procedure from the Intermediate Fix (IF) to the Final Approach Fix (FAF) and then

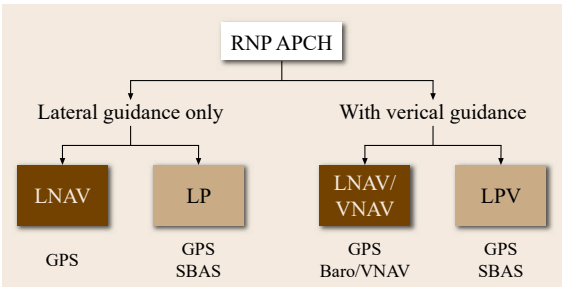

**Fig. 30.13** The four RNP Approach types specified by ICAO

the final approach segment down to the missed approach point (MAPt) generally located at the runway threshold. Below that are the approach minima that depend on the aircraft equipage and operational approvals. The LPV line is for aircraft equipped with SBAS, the LNAV/VNAV line for those with Baro/VNAV vertical guidance and the LNAV for GPS lateral navigation only.

It should be noted that all such approaches are RNP approaches in the PBN terminology, because on-board monitoring and alerting is required, but the title of the chart is $RNAV_{(GNSS)}$. This is a source of confusion and ICAO is proposing to evolve all chart names to use the RNP terminology in the future but this will take many years to achieve.

### Performance Requirements for RNAV Approach

To support Non Precision Approaches to LNAV mimina the RNP lateral accuracy in the Final Approach segment is 0.3 nmi (556 m). That means that the Total System Error (TSE) which includes both the NSE and FTE must be less than 556 m. The GNSS signal-in-space must meet the requirements in the third line of Table 30.3. The alert limit is set to 0.3 nmi and the horizontal NSE requirement is 220 m. This can be rather confusing as the 95% accuracy requirement and the Alert Limit are using the same value and yet they are not the same thing as can be seen from the definitions earlier. Setting the Alert limit to the 95% TSE requirement is actually very conservative. As the GNSS

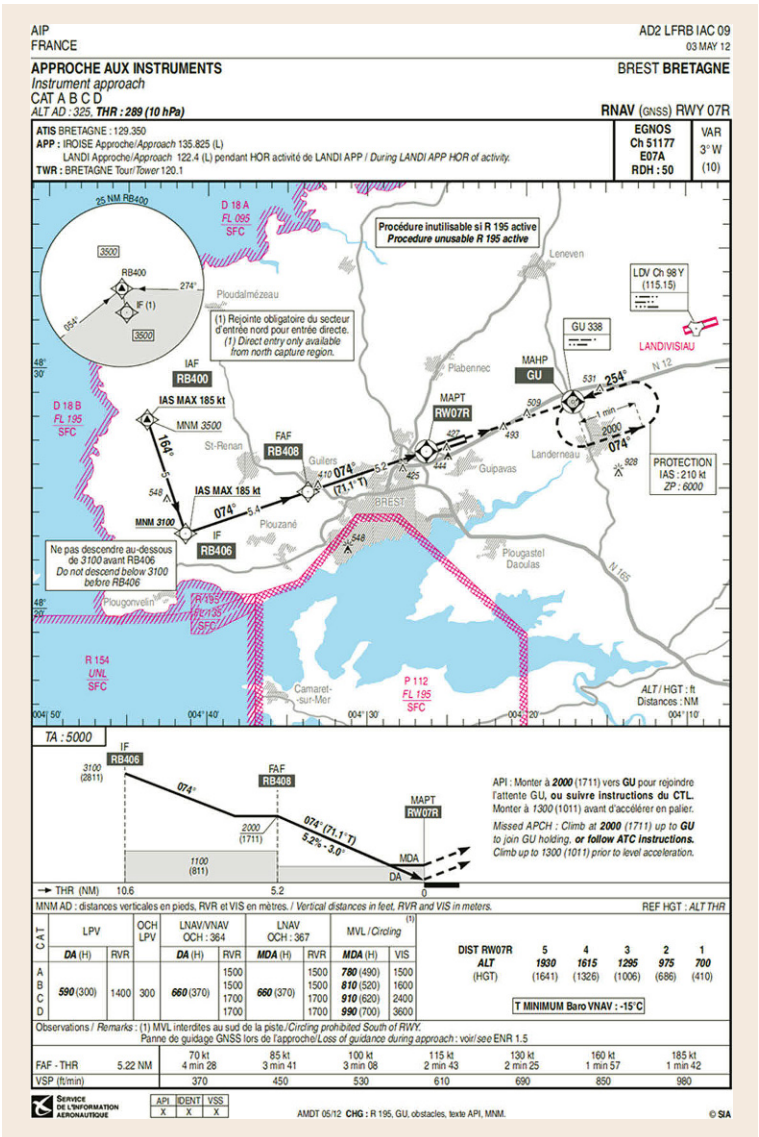

**Fig. 30.14** An example of an RNAV approach chart

position estimation is so good, the majority of the error is apportioned to the FTE and an FTE of 0.25 nmi is allowed for manual flight. The LNAV/VNAV procedures use the same lateral performance requirements but add the vertical guidance based on Barometric VNAV.

For the SBAS based LPV approach there is no single RNP value in the PBN manual as the required performance is angular and therefore varies with distance from the runway threshold. The procedure is protected by obstacle clearance surfaces as illustrated in Fig. 30.15. No obstacle should penetrate these surfaces. Although the total system performance requirement is angular the performance required from the GNSS element is fixed along the final segment of the approach. The requirements are provided in Table 30.3 where it can be seen that there are three lines applicable to the LPV approach, APV-I, APV-II and Category I precision approach. The lateral accuracy and alert limit requirements for these three operations are identical. The difference is in the vertical performance and the time-to alert. SBAS systems such as the US WAAS and the European EGNOS that have been designed to support LPV approach operations have initially targeted the APV-I performance level. The APV-II performance level is not used and will likely be removed from the ICAO standards in future updates. After gaining some experience and collecting data on the actual performance of the WAAS system and the relationship between the vertical accuracy and the alert limits the FAA assessed that a 35 m alert limit achieved the necessary performance to allow LPV operations down to 200 ft Decision Height which is equivalent to an ILS Category I procedure.

The type of RNP approach to implement at a particular aerodrome is highly dependent on the users and what their aircraft are equipped with. A significant proportion of commercial airliners from Boeing and Airbus are already equipped with Baro/VNAV capability. The first commercial airliner that offers SBAS LPV capability as an option is the Airbus A350. There are therefore very few commercial airlines with SBAS capable aircraft and so their preferred approach solution is Baro/VNAV. There is no Baro/VNAV system available for smaller general aviation type aircraft so their solution to have vertical guidance will be to equip with an SBAS receiver.

#### The SBAS FAS Data Block

The final approach segment of SBAS and GBAS Approach procedures are defined in a FAS data block which is stored in the on-board navigation database. The FAS data block contains all the relevant data necessary to define the final approach path and it is wrapped with a Cyclic Redundancy Check (CRC) in order to secure the integrity of the data (Fig. 30.16). The avionics receiver decodes the FAS data block and applies the CRC algorithm. If any data is changed then the CRC computation will produce a different result. If the CRC test fails then the approach is rejected.

### 30.6.3 RNP AR APCH

Another type of approach called RNP Approval Required (RNP AR) has been introduced which takes further advantage of GNSS performance combined with the FMS capabilities of modern aircraft and specific crew training. The performance required for RNP AR approaches are contained in a Navigation Specification in the ICAO PBN Manual [30.1]. They are not explicitly covered by Table 30.3 as they are more linked to the aircraft performance and do not impose additional requirements on the GNSS signal-in-space. The Minimum Obstacle Clearance (MOC) requirements for RNP AR approach procedures are illustrated in Fig. 30.17. The final approach requirements in the lateral dimension are equivalent to those for Non-precision approach and the vertical requirements are those for RNP Approach with Barometric VNAV.

RNP AR procedures can be used in challenging obstacle environments to allow instrument approach procedures to be implemented at locations where only visual procedures were previously possible. RNP AR is an operation where the aircraft's very tight lateral

performance capabilities enable operations into very challenging terrains. Only the very high end aircraft have this level of capability and the cost to certify and operationally approve the crew is high. To qualify for RNP AR the state of ownership of the procedure must specifically authorise the Aircraft Operator (AO). The AO in turn must have demonstrated to that State's Civil Aviation Authority (CAA) that they have the appropriate training, servicing and maintenance schedules in place to ensure that the aircraft will accurately maintain the defined path during the approach. This is very important as the designer will only protect the procedure to twice the RNP. Therefore, if the procedure was based on RNP 0.1 then there could be an obstacle at 0.2 nmi from the route.

GNSS is the only sensor that will support the level of accuracy required for these very demanding operations.

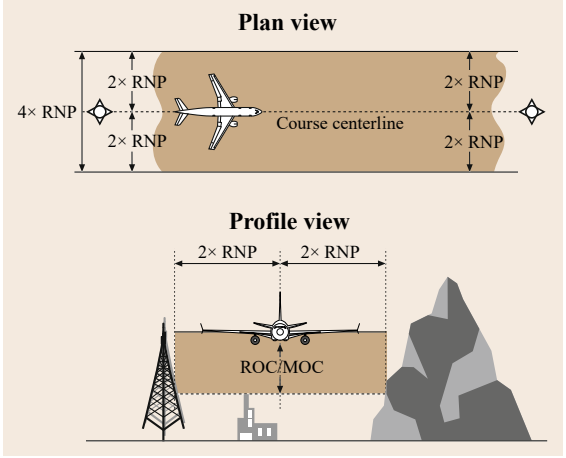

**Fig. 30.17** Minimum (Required) Obstacle Clearance for RNP AR operations

## 30.7 Flight Planning and NOTAMs

Information about the unavailability of navigation aids is traditionally communicated in the form of Notices to Airmen (NOTAM). In preparation for a flight a pilot will consult the NOTAMs relevant to the route being flown and the destination airport to find out if there are any issues that need to be considered. Conventional navigation aids were either on or off and the impact of an outage was very clear. With GNSS the situation becomes more complex. The effect of a satellite being unavailable can vary significantly depending on the number and geometry of other satellites available. It will also vary with time. The operational impact of an outage will also depend on the avionics equipment, the mask angle being used, the satellite selection algorithms and many other factors. This makes it rather difficult to predict.

Prediction tools such as the Eurocontrol AUGUR tool [30.35] and the FAA RAIM Service Availability Prediction Tool [30.36] have been developed to forecast GPS RAIM availability based on constellation status information that is available from the US Coast Guard. These tools are available via web interfaces for aircraft operators to verify the GPS RAIM availability at the destination airport at the expected time of arrival. In States that have published GNSS based instrument approach procedures predicted GPS RAIM outages are also provided to operators in the form of NOTAMs.

Much debate has taken place within the aviation community as to the value of GPS RAIM NOTAMs [30.37]. The predictions are not very reliable and must be tailored to the worst performing user equipment so they are inherently conservative. However, as GNSS performance varies in a way that is predictable it can also be argued that any advance warning of a possible outage would be a good thing. Work is ongoing to develop more accurate GNSS performance prediction capabilities. The debate is far from over and different solutions have been adopted in different parts of the world.

## 30.8 Regulation and Certification

Aviation is a highly regulated industry and all systems, equipment and procedures are governed by strictly enforced standards. As far as possible these standards are harmonised globally through ICAO. Aircraft fly all over the world and do not want to have to use different systems or follow different rules and procedures as they cross national boundaries.

### 30.8.1 Airworthiness Certification

A GNSS installation on an aircraft must meet the airworthiness certification standards and be approved by the appropriate regulatory authority governing the State of the aircraft manufacturer. Modifications to existing aircraft need to be approved by the regulatory authority governing the State of registry of the aircraft. In Europe airworthiness certification is performed by EASA, in the US by the FAA. As a general principle of the Chicago convention a certification in one country or region is generally accepted in another.

FAA and EASA publish Technical Standard Orders (TSOs) and European TSOs (ETSOs) respectively that are normally aligned with each other. These TSOs in turn make reference to industry standards from bodies such as RTCA and Eurocae.

The standard for basic GPS equipment is TSO C-129a [30.7] which requires RAIM fault detection as a minimum. This in turn makes reference to the Minimum Operational Performance Standards for Airborne Supplemental Navigation Equipment Using Global Positioning System (GPS) [30.6]. The TSO C-129a user equipment can support all operations from En-route down to NPA.

The TSO C-129 has been superseded by TSO C-196 [30.38]. The latter makes reference to DO 316 (MOPS for GPS ABAS, [30.39]), which requires the receiver to be aware that Selective Availability has been removed and employs RAIM FDE as a minimum.

Equipment with SBAS capability is addressed by the following standards:

- TSO C-145, *Airborne Navigation Sensors using GPS Augmented by SBAS* [30.40] for GNSS receivers that provide inputs to a Flight Management System,
- TSO C-146, *Stand-alone Airborne Navigation Sensors using GPS Augmented by SBAS* [30.41].

The SBAS receiver referred to in TSO C-145 [30.40] and C-146 [30.41] must meet the requirements that are specified in RTCA DO-229D [30.34] which defines different functional and operational classes of equipment depending on the specific application.

The TSOs govern the GNSS equipment itself. The integration of the equipment into the aircraft is governed by another set of standards. In the US these are

called Advisory Circulars (ACs). EASA uses the term Appropriate Means of Compliance (AMC).

In the US the Airworthiness requirements for all GNSS systems and augmentations are included in AC 20-138 [30.42].

EASA currently publishes different AMCs for each application. For example:

1. AMC 20-27: *Airworthiness Approval and Operational Criteria for RNP Approach Operations including APV Baro/VNAV operations* [30.43],
2. AMC 20-28: *Airworthiness Approval and Operational Criteria for RNAV GNSS Approach Operation to LPV Minima using SBAS* [30.44].

EASA processes are evolving and in the future the AMCs for Communications Navigation and Surveillance systems will all be combined into one single certification specification.

One negative impact of this strict certification process is that it makes any changes expensive and slow to achieve. Once an avionics system has been through the certification process it is approved for installation on-board aircraft the design is frozen. Any significant modification requires the system to be passed through the certification process again at great expense. An example of this is the slow adaptation of the avionics systems to incorporate receivers that are aware that Selective Availability (SA) has been switched off. Although SA was removed in May 2000 there are still a small number of brand new aircraft coming off the production line equipped with GPS receivers that are not SA aware. There is still therefore, a rather large population of aircraft equipped with non-SA aware receivers. Airlines are cost driven and will only upgrade their equipment if there is a clear operational or financial benefit. Hence, aircraft are rarely retrofitted with new equipment and they tend to die with the equipment they were born with.

### 30.8.2 Operational Approvals

The airworthiness approval covers the aircraft and its on-board systems. In addition to having a certified aircraft an operator also requires an operational approval in order to use it for specific operations. Operational approvals are given by the National regulatory authority of the State of registry of the aircraft. In Europe the approval is based on EASA rules captured in the same AMCs as for the airworthiness certification but these rules are applied by the national regulatory authorities. In the US the operational approval is based on a series of Advisory Circulars such as AC 90-105 for RNP operations including Baro/VNAV and AC 90-107 for LPV operations.

The operational approval covers issues such as the necessary modifications to the aircraft Flight Manual, the operating guides for the on-board avionics and the flight Crew Training. It also covers flight planning procedures such as the requirement to have a non-GNSS approach procedure available as an alternate in case of a GNSS outage and the requirement to check GPS RAIM availability or NOTAMs indicating RAIM outages.

## 30.9 Military Aviation Applications

The military fly many different types of aircraft. Those that fly in the civilian airspace must comply, as far as possible, with the same rules and regulations as the civil aircraft they are sharing the airspace with. However, there are often exceptions.

There are also some specific aviation military applications that make use of GNSS such as the Joint Precision Approach and Landing System (JPALS) which is under development for the US military. JPALS is effectively a military version of GBAS and it comes in several versions to support different missions. There are two main categories – Shipboard Relative GPS (SRGPS) for use at sea to guide aircraft to carriers and the Local Area Differential GPS (LDGPS) for use on land. There are three different versions of LDGPS:

- Fixed base, which is very similar to GBAS.
- Tactical, which is portable for temporary installation in the field.
- Special missions – highly portable for rapid deployment in support of special operations.

JPALS will have different requirements to GBAS, in that it will need to be resistant to jamming, be difficult to detect and localise and must have the ability to operate in higher dynamic environments. This will lead to the combined use of INS/GPS integration and adaptive antenna designs as part of the solution.

The principle differences between the civil GBAS and the military JPALS are the use of:

- Dual-frequency P(Y) code GPS providing greater precision than the C/A code
- Anti-jamming technology using digital nulling and beam steering antennas
- UHF encrypted data link in place of the civil VHF datalink used in GBAS.

JPALS will also be produced in a mobile form factor suitable for rapid deployment and setup in the field. The avionics will be compatible with civil GBAS and SBAS so that military aircraft will be able to use the approach procedures available at civil airfields.

The shipboard version of JPALS, SRGPS [30.45] aims to provide a system capable of automatically landing an aircraft on a moving aircraft carrier. It uses a relative navigation approach, the reference station being installed on the ship. In this challenging environment the system applies carrier phase tracking and the integration of inputs from inertial sensors which enables very precise positioning to be achieved relative to the desired touchdown point. Sea based JPALS is expected to reach its initial operational capability (IOC) in around 2020.

## 30.10 Other Aviation Applications of GNSS

### 30.10.1 Surveillance (ADS-B)

At the centre of an air traffic management system is the need for Air Traffic Controllers to have a real-time picture of where the aircraft are in the airspace. This picture is generally constructed by using inputs from radar stations that detect the positions of the aircraft.

Automatic Dependent Surveillance (ADS) is a surveillance technique where each aircraft automatically broadcasts its own position periodically via data-link. This is a dedicated GNSS position which is then used for ATC purposes. There are two forms of ADS, ADS Contract (ADS-C) and Broadcast (ADS-B). ADS-C by its name is a dedicated *handshake* between an aircraft and a ground station. The aircraft can only set up 5 contracts at once but the advantage is that one or both parties are made aware if transmitted data fails to be received. ADS-B is just a broadcast of data to all other stations, both air and ground, within line of sight [30.46]. ADS data can be received by ground stations and used to construct a surveillance picture for ATC which is independent from the traditional radar surveillance network. The ADS-B service also requires quality measures to be provided with the broadcast position information. Unlike conventional navigation sources the GNSS position includes the built-in integrity monitoring capabilities described earlier. It is therefore the GNSS position that is being used as the source for the broadcast position of the aircraft. There are several reasons ADS-B is being promoted not least being the possibility to reduce the number of expensive surveillance radar stations. The GNSS position is also more accurate than the current radar derived positions. In oceanic airspace today the service providers are looking at space-based ADS-B [30.47] which will use a low Earth orbit satellite constellation, such as Iridium, to receive the ADS-B transmissions and forward them on to an ATC centre.

The increased reliance on GNSS for navigation purposes and the additional use of the same information for surveillance raises the potential for common failure modes. If ATC were relying entirely on ADS-B for surveillance which uses the same GNSS position as the aircraft is using for navigation then the impact of a GNSS outage becomes potentially much more significant. This issue needs to be considered carefully in a safety assessment.

Fortunately, in busy areas of the world there are already multiple layers of radar surveillance coverage and ADS-B is not intended to become the only means of surveillance. However, an ADS-B surveillance layer may be used to remove some of the redundancy in the current system and could lead to significant savings. In remote areas ADS-B can provide a surveillance capability where there was none previously but care must be taken to ensure that a safe contingency procedure is available to cover GNSS outages.

Multilateration (MLAT) [30.48] is another emerging surveillance technique which works by receiving the *squawk* from an aircraft's secondary surveillance radar (SSR) transponder. This squawk is received by a series of ground receivers and the location of the aircraft is computed using triangulation. MLAT position estimations rely on accurate timing and it is common for the GNSS timing pulse to provide the common time source. Loss of the GNSS signal would mean that the ground stations would slowly become unsynchronised.

### 30.10.2 Datalink

Air Traffic Control centres are currently implementing controller pilot data-link communications (CPDLC) which allows the exchange of text messages between pilots and controllers [30.49]. CPDLC complements the exchange of information by voice and enables a reduction in the use of the VHF communications channels. The messages exchanged in CPDLC are time stamped and many of the systems use GPS time as the reference. In order to limit the vulnerability of such systems to GPS outages, terrestrial time reference signals, such as the DCF77 long wave time signal [30.50] broadcast by the German National Physics laboratory from Mainflingen, near Frankfurt are also integrated in the system.

## 30.11 Future Evolution

### 30.11.1 GNSS Vulnerability and Alternative-PNT

One of the most significant issues around the use of GNSS in aviation is vulnerability [30.51–53]. GPS signals are low power and are broadcast on a single frequency so interference, either deliberate of unintentional, is a potential threat (Chap. 16). This has not stopped aircraft equipping with GPS receivers but it has made it difficult to show the real benefit and added value. GPS has been incorporated in addition to the existing terrestrial navigation infrastructure. There has been no cost saving due to a reduction in the number of conventional navigation aids. They have been kept as a fall back capability for the case when GPS is unavailable. The route structures being flown are not dependent on the availability of GPS and can be supported using conventional navigation aids. This is however going to change as benefits from the implementation of Performance Based Navigation start to be realised. PBN procedures already exist in a few Terminal Areas such as those around Zurich and Amsterdam Schiphol airports and will be mandatory in the majority of Europe's Terminal Airspace by January 2024. PBN procedures will make use of GPS as the primary means of navigation. In order to cope with GPS outages and maintain the level of safety an alternative positioning system needs to be available.

In the USA the term Alternative Positioning Navigation and Timing (A-PNT) is being used to describe this *back-up* to GPS [30.54]. The objective is to ensure that operations can continue safely during a GPS outage without an unacceptable increase in workload for either the pilot of the Air Traffic Controller. The FAA has launched an A-PNT programme [30.55] with the aim to determine how the alternative method of PNT can be implemented at the lowest possible cost. In Europe there have been studies and simulations to assess the impact of GNSS outages and assess the need for a back-up. These have concluded that in the near term the current network of DMEs can support a reversion capability so long as a number of operational measures are put in place. These include:

- ATC need to be informed of the geographical location and size of the GNSS outage area.
- ATC need a means to identify which aircraft are affected.
- Aircraft relying only on GPS should be blocked from entering the affected sectors.

Aircraft in the affected airspace with DME/DME RNAV systems will be able to continue to navigate although they may have lost the ability to perform on-board performance monitoring and alerting. They will have effectively switched from RNP to RNAV. DME/DME coverage is available for all European ATS routes. The number of aircraft that are solely dependent on the use of GPS for navigation is very limited and ATC can manage these by monitoring the surveillance picture and giving radar vectors.

In the longer term it is anticipated that multi-frequency, multi-constellation GNSS will provide a higher level of robustness and the requirements on the back-up solution will diminish. However, it has not yet been demonstrated that the level of robustness will be sufficient to avoid the need for retaining a ground based alternative as a back-up.

### 30.11.2 Rationalisation of the Navigation Infrastructure

Ever since the arrival of GPS in aviation there have been discussions about the rationalisation of the conventional navigation aid infrastructure. The role of the conventional navigation aids is changing from being the primary means of navigation to being a support to reversion scenarios during GNSS outages. There is an expectation that this will allow a reduction to a *minimum network* that allows safety to be maintained while supporting a certain capacity of traffic in the airspace. The situation differs between the en-route and approach phases of flight.

In the en-route phase GNSS is rapidly becoming the primary navigation source and, as discussed in the previous section the favoured reversion solution for aviation is DME/DME RNAV as a sufficient number of aircraft are already equipped. The VOR and NDB will not be necessary in the future but they cannot all be removed overnight. The rationalisation of the infrastructure takes time and costs money. A broad consultation with potential users is needed and sufficient advanced warning must be given. Many published procedures are published in relation to VOR installations and these procedures would need to be replaced before the removal of the navigation facility.

Many NDB facilities are installed at aerodromes and support Non-Precision approach procedures. In order to remove the dependency on the NDB the existing procedures would need to be replaced by $RNAV_{(GNSS)}$ procedures but until all users are equipped to fly the RNAV procedures then the old ones will need to be maintained. These facilities are also often used to train pilots in instrument flying as the ability to fly a non precision approach using an NDB is a nec-

essary part of the basic training syllabus which may need to be modified to change the training requirements.

In France a plan has been initiated to replace a certain number of Category I Instrument Landing Systems with SBAS LPV procedures which can achieve similar minima. Once again it has to be verified that the users of these airfields are all equipped with the SBAS capability needed to fly the LPV operations.

### 30.11.3 Multi-Constellation

Today the use of GNSS in civil aviation is limited to single frequency, GPS L1. Although the GPS system is broadcasting signals on another frequency (L2) this is not used in civil aviation as it is not in a protected frequency band. The introduction of the new L5 signal in GPS which is in a frequency band protected for aviation applications will allow the use of dual frequency GNSS in the future. The availability of multi-frequency, multi-constellation GNSS will bring more robustness to the navigation solution for aviation and will help to address some of the fears related to the vulnerability of the current GPS [30.56, 57].

The US GPS has been embraced by the aviation community and is providing significant operational benefits. Additional core constellations from the Russian GLONASS to the coming European Galileo and Chinese BeiDou are going to bring further benefits [30.58, 59] but the increased number of signals and their complexity will bring some challenges, particularly in the area of standardisation.

Standards are already available in ICAO Annex 10 for the GPS and GLONASS constellations and the ICAO Navigation Systems Panel is working on the standards for Galileo and BeiDou. However, globally accepted avionics standards are currently only available for GPS user equipment. The future avionics will clearly be multi-constellation but the way to standardise the user equipment that could be using a wide variety of signals from four different constellations is a problem that has yet to be resolved.

In addition to the technical difficulties there are institutional and political issues. At an ICAO Air Navigation Conference in 2012 the Russian Federation announced that from 2017 all Russian registered aircraft would be required to carry GLONASS equipment. This raised significant concerns among the aviation community that there would be a loss of global interoperability concerning GNSS with the potential to have different forms of GNSS mandated in different regions of the world.

The community is working hard to establish a means of standardising a multi-constellation user equipment for aviation that includes all four constellations and it must be hoped that they succeed.

# 31. Ground Based Augmentation Systems

Sam Pullen

This chapter explains the fundamentals of ground-based augmentation systems (GBASs). GBASs are fielded at airports to support civil aviation operations down to and including precision approach and landing. This chapter describes how GBAS generates differential corrections for Global Positioning System (GPS) pseudorange (L1 C/A-code) signals based on measurements taken at known (reference) locations, how reference measurements are monitored to protect against GPS and GBAS faults or anomalies, and what information is broadcast to users to support enhanced accuracy and integrity (or safety). The application of GBAS to civil aviation precision approach and landing is explained along with the key considerations in fielding GBAS reference equipment at airports. Augmentation systems that transmit additional global navigation satellite system (GNSS)-like ranging signals to users are also briefly introduced.

Terrestrial augmentation of GNSSs can take the form of differential correction broadcasts and/or the broadcast of GNSS-like ranging signals from ground locations by so-called *pseudolites*. The original motivation for adding pseudolites to GNSSs was to compensate for the limited number of GPS satellites in the sky. For example, over-the-air tests of GPS transmitters at the Yuma test ground in the late 1970s were used to verify the performance of the GPS signal concept before sufficient satellites were in orbit to obtain position fixes solely from space [31.1]. While GPS today almost always provides four or more visible satellites above 10° of elevation, users with restricted sky visibility may still benefit from local ground-based transmitters [31.2]. Pseudolites have also been used to improve ranging geometry in such a way that carrier-phase integer ambiguities can be resolved once a user passes nearby [31.3].

The original motivation for broadcasting differential corrections to GNSS ranging signals came from the deliberate degradation of the timing accuracy of the GPS L1 C/A-code signals, which was known as selective availability, or S/A [31.4]. Error on the order of 10–20 m was artificially induced on the clock component of each GPS satellite (when receiving C/A-code) in order to prevent civil users from obtaining greater accuracy than was originally intended by the system designers. The error induced by S/A on a given satellite was the same for all C/A-code users tracking that

satellite. It was soon realized that receivers located at fixed and known (precisely surveyed) sites could estimate the error in each satellite ranging measurement and, by broadcasting this information, allow nearby users to remove the impact of S/A from their measurements [31.5]. This relatively simple means of defeating S/A was one reason that the US decided to deactivate S/A in May of 2000 [31.6].

Well before S/A was deactivated, the other advantages of what became known as *differential GPS* had become apparent. Once S/A was removed, other natural error sources such as satellite clock and ephemeris errors and ionospheric and tropospheric delays became significant contributors to GPS navigation accuracy. These are all highly correlated over short to medium distances; thus the application of differential corrections removes most of their effects. In addition, differential GPS was a key component of the task of verifying the integrity, or safety of use, of GPS signals using individual ground stations or networks of stations. Ground systems that combine differential corrections with real-time integrity information became known as GNSS *augmentation systems*.

This chapter will focus on augmentation systems that are based on a single ground station site and dissemination of corrections and integrity information via radio link. This approach is generally denoted as local area differential GNSS, or LADGNSS. The adaptation of this technology for civil aircraft precision approaches and landings, known internationally as ground-based augmentation systems (GBAS) and as local area augmentation systems (LAAS) in the US, will be discussed in detail, as it covers almost all of the key considerations that apply to single-reference-site (SRS) augmentation systems. In particular, LAAS and GBAS have been approved to support precision approaches (with assured lateral and vertical guidance) down to Category I criteria – 200 ft above the surface – and extensions of this technology are expected to support approaches all the way to the ground (Category IIIB).

## 31.1 Components

Figure 31.1 shows the primary components of a GBAS reference station sited at an airport [31.7]. GBAS includes multiple (four or more) ground reference receivers and antennas for redundancy and integrity monitoring. Each receiver antenna is located in a carefully presurveyed site and is tested in advance to confirm that the multipath characteristics of the site selected are bounded by predetermined models that are used in determining the standard deviations (or *sigmas*) of the errors in the pseudorange corrections that are broadcast to aircraft. These antenna sites are separated by enough distance for their multipath errors (from ground reflections and distant obstacles) to be approximately statistically independent, allowing averaging of these errors under nominal conditions and making it easier to distinguish faulty measurements in a single reference receiver. For GBAS, it is important to minimize multipath errors at these receiver antennas because these errors will not be correlated with user ranging errors and thus will not be mitigated by differential corrections. Therefore, specialized ground antenna designs are used, and these will be described further in Sect. 31.3.

In GBAS, a master control processor typically located near or next to the reference receivers collects the receiver measurements and determines the pseudorange corrections and correction rates to broadcast for each satellite approved for use. This includes determining, using a series of monitor algorithms and exclusion logic, which satellite and ground measurements are safe for the intended purpose, as will be discussed further in Sect. 31.3. This information is updated twice per second and includes (at lower update rates) information on station characteristics as well as the ideal approach geometries to be followed for all allowed precision approaches at this airport. It is packaged into several different message types, transferred by wire or optical fiber to a very high frequency (VHF) data broadcast (VDB) transmitter and antenna somewhere on airport property, and broadcast to users using the instrument landing system (ILS) localizer band from 108–118 MHz [31.8]. Siting of the VDB antenna at each airport is key to maximizing the airport surface area where the signal can be received while also ensuring acceptable signal levels throughout the precision approach coverage region in the air.

Because of the very high demands on GBAS for integrity and continuity (safety) and availability (the percentage of time operations are possible), multiple degrees of redundant equipage are essential. The same is not true of many less-demanding uses of LADGNSS. Many short-duration applications (such as day-long survey activities) can be adequately supported by a single reference receiver and antenna. In these cases, the equipment can be checked out before and after each application, and the penalty for a failed application is limited to repeating it after the equipment is

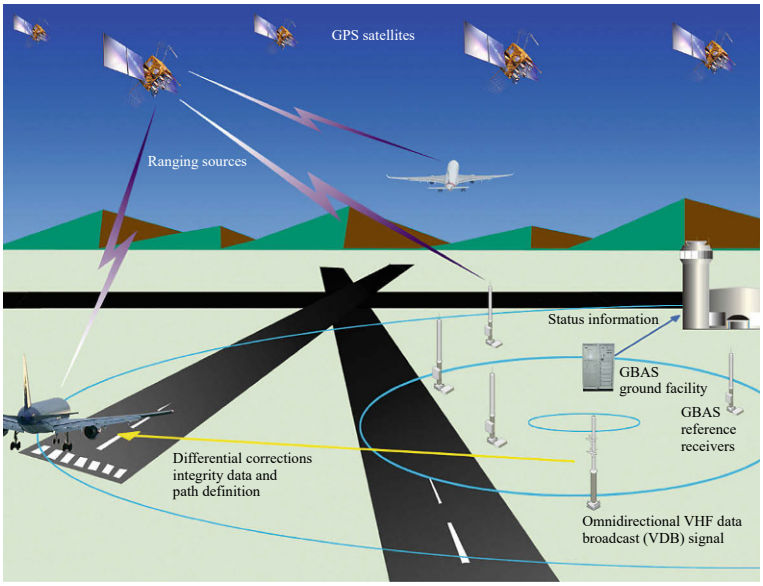

**Fig. 31.1** GBAS ground station components-advanced example of terrestrial local area differential GNSS (DGNSS) systems (courtesy of the FAA satellite navigation team)

fixed. Permanent, fixed local area differential GNSS (LADGNSS) reference stations or networks will likely possess at least some redundancy to minimize maintenance demands, but practically all LADGNSS applications other than GBAS are likely to need a subset of the equipment needed for GBAS.

## 31.2 An Overview of Local Area Approaches

While the hardware components for most LADGNSS systems are similar, significant differences exist between the algorithms used to generate differential corrections and the specific measurements that are corrected. This section will describe a few of these variations and refer to other chapters of this volume for more details.

### 31.2.1 Pseudorange Corrections

Almost all LADGNSS systems broadcast either corrections to pseudorange measurements or pseudorange measurements themselves so that users can remove common-mode errors by applying the broadcast information to their own measurements. In the most common case, where pseudorange corrections are sent, these corrections express the ground's best estimate of the pseudorange error on each visible satellite as measured by nearby users based on knowledge of the true positions of the reference receiver antenna(s) and the satellite locations included in the navigation data. Users then simply subtract this correction from their own pseudorange measurements to arrive at improved ones that are used in positioning calculations (Chap. 26). Note that a common procedure is required between reference and user systems to ensure that common terms are applied or not applied at both ends. GBAS, for example, applies satellite clock corrections (based on navigation data) to its reference measurements. These corrections will be the same for reference and user receivers. To maintain proper error cancellation, GBAS users must also apply satellite clock corrections but not relativistic corrections [31.9].

When a *corrections* approach similar to GBAS is used, the broadcast corrections should be close to zero and should approximate the actual error on the pseudoranges measured by users due to satellite (clock and ephemeris) and atmospheric (ionosphere and troposphere) causes. The small magnitude of this number makes it easy to broadcast with a small dynamic range; i. e., a small number of bits in a digital message format (one value for each usable satellite). Because standalone user errors are often dominated by ionospheric delay, pseudorange corrections under nominal conditions are typically their largest for low-elevation satellites when the ionosphere is particularly active (Chap. 39). The maximum magnitude of GBAS pseudorange corrections is $\pm 327.67$ m [31.8], but anything larger than $\pm 125$ to 150 m suggests a potential satellite anomaly, as this exceeds the range

of ionospheric delays even under extreme conditions.

Due to the time delay that exists between the measurements used to generate differential corrections on the ground and the application of the resulting corrections to user measurements, pseudorange rate corrections or other means to interpolate over the resulting latency are needed. GBAS provides a time tag for each pseudorange correction and broadcasts pseudorange rate corrections based upon the difference between the last two pseudorange corrections divided by the time interval. Users apply this pseudorange correction rate to linearly extrapolate forward from the correction time tag to the time of their measurements as long as this latency is within a time to alert that is protected by the ground station. Satellites suffering from *clock* failures can have range measurements that vary wildly and nonlinearly over a few seconds to minutes; thus these faults need to be detected quickly to protect the linear extrapolation performed by GBAS users.

### 31.2.2 Carrier-Phase Corrections

In addition to broadcasting pseudorange corrections, some LADGNSS systems also transmit raw carrier-phase measurements or corrections to them in support of users applying what is known as carrier-phase differential GNSS (CDGNSS) or real time kinematic (RTK) GNSS processing. CDGNSS users include those with centimeter- or even millimeter-level positioning accuracy requirements, such as surveyors and scientific users.

Carrier-phase measurements contain unknown integer ambiguities (i. e., integer numbers of sine-wave cycles) and thus do not provide unambiguous range estimates. Solving for these ambiguities is a key component of most algorithms applied by CDGNSS and RTK users, and it is this step that provides centimeter-level or better range and position accuracy (Chap. 23 and [31.3]). Some CDGPS techniques do not depend upon always resolving integer ambiguities (*fixed* solutions) but instead upon refining *floating* estimates of these ambiguities over time; thereby improving upon the performance that can be obtained from pseudorange-based LADGNSS alone. For examples of these techniques used for aviation, see [31.10, 11]. Existing GBAS systems do not broadcast carrier-phase corrections, but because of these potential benefits, Message type 6 has been reserved to support future carrier-phase corrections in the GBAS interface control document (ICD) [31.8].

### 31.2.3 Reference Station Distribution

Most LADGNSS systems derive and broadcast corrections from essentially a single location. This includes GBAS and other systems with reference receiver and antenna siting redundancy on a local scale (i. e., within several kilometers), because antennas this close together are observing almost identical GNSS satellite and atmospheric behavior under normal conditions. The alternative technique of distributing reference stations widely (hundreds of kilometers) apart and developing corrections that can be used over entire countries or continents is normally supported by corrections broadcast from space (so-called *space-based augmentation systems*, or SBAS) and is described in Chap. 12. In between these extremes are terrestrial LADGNSS systems, which also use networks of reference stations instead of single sites. These networks are defined as *terrestrial* instead of *space-based* because they broadcast corrections using ground-based means (Sect. 31.2.4). Station separations in terrestrial networks tend to be shorter than those in space-based networks, but this is not always the case.

The primary motivation for LADGNSS reference station networks is to provide service to a relatively large area without the need to place a large number of individual reference stations, as demonstrated for CDGNSS users in [31.12]. One system of this type conceived for aviation use in Australia was the ground-based regional augmentation system, or GRAS, described in [31.13]. It married the network concept of multiple widely-spread reference stations transmitting corrections to a central processor (as in SBAS) with the GBAS method of broadcasting corrections via terrestrial VHF radio on the ILS localizer band. The GBAS message format from [31.8] was extended with an additional message type (*type 101*) to accommodate GRAS, while the single-transmitter approach of GBAS was replaced with a network of VHF transmitter stations that already existed in Australia [31.14]. This *hybrid* approach, while not actually put into operation, illustrates the many possible variations of LADGNSS and wide-area GNSS technology that can be applied to support particular service providers and classes of users.

### 31.2.4 Broadcast Techniques

The most common means of communicating LADGNSS corrections to users is by radio frequency (RF) transmissions using separate transmitters and receivers. The use of the VHF ILS localizer band from 108–118 MHz for this purpose in GBAS allows the reuse of ILS localizer antennas that already

exist on almost all aircraft that will be equipped with GBAS [31.7, 8]. An RF technique commonly used in marine LADGNSS systems is digitally encoding messages on existing direction-finding radiobeacons transmitting at around 300 kHz, as is done by the US Coast Guard NDGPS [31.5, 15]. Ultra high frequency (UHF) radiomodems are commonly used in relatively low-cost commercial and experimental systems. An example of a radiomodem transmitter used in unmanned aerial vehicle (UAV) LADGNSS flight tests conducted by KAIST in Daejeon, Korea is the IP-921 made by Microhard Systems, Inc [31.16]. It transmits at a frequency range of 902–928 MHz with a maximum data rate of 1.1 Mbps out to a line-of-sight range of 100 km or more at a lower data rate of 345 kbps, which should be completely adequate for single-reference-site LADGNSS [31.17].

Now that Internet connectivity is widespread, disseminating corrections via the Internet is also possible for some applications that do not require the highest levels of timeliness or reliability. The corrections of some existing GBAS and SBAS systems are available on the Internet after some delay. For example, the Federal Aviation Administration (FAA) William J. Hughes Technical Center, which oversees the fielding and operations of GBAS (LAAS) sites in the Conterminous United Stated (CONUS), includes near-real-time and archived corrections and other broadcast information for several CONUS GBAS sites on a website for analysis [31.18].

## 31.3 Ground-Based Augmentation Systems

### 31.3.1 Overview and Requirements

As described previously, GBAS is a subset of LADGNSS that supports civil aviation precision approach and landing operations at airports where a GBAS ground station is sited. The key components of a GBAS ground station are shown in Fig. 31.1 and are described briefly in Sect. 31.1. This section will describe in more detail the requirements that GBAS must meet and how GBAS satisfies these requirements through a combination of high-accuracy differential corrections, monitoring of possible faults and anomalies to protect integrity, and optimization to maximize availability and continuity in the presence of these anomalies.

Figure 31.2 expands upon Fig. 31.1 to show how the GBAS ground system components are typically sited relative to the territory of a given airport and how they support precision approaches to all runway ends at that airport. In existing sites, the GBAS reference receivers and antennas are placed relatively close together but just far enough apart to keep multipath errors at each antenna uncorrelated, as discussed in Sect. 31.1. The central processing unit that determines the information to be broadcast is also nearby, but the VHF transmitter antenna may be some distance away to cover as much of the airport and its surrounding approaches as possible. Note that most airports have multiple runways and can at least theoretically support precision approaches in two directions (two runway ends) for each runway. Approaching aircraft are supported by GBAS to at least the Category I approach minima at all runway ends for which GBAS precision guidance is allowed (and path-guidance information is broadcast). Aircraft using GBAS derive Cartesian (e.g., east-north-up) positions from their corrected GNSS measurements and convert these to angular *ILS-lookalike* measurements to be compatible with existing avionics built for the angular measurements (offsets from desired vertical glidepath and lateral localizer) provided by the instrument landing system (ILS) [31.7, 9].

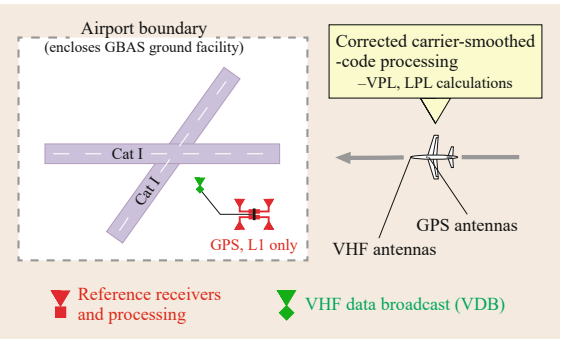

**Fig. 31.2** GBAS ground station and airborne operations at a typical airport (Category I precision approach operations)

The development of GBAS from LADGNSS over the last 25 years has been spearheaded by aviation service providers such as the FAA in the US, companies that provide equipment for civil aviation such as Honeywell, Raytheon, Rockwell Collins, and Thales Group, and universities and other research groups. The requirements for GBAS have been developed from earlier systems such as ILS by Radio Technical Commission for Aeronautics (RTCA) in the US, European Organisation for Civil Aviation Equipment (EUROCAE) in Europe, and the International Civil Aviation Organization (ICAO), which devises *Standards and Recommended Practices* (SARPS) for various aircraft systems [31.7–9].

In practice, RTCA and EUROCAE standards are *harmonized* at ICAO so that GBAS ground and airborne designers work to a single, unified set of requirements to the greatest extent possible.

Table 31.1 summarizes the requirements for different modes of aviation precision approach under limited visibility as defined for GBAS [31.19]. The term *GSL* in the left-hand column stands for *GBAS Service Level* and refers to different *categories* of precision approach, which correspond to different levels of pilot visibility in horizontal (*RVR*, runway visual range) and vertical (*ceiling*). Current GBAS systems primarily support GSL C, which corresponds to *Category I* precision approaches down to a 200 ft minimum decision height above the runway threshold. GSL A and B support less-demanding variations of Category I precision approach that can be supported, with slightly different values, by SBAS (Chap. 12 and [31.20]). GSL D, E, and F refer to versions of Category II and III precision approaches that support lower decision heights. GBAS ground systems and airborne equipage that support GSL D and allow for Category III operations (including zero-visibility landings) are now under development [31.21, 22].

The columns in Table 31.1 express requirements in terms of *accuracy*, *integrity*, and *continuity*. The *accuracy* requirement is expressed as a 95th-percentile bound on navigation system error (NSE), or the difference between true (unknown) position and that output by a GBAS-qualified airborne receiver. *Continuity* is expressed as an upper bound on the probability (per 15 or 30 s exposure interval) that an operation in progress is unexpectedly aborted due to a GBAS system interruption, which can take one of several forms. *Integrity* generally refers to the trust that can be placed in the outputs of a system and the ability of a system to alert when its outputs cannot be trusted (i. e., are unsafe to use). For GBAS, this is expressed by three related requirements. The first is an upper bound on the probability (per exposure interval – typically the length of a precision approach, or about 150 to 200 s) that integrity is lost, meaning that unsafe or *misleading* information is output. The second is a *time to alert* within which a warning from the system needs to be output to avoid an unsafe condition. In other words, if the output of misleading information lasts for less than the time to alert before the system alerts that the information should not be used. This condition is not unsafe and does not count against the integrity loss probability. The third requirement, the *alert limit*, expresses the maximum error in both vertical and lateral dimensions that is regarded as *safe* for a given operation [31.23].

*Availability* requirements are not shown in Table 31.1 because they vary widely by airport. The most common definition of availability is the percentage of time that the accuracy, integrity, and continuity requirements are met simultaneously, allowing GBAS-supported operations to take place. When one or more of these requirements are violated, this will be known to users and operators so that operations can be avoided. If operations begin and then must stop suddenly due to an unexpected change of system state (e.g., the failure of a GNSS satellite needed for acceptable performance, which is known as a *critical satellite*), *continuity* is lost. This means that implementing the integrity monitoring needed to meet the integrity requirements unavoidably increases the probability of continuity loss. Since integrity and continuity requirements thus compete directly with each other, the design of integrity monitoring algorithms and measurement-exclusion logic is a much greater challenge than it appears at first glance.

### 31.3.2 Generation of Differential Corrections

As described in Sect. 31.3.1, GBAS generates pseudorange differential corrections and correction rates for each satellite from redundant reference receiver measurements. This section provides the specified equations used to compute these values to clarify the procedure [31.24].

The first step in processing pseudorange and carrier-phase measurements from each reference receiver is to perform what is known as carrier smoothing, which takes advantage of the greater precision of carrier-phase measurements to attenuate noise and multipath errors in the pseudorange measurements (Sects. 22.3.1 and 20.4). To maximize commonality in smoothing between ground and airborne equipment, a specific algorithm is mandated for the ground system, and the airborne is given a very small tolerance for variation given nominal input conditions [31.9]. This typically requires that the same smoothing time of 100 s is used in both ground and airborne systems. The ground smoothing algorithm (at least for FAA LAAS systems) is given by [31.24]

$$\mathrm{PR}_s(k) = \left(\frac{1}{N}\right)\mathrm{PR}_r(k) + \left(\frac{N-1}{N}\right)\left[\mathrm{PR}_s(k-1) + \phi(k) - \phi(k-1)\right], \tag{31.1}$$

where $\mathrm{PR}_r$ is the raw (measured) pseudorange for a given GNSS satellite at a given reference receiver, $\mathrm{PR}_s$ is the output smoothed pseudorange, $f$ is the carrier-phase (accumulated Doppler) measurement, $k$ represents the current time epoch, and $N = S/T$ (nom-

**Table 31.1** GBAS precision approach requirements summary

| GSL | Accuracy | | Integrity | | | | Continuity |
|---|---|---|---|---|---|---|---|
| | 95% Lat. (NSE) (m) | 95% Vert. NSE (m) | Pr (loss of integrity) (s) | Time to alert (s) | LAL (m) | VAL (m) | Pr (loss of continuity) (s) |

NSE – navigation system error

inally 200 at filter steady-state) represents the number of samples used in the smoothing filter, where $T$ is the measurement sampling interval (nominally 0.5 s), and $S = 100$ s.

The smoothed pseudoranges from (31.1) are the basis of the pseudorange corrections ($PR_{sc}$) computed for each reference receiver $m$ and each satellite $n$ [31.24]

$$PR_{sc}(n,m) = R(n,m) - PR_s(n,m) - t_{sv_gps}(n)\ , \tag{31.2}$$

where R is the predicted range based on the surveyed antenna position and the satellite position provided by the broadcast ephemeris data, and $t_{sv_gps}$ is the clock correction for satellite $n$ (for L1 C/A-code) as computed from the GPS navigation data, including relativistic terms. Note that neither ionospheric nor tropospheric corrections are applied. As mentioned in Sect. 31.2.1, corrections that would be the same (or very nearly the same) at both ground and aircraft must either be applied in both places or neither place to avoid introducing uncommon errors.

The next step for GBAS is to perform a *clock adjustment* to the corrections generated by each reference receiver. This is done to remove the large common bias created by reference receiver clock errors from the broadcast corrections and to allow straightforward comparison or corrections across reference receivers (all variables apply for a specific epoch $k$) [31.24]

$$PR_{sca}(n,m) = PR_{sc}(n,m) - \frac{1}{N_c}\sum_{n\in S_c} PR_{sc}(n,m)\ , \tag{31.3}$$

where $PR_{sca}$ is the resulting smoothed and clock-adjusted correction for receiver $m$ and satellite $n$, $S_c$ is the *common set* of satellites, meaning the set of satellites tracked by all healthy reference receivers, and $N_c$ is the number of satellites in set $S_c$. For each receiver $m$, (31.3) removes the average bias in the nonadjusted pseudorange correction across the $N_c$ satellites in the common set. This works well because the receiver clock bias on each receiver is the same for all satellites tracked by that receiver.

Under nominal conditions when no receivers are removed due to detected anomalies, the broadcast pseudorange correction ($PR_{corr}$ or PRC) for each satellite $n$ is simply the average over the $M(n)$ smoothed and clock-adjusted corrections from each receiver tracking that satellite [31.24]

$$PR_{corr} = \frac{1}{M(n)}\sum_{m\in S_n} PR_{sca}(n,m)\ . \tag{31.4}$$

The broadcast range rate correction ($RR_{corr}$ or RRC) for satellite $n$ is derived by differencing the current and immediately previous pseudorange correction values for that satellite divided by the time gap $T$ between them (nominally 0.5 s).

Figure 31.3 shows a block-diagram representation of the functions carried out by the GBAS ground system. It corresponds specifically to the integrity monitor testbed (IMT) developed at Stanford University as a ground system prototype and algorithm development tool [31.25], but the same (or very similar) functions are carried out by all GBAS ground systems. The functions shown in Fig. 31.3 that have been described in this section include SISRAD (signal-in-space receive and decode), smooth (31.1), correction ((31.2) and (31.3)), and average (31.4). The other functions shown in this figure are needed for integrity verification and are described (at least briefly) in the following section.

### 31.3.3 Fault Monitoring

While the processing needed to generate pseudorange corrections from raw measurements is not demanding,

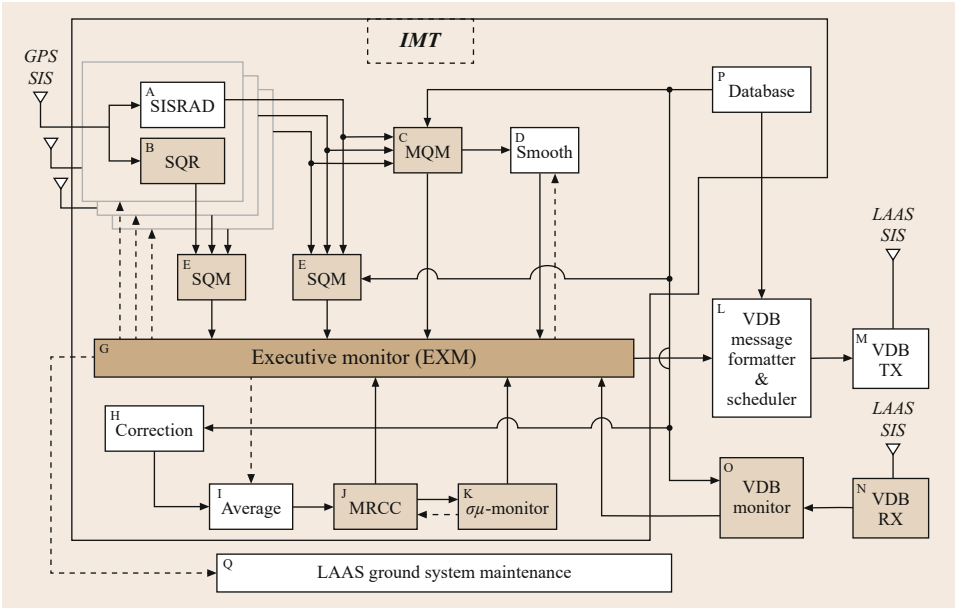

**Fig. 31.3** Block diagram of GBAS ground station processing, integrity monitoring, and measurement exclusion logic

it is dwarfed by the many different algorithms used to verify the integrity of these measurements (and thus the broadcast corrections) in real time. Detailed descriptions of these algorithms are beyond the scope of this chapter. Summaries of the key algorithms and the anomalies that they address are provided along with references that contain further details.

The failures and/or anomaly conditions that could create hazardous errors for GBAS users if not detected or mitigated can be broken down into three categories:

- *Faults within GNSS*: This includes failures within GNSS satellites and failures or errors in the control segment that manages a given GNSS constellation, such as the GPS operational control segment (OCS).
- *Faults within augmentation system equipment*: This includes failures within individual GNSS reference receivers as well as anomalous multipath at reference receiver antennas.
- *Signal propagation anomalies*: This includes anomalous spatial gradients when GNSS signals pass through the ionosphere or the troposphere on their way to reference and user antennas. This can result in measured pseudoranges at the reference receiver that are significantly different than those measured by users. Other impacts, such as ionosphere *scintillation* (Chap. 39), are much more likely to cause loss of lock (or monitor detection) and thus lead to continuity breaches as opposed to loss of integrity.

The terminology of Fig. 31.3 is useful in further classifying the threats that the GBAS ground system must guard against. The following functions in that figure protect against the following subclasses of failures or anomalies.

### Signal Deformation Monitoring (SDM)

This examines both the received power of the incoming satellite signals and the quality of the L1 C/A-code waveforms, meaning the degree to which the transmitted waveforms match the ideal ones. Significant waveform anomalies have occurred at least once, on GPS space vehicle number/pseudo-random noise (SVN/PRN) 19 as discovered in 1993, and nominal waveforms have small imperfections that must be accounted for in the design of GBAS [31.26, 27]. While most waveform abnormalities are highly correlated between reference and user receivers, these receivers are not required to be identical; thus large anomalies can cause significant user errors [31.28]. A threat model describing and bounding anomalous signal deformation for existing GPS satellites on L1 was developed based on a detailed analysis of the SVN/PRN 19 event [31.26, 28] and is used to quantify the integrity threat to GBAS from signal deformation after the implementation of the monitoring described below.

Detection of waveform abnormalities requires receivers that output GNSS measurements at multiple points along the code correlation peak so that asymmetries and unusual features can be observed and identified [31.28, 29]. This is performed by the *SQR* or *signal quality reception* function in Fig. 31.3. In prac-

tice, to avoid hardware duplication, this *SQR* capability is built into the reference receivers that also provide the measurements from which pseudorange corrections are generated [31.30].

Figure 31.4 shows an (exaggerated) example of a deformed code correlation peak and illustrates the monitor test statistics that are defined to detect significant deformations. The *ideal* code correlation peak differs slightly with pseudorange noise (PRN) code but is basically a perfectly symmetric triangle with *rounding* at the top due to the limited RF bandwidth in the GPS receiver. Multipath deforms the trailing (right-hand) side of the correlation peak, while satellite-generated signal deformation can alter both sides. The *delta* and *ratio* metrics shown in Fig. 31.4 quantify the difference between the observed correlation peak for each satellite (provided by the SQR function) and the ideal peak for the PRN broadcast by that satellite [31.28]. Thresholds on these metrics (to identify actual SDM faults within the continuity budget) must consider nominal deformations due to multipath and the nominal signal deformations mentioned above.

SDM is the major component of *signal quality monitoring*, or SQM, which is shown within Fig. 31.1. Additional monitoring that falls within this category includes testing the measured signal power from each satellite at each reference receiver to confirm that it falls within expected norms [31.31, 32]. This is not only a test of satellite performance but also a potential indicator of external RF interference (RFI), which will be discussed later.

Another satellite performance monitor with multiple purposes is that for code-carrier divergence, or CCD. CCD is caused by ionospheric delay that affects pseudorange and carrier measurements with equal magnitude but opposite sign. This degrades the accuracy of carrier smoothing to an acceptable degree as long as the CCD rate (twice the rate of ionospheric delay change) is small, as it typically is. The CCD monitor in GBAS estimates the CCD rate in real time based on feeding the difference between raw L1 code and carrier-phase measurements into two successive smoothing filters, both with time constants of around 30 s. The resulting estimate of CCD rate is compared to a threshold, and a flag is issued if this rate exceeds an acceptable level [31.33]. In theory, it is possible for satellites to lose coherence between code and carrier elements of the broadcast signal and thus generate an unacceptable level of CCD. This is thought to be exceedingly unlikely, which means that, in practice, the CCD monitor serves as a means to detect unusual ionospheric behavior. The importance of this feature in mitigating threats due to large ionospheric spatial gradients will be explained later.

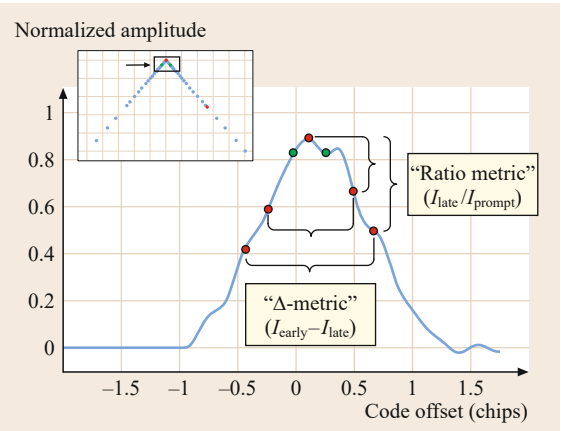

**Fig. 31.4** Code correlation peak monitor test statistics for SDM

### Data Quality Monitoring (DQM)

While this considers all of the navigation data broadcast by each satellite, its focus is the correctness of the ephemeris data that provides knowledge of the satellite position in space at any given time. Because GBAS reference receivers and aircraft are separated by no more than 10–20 km during the most critical flight phases, only very large ephemeris errors, such as a difference of over 1000 m between reported and actual satellite position, are potentially threatening. Errors so much larger than what is typical (differences of several meters) are considered to be possible from two causes [31.34].

*Type A failure.* OCS generation and upload of erroneous navigation data along with a maneuver of the affected satellite (i. e., the satellite changes orbits).

*Type B failure.* OCS generation and upload of erroneous navigation data without a maneuver of the affected satellite (i. e., the satellite remains in the same orbit).

Type B failures represent the simpler scenario where an observation, mathematical, or transcription error occurs in the process of generating updated ephemeris parameters for satellites that do not experience any external thrust that would cause an orbit change. GPS users would see a series of valid (correct) ephemeris messages (typically updated at 2 h intervals) followed by the sudden appearance of invalid (grossly erroneous) data after a particular message update. Therefore, consistency checking between old and new ephemerides is one means of detecting changes large enough to represent errors hazardous to GBAS. Because individual ephemeris messages are tightly fit to 2–4 h periods to maximize accuracy, and GPS satellite orbits change significantly (relative to the errors of con-

cern) over periods of 6–12 h, some degree of correcting for nominal satellite motion is desirable. The so-called *FOH-YETE* test described in [31.34] is a good compromise between simplicity and ability to detect significant type B failures. More involved orbit fitting of GPS satellites can greatly reduce the size of detectable errors, but the practical benefits of this additional complexity are small.

Type A events may also involve generation or upload mistakes but are complicated by the existence of a satellite maneuver. Deliberate satellite maneuvers are conducted occasionally to maintain the constellation and correct for normal orbit variation. Maneuvers change satellite orbits significantly; thus ephemeris parameters broadcast prior to a maneuver would be hazardous to use. To prevent this, satellites are flagged as *unhealthy* preceding maneuvers (meaning that their broadcast health bits indicate *do not use*) and are not flagged as *healthy* again until the maneuver is completed and new ephemeris messages reflecting the revised orbit are generated, uploaded, and double-checked for accuracy. Faults during this process that lead to hazardously incorrect ephemeris messages being broadcast by satellites flagged as healthy are denoted as type A failures.

Figure 31.5 shows an example of a relatively simple type A failure that occurred on GPS SVN 54 (PRN 18) on 10 April 2007 [31.35]. The plot shows the effects of this failure on uncorrected C/A-code range error of the affected satellite as measured at Honolulu, Hawaii along with the resulting 3-D position error at Honolulu, Los Angeles, California, and Billings, Montana (all in the western part of the US). The measured range error at Honolulu grew to about 350 m, and position error at Honolulu grew to over 500 m before the fault was noticed and the satellite uploaded to broadcast an *unhealthy* flag, which occurred about an hour after the fault began.

Subsequent investigation of this event showed that this was the result of a normal, planned orbit maneuver of SVN 54. The only problem was that the satellite was not updated to broadcast a status of *unhealthy* prior to beginning the maneuver. As a result, SVN 54 began moving away from its old broadcast ephemeris while still indicating its status as *healthy*. The fact that SVN 54 would be maneuvered was alerted ahead of time by a forecast Notice Advisory to Navstar Users (NANU) message, but NANU messages are not included in the broadcast navigation data and are not meant to substitute for the broadcast health status.

Type A faults of this sort are not directly observable to GBAS ground stations, but they can be readily detected by observing the computed pseudorange and carrier-phase corrections and changes over short intervals (carrier-phase corrections are not normally broadcast but can be computed and used for monitoring – see [31.8]) [31.34]. In Fig. 31.5, the increasing range error experienced at Honolulu would have appeared as an increasing pseudorange correction to a GBAS ground station sited there and would have exceeded any reasonable value of this correction well before the satellite was flagged as *unhealthy* (and before any significant error was experienced by GBAS users). Demonstrating that all possible type A faults are protected by these checks requires extensive Monte Carlo simulations of possible orbit maneuvers in which conditions most difficult for these checks to detect are emphasized in the sampling of possible maneuvers [31.36].

### Measurement Quality Monitoring (MQM)

This refers to monitoring of the time consistency of pseudorange and carrier measurements received at each ground reference receiver (or the average of all reference receivers). Sudden, sizeable inconsistencies in the received pseudorange, carrier-phase, or the difference between the raw pseudorange measured on a particular epoch and the pseudorange projected by the carrier-smoothing filter from the two most recent carrier-phase measurements (*carrier-smoothed-code innovations* – see (31.5) below) indicate the presence of a fault either in the received satellite signals or in one or more receivers tracking the affected satellites. To protect users, these must be detected quickly after they occur and either removed or corrected depending on their source and nature. Note that *cycle slips* in receiver carrier-phase tracking loops are an example of a receiver fault and are mitigated by MQM. Cycle slips must be sufficiently rare to meet the prior probability assumed by MQM, which places a lower bound on the signal power at which reliable carrier-phase measurements can be obtained in GBAS.

MQM algorithms for checking the time consistency of adjacent carrier-phase measurements and carrier-smoothed-code innovations are given in [31.25, 37]. The former is complicated by the need to duplicate the clock-adjustment steps shown (for computing pseudorange corrections) in (31.3) and (31.4). For each receiver at each epoch, clock-adjusted carrier-phase measurements for the last ten epochs (5 s) are used to fit a second-order polynomial that is then applied to predict the current (just acquired) phase measurement. The difference between actual and predicted phase measurement is compared to a threshold based both on expected noise of nominal carrier-phase measurements fit over 10 s and the minimum differences that could lead to threatening user errors. The *acceleration* and *velocity* values resulting from the second-order polynomial fit are also compared to their own thresholds.

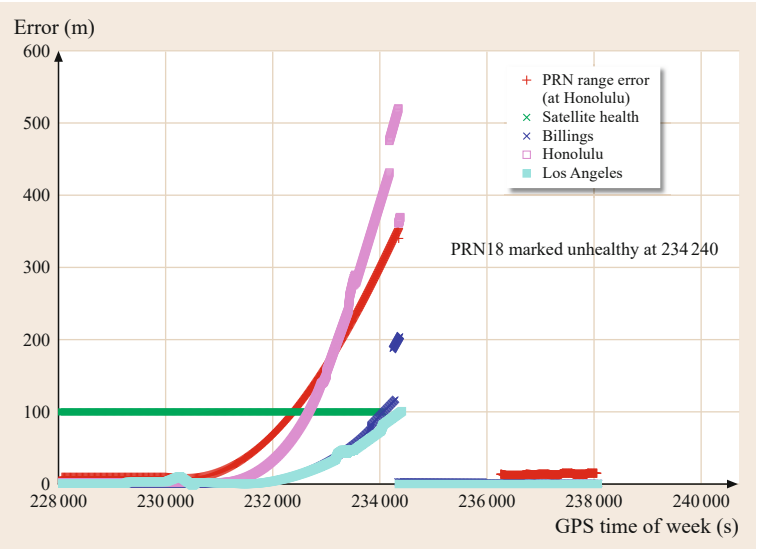

**Fig. 31.5** Ephemeris type A failure example from April 2007. Standard positioning service (SPS) 3-D position error during PRN 18 anomaly

The monitor that detects anomalies in carrier-smoothed-code innovations is much simpler and can be expressed as follows using the notation of the smoothing filter definition in (31.1)

$$\mathrm{Inno}(k) = \mathrm{PR_r}(k) - [\mathrm{PR_s}(k-1) + f(k) - f(k-1)] \,. \tag{31.5}$$

As with the carrier-phase consistency test, the innovation (Inno) derived from (31.5) is compared to a threshold that separates acceptable from unacceptable discrepancies.

Distinguishing between satellite and receiver faults detected by MQM is important but is typically left to executive monitoring (EXM), which will be described next. Unlike satellite faults, which normally lead to the exclusion of the affected satellite(s), faults that can be confidently limited to failures or cycle slips of a single reference receiver can often be *patched* by a variation of the algorithm that detects (and thus measures) the inconsistency between measurements. For the innovations test shown in (31.5), patching is performed by replacing the raw pseudorange measurement for this epoch with the one projected from the carrier-phase measurement update (presuming that this condition is limited to one reference receiver and did not also occur on the previous epoch). Patching of carrier-phase discrepancies is more complex but uses the same concept of replacing the (faulty) current measurement with the projection of what the measurement should have been from past measurements. If the code and/or carrier phase offsets resulting from a cycle slip can be patched with acceptable integrity, continuity is improved by preventing the loss of measurements from the affected reference receiver.

Detection and exclusion of satellite-driven faults detected by MQM, which are normally due to clock failures and are the most common GPS satellite anomalies, is important for two reasons. First, satellite faults that affect the time consistency of GPS measurements make it potentially unsafe to linearly extrapolate old pseudorange corrections forward several seconds in time using the range-rate correction (RRC), which is allowed when VDB messages are missed by the aircraft. For this reason, monitoring of unsafe levels of range acceleration (i. e., time-changing terms not included in the estimated range rate) is known as *excess acceleration monitoring*. Second, satellite behavior that falls well outside specified levels (e.g., those given in the *GPS SPS Performance Standard* [31.38]) indicates that the satellite is in an unhealthy mode, which means that the prior probability of failure assigned to healthy satellites (typically $10^{-5}$ per satellite per hour for GPS) no longer applies to this satellite [31.39]. This logic also applies to observed low satellite signal power under SQM, which may not be hazardous by itself but which invalidates the assumptions under which the safety of use of the affected satellite is guaranteed.

### Executive Monitoring (EXM)

As mentioned above, EXM represents a series of logical functions and software execution paths that manage the flow of results from the monitors listed above (and those to follow). It determines which measurements are safe to use in calculating the broadcast pseudorange corrections and other integrity-sensitive values based on the combined monitor outputs, usually expressed as binary flags (pass-fail) for each measurement tested by each monitor. Because integrity must be protected to very

low probabilities, measurements made *questionable* by the combined monitor outputs may be discarded even if they are not individually *flagged* (result in failed tests) by any monitor.

Figure 31.3 helps to illustrate how EXM interacts with monitoring and measurement processing in the Stanford Integrity Monitor Testbed developed to show the feasibility of GBAS ground system monitoring [31.31, 37]. Here, while EXM activities occur throughout the processing of each epoch of measurements, the key logical elements of EXM are divided into two phases. In each epoch, the first phase occurs once the calculations and monitors shown above the *EXM* box in Fig. 31.3 are completed, which includes the monitors discussed to this point. Each of these monitors produces one *pass-fail* flag for each receiver channel, meaning each visible satellite tracked on each operating reference receiver. For example, if four reference receivers are tracking ten satellites, a total of 40 channels are tracked, and each channel has multiple *pass-fail* flags from each of the monitors executed to this point. These monitor flags are *OR*-combined such that a given channel receives a *fail* flag if any of its tests produce a *fail* result. From this point, a series of logical *measurement isolation cases* are applied as described in [31.31].

In most cases, measurements excluded by EXM enter *self-recovery* mode, in which the smoothing filters for the affected channels are restarted, and the measurements are retested with much tighter thresholds to see if any evidence of a fault remains. Tighter thresholds are used for recovery because excluded measurements are presumed to still be faulted until proven otherwise, whereas unexcluded measurements assume a low prior probability of failure before exclusion. If self recovery is unsuccessful after two or three attempted restarts, the measurements enter *external maintenance* mode, meaning that external maintenance is needed to restore them to service. Under certain threatening circumstances, including the case where all ground system measurements enter *external maintenance* mode, an *alarm* is issued that terminates service from that GBAS facility until external maintenance arrives to check and restore the system to full working order.

A *second phase* of EXM applies to the monitors derived from *B-value* statistics that compare measurements across reference receivers, as described under *multiple receiver consistency check* below. The same logical concepts apply, but the process of exclusion is iterative and includes multiple steps because the inclusion of receiver clock adjustments from this point forward affect all corrections and B-values.

Note that there are many ways to integrate EXM within the processing structure of a GBAS ground system. The method outlined above focuses on several steps of logic resolution to remove all threatening measurements. Another approach is to specifically arrange the order of monitor execution so that each monitor acts as a *gate* on the measurements. In other words, all measurements that pass the previous monitors are fed into the next monitor, and only those that pass that monitor get propagated onward. The general order of Fig. 31.3 is followed, in that monitors that are aimed at detecting satellite failures precede those that are aimed at detecting receiver faults. However, this successive-gating procedure is insufficient by itself. Logical steps and cross-checks among multiple monitors need to be added to this *order-based* approach to assure that all potentially hazardous measurements are removed.

### Multiple Receiver Consistency Check (MRCC)

Once the first phase of monitor tests and EXM resolutions described above has been completed, the surviving measurements are used in equations (31.2), (31.3), and (31.4) to calculate receiver clock adjustments and pseudorange corrections for each satellite. Reference receiver redundancy is now exploited to cross-check the smoothed and clock-adjusted candidate corrections from each receiver. For each satellite $n$ with a computed correction $\mathrm{PRC}(n)$ from (31.4), *B-values* are calculated as follows for all receivers who contributed to that correction [31.24]

$$B_{\mathrm{PR}}(n,m) = \mathrm{PR}_{\mathrm{corr}}(n) - \frac{1}{M(n)-1}\sum_{\substack{i\in S_n \\ i\neq m}} \mathrm{PR}_{\mathrm{sca}}(n,i)\ . \tag{31.6}$$

Each $B_{\mathrm{PR}}(n,m)$ (or $B_{n,m}$) value represents the error in the resulting pseudorange correction on satellite $n$ that would occur if the measurement from receiver $m$ were faulty. Here, faulty means that the measurement is not bounded by the zero-mean Gaussian distribution assumed for it under nominal conditions (more on this to follow). If receiver $m$ were faulty, the *true* correction would be given by the average of the measurements from the other (nonfaulted) receivers tracking satellite $n$. Since the faulted measurement from receiver $m$ is in fact included in the average used to generate the correction, the value $B_{i,j}$ indicates the error induced by this.

Given this logic, large values of $B_{n,m}$ suggest that the channel on receiver $m$ tracking satellite $n$ is faulted, and it is the role of MRCC and its associated EXM to exclude these channels before the final pseudorange correction is generated and broadcast. This starts by identifying (*flagging*) the B-values of any channels that exceed a preset threshold based on the bounding zero-mean distribution of B-values under nominal conditions. If any channels are flagged, at least one must

be removed, which means that the common satellite set and thus the clock-adjustment values for each reference receiver will change according to (31.3), leading to revised corrections and B-values.

Because it is possible (and indeed likely) for multiple B-value *failure* flags to be generated by a large-magnitude fault on a single measurement that propagates to other channels via the clock adjustment, EXM uses a special procedure of first excluding the *largest* fault (meaning the channel whose B-value exceeds its threshold by the highest percentage). This exclusion results in new corrections and B-values that are rechecked by MRCC. If flags remain on the (recomputed) B-values, logical isolation steps targeted at individual channel flags based on the EXM isolation cases shown above are applied in an iterative manner, meaning that the process of clock adjustment, correction, B-value recalculation, and threshold checking is repeated after each set of trial exclusions. This process should terminate in a viable, valid set of broadcast corrections and B-values within 1–3 iterations. If not, further exclusion iterations are abandoned, and the ground station is unable to broadcast any valid pseudorange corrections for this epoch (*self recovery* begins on all channels) [31.31].

#### Sigma-Mu Monitor

*Receiver faults* detected by MRCC as described above are rare for well-sited ground receivers. When they occur, the presence of large and unusual multipath from nearby reflecting sources is one likely cause (in addition to internal failures of the receiver, antenna, and connection hardware). MRCC and EXM remove faults that are potentially hazardous right away, but an additional concern is that unusual multipath is not immediately hazardous but is sufficient to violate the error bounds computed by GBAS users (to be discussed later). These more subtle receiver faults may be detected by MRCC given enough time, but additional monitors of the statistics of ground station receiver errors are added here to attempt to detect these conditions sooner: within hours for significant error increases or days for smaller ones.

Both the mean and the sigma of reference receiver errors are estimated using the just-computed (and passed by MRCC) B-values as inputs. Standard statistical estimation of the mean and sigma of a random process is used as one monitor, and this will normally detect significant error increases within hours to days. However, detection of larger errors (those just small enough not to be reliably detected by per-epoch MRCC) in minutes to several hours is desired, and this can be achieved by one or more additional approaches adapted from statistical quality control techniques. One is cumulative sum or *CUSUM* filtering, as described in detail in [31.40]. Exponential (weighted toward the present) moving averages is another standard technique that achieves similar results. A simplification of the CUSUM technique is to accumulate the number of B-value threshold exceedances over time (using multiple thresholds below the MRCC threshold) and use these statistics to alert to significant error increases.

For well-sited ground systems with a significant performance margin built into them, flags from any of these monitors should be very rare. If they occur, the same iterative EXM procedure used to resolve MRCC flags can be used.

#### Message Field Range Check (MFRC)

The last step before the computed pseudorange corrections and correction rates can be approved for broadcast is to confirm that they fall within the message sizes that can be transmitted to users according to the ICD definition of GBAS message type one (this also applies to any broadcast parameters that change in real time based on reference receiver measurements). These limits are $\pm 327.67$ m for the pseudorange correction (PRC) and $\pm 32.767$ m for the correction rate (RRC) [31.8]. In practice, preliminary versions of these values are checked in advance (with tighter thresholds) as part of DQM monitoring to protect against type A ephemeris faults as described above. Therefore, this second check just before the values are sent to the VDB transmitter represents a *sanity check*.

### 31.3.4 User Processing and Integrity Verification

GBAS users who receive differential corrections and integrity information from it apply the broadcast information to improve their accuracy and guarantee their integrity in several steps [31.9]. First, the GPS satellite measurements of multiple redundant airborne receivers are individually checked for received signal power, properly decoded navigation data, CCD (for Category II/III users), and other basic quality tests. (Note that, unlike the ground system, the outputs of multiple airborne receivers are treated independently with regard to GBAS and are not compared together until later in the chain of airborne navigation processing, after GBAS position outputs are provided from each receiver). Measurements deemed acceptable for use then have the broadcast pseudorange corrections applied to them. The basic equation for the application of corrections is [31.9]

$$\begin{aligned} \mathrm{PR}_{\mathrm{corr_air}}(n) = {} & \mathrm{PR}_{\mathrm{air}}(n) + \mathrm{PR}_{\mathrm{corr}}(n) \\ & + \mathrm{RR}_{\mathrm{corr}}(n)(t - t_{\mathrm{z_count}}) \\ & - \mathrm{TC} + c(\Delta t(n))_{\mathrm{L1}} \end{aligned} \tag{31.7}$$

with:

- $PR_{corr_air}(n)$ is the resulting corrected smoothed pseudorange airborne measurement for satellite $n$ and the current time $t$
- $PR_{air}(n)$ is the smoothed pseudorange airborne measurement for satellite $n$ and time $t$ before applying the correction
- $PR_{corr}(n)$ is the pseudorange correction for satellite $n$ broadcast by the ground system (31.4) that is valid at time $t_{z_count}$, which is also included in the broadcast message
- $RR_{corr}(n)$ is the range rate correction for satellite $n$ broadcast by the ground system that is valid at time $t_{z_count}$
- TC is the tropospheric delay correction computed according to [31.9]
- $c$ is the speed of light in vacuum
- $(\Delta t(n))_{L1}$ is the L1 clock correction from the navigation message for satellite $n$ applied at time $t$.

Several protocols apply to the use of GBAS corrections [31.9]. The most important is that only satellites for which corrections are broadcast can be applied to compute GBAS user locations. It is not uncommon for an airborne receiver to track more satellites and obtain more valid measurements than the ground system provides corrections for. The primary reason for this is that the ground system reference receiver antennas cannot reliably track down to elevation angles as low as those that are visible from aircraft. Note that this protocol allows the ground system to protect users from threats detected on the ground – excluding the affected measurements means that no corrections will be generated for them, and users will also have to discard them. Users also confirm that, for each satellite corrected with ground measurements, the received clock and ephemeris navigation data at the user matches what was used by the ground system to compute the corrections. The ground supports this by broadcasting the 16 bit encoded cyclic redundancy check (CRC) of its received data for each approved satellite, allowing the airborne system to execute the same CRC algorithm on its received data and confirm that there is a match [31.8].

User position (in three dimensions: along-ground track, cross-track, and up) and time is computed first by defining a measurement weighting matrix $\mathbf{W}$, which is the inverse of an $N \times N$ diagonal matrix ($N$ is the number of usable satellites) with entries given by the total (fault-free) error variances ($\sigma_i^2$) of each satellite $i$. This *total variance* is the root-sum-square (RSS) of ground and airborne noise components as follows [31.9]

$$\sigma_i^2 = \sigma_{pr_gnd}^2[i] + \sigma_{tropo}^2[i] + \sigma_{pr_air}^2[i] + \sigma_{iono}^2[i] \,. \quad (31.8)$$

Here $\sigma_{pr_gnd}$ bounds the ground pseudorange measurement error after carrier smoothing. It is a key parameter broadcast for each satellite in message type 1 and is based on the known azimuth and elevation angles of that satellite from the ground station, data collected at the ground station, and multipath error models [31.8]. Demonstrating that the broadcast values of $\sigma_{pr_gnd}$ are sufficient bounds on actual rare-event errors is a significant challenge for ground system design – see [31.41–43].

$\sigma_{pr_air}$ bounds the airborne pseudorange measurement error after carrier smoothing. It is determined by each user and is bounded by the airborne accuracy designator A or B models given in [31.9].

$\sigma_{tropo}$ bounds the impact of tropospheric decorrelation due to altitude offset between user and ground station. It is determined by the user-estimated height offset and a sigma parameter broadcast by the ground in message type 2 [31.8, 9].

$\sigma_{iono}$, finally, bounds the impact of ionospheric decorrelation due to horizontal separation between user and ground station. It is determined by user-estimated horizontal separation and velocity estimates and a $\sigma_{vert_iono_gradient}$ (or $\sigma_{vig}$) parameter broadcast by the ground in message type 2 [31.8, 9]. The broadcast value of $\sigma_{vig}$ may be inflated to help mitigate rare, very large spatial gradient events that cannot be bounded by the broadcast $\sigma_{vig}$. This is described further in Sect. 31.3.5 to follow.

The standard equation to solve for the four position states (vector $\boldsymbol{x}$) from the $N$ smoothed and corrected measurements (vector $\boldsymbol{y}$) then applies (this ignores the successive steps of linearization needed to make this model valid [31.9])

$$\boldsymbol{x} = (\mathbf{G}^\top \mathbf{W} \mathbf{G})^{-1} \mathbf{G}^\top \mathbf{W} \boldsymbol{y} \,, \quad (31.9)$$

where $\mathbf{G}$ is the standard $N \times 4$ *geometry matrix* in which each row $i$ ($i = 1, \ldots, N$) is defined by the unit vectors from the user to satellite $i$

$$\boldsymbol{G}_i = \begin{bmatrix} -\cos \mathrm{El}_i \cos \mathrm{Az}_i \\ -\cos \mathrm{El}_i \sin \mathrm{Az}_i \\ -\sin \mathrm{El}_i \\ 1 \end{bmatrix}^\top . \quad (31.10)$$

User integrity is provided first by requiring users to exclude satellites for which corrections are not broadcast and is verified (or quantified) in real time by the user's calculation of *protection levels* in the position domain. These represent bounds on user position error at specific (very low) probabilities suballocated from the required loss-of-integrity probabilities for GBAS flight applications, including Category I/II/III precision approach. Protection levels are unique to each GBAS user

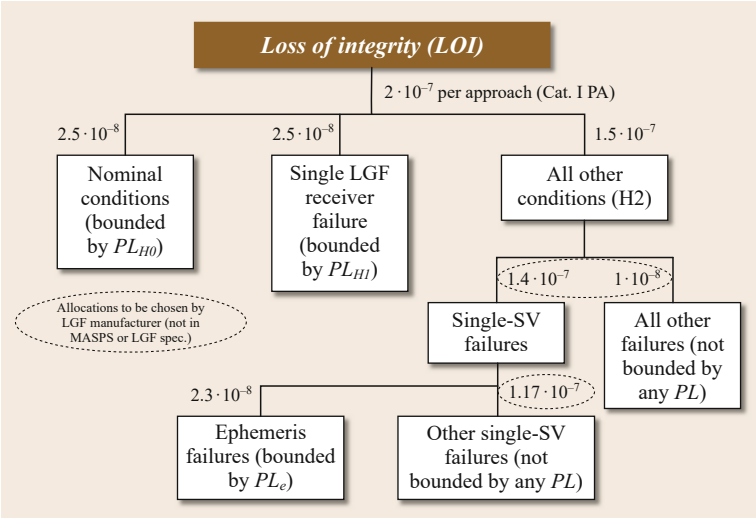

**Fig. 31.6** GBAS top-level integrity risk allocation for Category I precision approach

because they include user-specific error terms, for example $\sigma^2_{\text{pr_air}}$ in (31.8), and include only the intersection of the set of satellites tracked by ground and airborne receivers. By comparing protection levels computed in real time to the safe error limits (*alert limits*) for a given type of operation, they allow each user to determine if continuing the operation is safe or if the operation should be aborted.

In simple terms, protection levels are constructed by extrapolating bounding probability distributions of expected user errors to the suballocated integrity probabilities mentioned above. Multiple protection levels are defined as needed to account for specific failure conditions, and the final protection level applied by users is the maximum of the protection levels defined to cover specific conditions. Figure 31.6 illustrates how the overall integrity requirement for Category I (GBAS Approach Service Type GAST-C) GBAS is suballocated to a set of scenarios, some of which are assigned protection levels. The top-level allowed integrity risk from Table 31.1 is $2 \cdot 10^{-7}$ per approach. This is first subdivided into three categories: *H0*, *H1*, and *H2*. The first two of these are defined below and are covered by protection levels. The third, *H2*, represents all other conditions (not *H0* or *H1*) and includes satellite faults and atmospheric anomalies, which is why it receives the bulk (75%) of the integrity allocation. Within the *H2* category, faults of single satellites are separated out, and among these, ephemeris faults are distinguished and given a unique suballocation because they are covered by a specific protection level. The other single-satellite faults, along with multiple-satellite faults and all other faults not yet described, do not have protection levels assigned to them. Each ground-system manufacturer can allocate probabilities among the faults not specified to have protection levels, which provides some flexibility.

The simplest protection level is that which applies to nominal conditions, called the *H0 case* to represent the *default hypothesis* in GBAS. Nominal conditions mean that a zero-mean Gaussian distribution with the total (ground plus airborne) variance computed in equation (31.1) bounds the actual distribution of range errors to the required integrity probability. If this is the case and range-domain error bounding persists in the position domain (e.g., errors among different satellites are uncorrelated), the *H0* protection level for the vertical direction is [31.9]

$$\text{VPL}_{\text{Apr_H0}} = K_{\text{ffmd}} \sqrt{\sum_{i=1}^{N} s^2_{\text{Apr_vert},i}\sigma_i^2 + D_{\text{V}}} \,, \quad (31.11)$$

where $s_{\text{Apr_vert},i}$ is the vertical component for satellite $i$ from the matrix $\mathbf{S}$, which is the pseudo-inverse of the geometry matrix $\mathbf{G}$ and is computed from (31.9)

$$\mathbf{S} = (\mathbf{G}^{\top}\mathbf{W}\mathbf{G})^{-1}\mathbf{G}^{\top}\mathbf{W} \,.$$

$K_{\text{ffmd}}$ is a scalar multiplier that represents the required integrity risk under the fault-free scenario (it is about 5.8 for Category I GBAS), and $D_{\text{V}}$ is the difference in vertical position between 30 s-smoothed and 100 s-smoothed pseudorange solutions. Only 100 s smoothing is used in GAST-C for Category I, so $D_{\text{V}} = 0$. In GAST-D, 30 s smoothing is used in both ground and airborne positioning, but much of ground monitoring is still based on 100 s-smoothed pseudoranges. $D_{\text{V}}$ represents the position-domain difference of the two different smoothing times, which is sensitive to anomalous ionospheric divergence. Thus, (31.11) propagates

the bounding range domain error distribution into the position domain, extrapolates it to the appropriate suballocated integrity probability (via $K_{\text{ffmd}}$), and adds an estimate of ionospheric divergence in the position domain ($D_{\text{V}}$) for Category II/III approaches.

Two additional protection levels are defined that cover two specific failure conditions. The first is a failure of a single reference receiver that was not detected and excluded by MRCC within the ground system. This is known the *H1 case* and has the following protection level [31.9]

$$\text{VPL}_{\text{Apr_H1}} = \max\left(\text{VPL}_{\text{Apr_H1}}[j]\right) + D_{\text{V}} \,, \tag{31.12}$$

where

$$\text{VPL}_{\text{Apr_H1}}[j] = |B_{j,\text{Apr_vert}}| + K_{\text{md}}\sigma_{\text{Apr_vert_H1}} \tag{31.13}$$

$$B_{j,\text{Apr_vert}} = \sum_{i=1}^{N} s_{\text{Apr_vert},i} B_{i,j} \,. \tag{31.14}$$

Here, the B-values come from the broadcast products of MRCC as described before for satellite $i$ and reference receiver $j$, while $K_{\text{md}}$ is the scalar multiplier that represents the missed-detection probability needed to cover the *H1* fault scenario. As in MRCC, the B-values express the actual correction errors that would occur under each *H1* fault subhypothesis, and *H1* protection levels include this as a bias (converted to the position domain) that is added to nominal errors extrapolated to a suballocated probability for *H1* events after correction for the relative rarity of these events. To be used in this way, B-values must be for each ground receiver (up to $M = 4$ receivers) and satellite must be included in the broadcast message type 2 [31.8]. The $K_{\text{md}}$ values given in [31.9] assume a per-receiver failure value (for these purposes) of approximately $10^{-5}$ per approach; thus this value becomes a requirement on ground system design (in practice, continuity requirements on reference receiver failures are more constraining).

Note that $\sigma_{\text{Apr_vert_H1}}$ and $B_{j,\text{Apr_vert}}$ in (31.13) have already been converted into the position domain using the same approach as applied to (range-domain) $\sigma_i$ in (31.11). The range domain version of $\sigma_{\text{H1}}$ is slightly higher than $\sigma_i$ because the *H1* scenario has one fewer nominal reference receiver that contributes to the nominal vertical error distribution. In fact, (31.13) can be interpreted as the sum of the nominal error distribution from the nonfaulted measurements plus the bias due to the faulted measurement. In the *H1* scenario, this bias results from a (hypothetical) single reference receiver fault as measured by the B-values computed on the ground, but the same approach applies to all protection levels computed for fault hypotheses.

Note that one value of $\text{VPL}_{\text{H1}}$ is computed for each reference receiver $j$ (from 1 to $M$) in (31.13), and the maximum combined B-value over all $M$ reference receivers is applied in (31.13). This follows from the general approach of computing individual values for each scenario and taking the maximum (rather than a weighted average) to cover all of them.

The second failure condition with its own protection level models undetected satellite ephemeris faults [31.9]

$$\text{VBP}_{\text{Apr_e}} = \max\left(\text{VBP}_{\text{Apr_e}}[k]\right) + D_{\text{V}} \,, \tag{31.15}$$

where

$$\text{VBP}_{\text{Apr_e}}[k] = |s_{\text{Apr_vert},k}| x_{\text{air}} P_{k_x} + K_{\text{md_e_x}} \sqrt{\sum_{i=1}^{N} s^2_{\text{Apr_vert},i}\sigma_i^2} \,. \tag{31.16}$$

Here, $K_{\text{md_e_x}}$ is the scalar multiplier that represents the missed-detection probability needed to cover the ephemeris fault scenario, and $x_{\text{air}}$ is the horizontal distance between user and reference station (the geographic centroid of the reference receiver antennas is broadcast to users for this and other purposes). $P_{k_x}$ is a broadcast parameter that expresses the ground system's ephemeris detection capability in terms of the smallest spatial error gradient (for satellite $k$) that is assured to be detected with the required integrity probability. Therefore, the user remains potentially vulnerable to ephemeris faults that cause spatial error gradients at or below this level, and these must be accounted for by the ephemeris protection level. The inclusion of $x_{\text{air}}$ allows each user to apply its own distance from the ground station, which is important for a fault whose user impact increases linearly with separation.

Analogous equations are used in real time to generate lateral protection levels (LPLs), meaning protection levels in the lateral (cross-track) direction. During precision approach, the requirements on vertical protection level (VPL) are almost always more constraining and are thus the focus of offline requirements analysis.

Protection levels resulting from failure modes other than the two for which specific protection levels exist (e.g., excess acceleration from satellite clock, signal deformation, etc.) must be covered by the three protection levels that are defined. In practice, since the equations for *H1* and ephemeris faults are specific to those cases, the *H0* protection level must bound all of these events. Demonstrating that this is the case requires analysis and (in most cases) simulation of each fault type to generate the worst-case range-domain user errors resulting

from them and comparing these to the range-domain protection level implied by the *H0* scenario. *Worst-case* in this context means the failure subscenario that potentially causes the largest differential range error either without detection or with monitor detection within the ground system time-to-alert. A detailed methodology for addressing the results of failure simulations is given in [31.44].

### 31.3.5 Additional Threats: RF Interference and Ionosphere

The consequences of two additional threats have become apparent over time as GBAS prototype systems have been fielded in various places. Both of these threats were recognized and treated by the original design of GBAS ground and airborne equipment but have proven to be more severe than first thought.

#### RF Interference (RFI)

RFI, as described in Chap. 16 refers to the imposition of external RF signals onto received GPS signals at the ground station or users in a manner that either makes the GPS signals unusable or subtly makes them less accurate. Strong interference to GPS from individual transmitters has been discovered several times in the past and can prevent the use of GPS signals over wide areas [31.45]. These events are rare, but more common interference results from what are known as *personal privacy devices* or *PPDs*, which are low-power jammers designed to *protect the privacy* of their users by preventing the use of GPS for tracking and surveillance. They are most commonly fielded in vehicles and typically achieve an effective jamming range of meters to tens of meters. personal privacy devices (PPDs) are illegal to operate in most places but are relatively easy and inexpensive to obtain over the Internet. The variety of devices available for purchase and their illicit nature means that their actual performance is variable; thus some devices may affect GPS over several hundred meters rather than the much shorter distances needed to *protect* a single vehicle [31.46]. For this reason, they can be troublesome to GBAS ground stations sited near major roadways [31.47].

The potential impact of PPDs on GBAS ground stations became evident in 2009, when the newly-fielded Honeywell SLS-4000 LAAS ground facility (LGF) began initial operation at Newark International Airport (EWR) in New Jersey, USA. The layout of this ground system is shown in Fig. 31.7. The site chosen within the property assigned to Newark Airport was not ideal and was selected due to the lack of suitability of several other locations considered. As a result, the four reference receivers fielded at Newark are in almost a straight line with separations of about 100 m to make multipath errors among the antennas as statistically independent as possible. All four antennas are within 200 m of both lanes of the (very busy) New Jersey Turnpike (I-95). Several times a day, vehicles with strong PPDs passing by the airport would first make GPS unusable at one receiver, then the next, until service was lost (no valid corrections), and recovery from this condition took a significant period. The need to protect the integrity of the ground station measurements led to measurements being affected by PPDs to be excluded due to violations of one or more monitors, including the low-signal-power monitor, before the jamming became strong enough to prevent the receivers from making measurements [31.47].

Once this threat was evaluated and better understood, both physical and software changes were made to the Newark LGF (and other GBAS sites) to minimize the impact of PPD jamming. Software refinements to the monitors affected by PPDs and the EXM that handled monitor flags were key in preventing shutdown from PPD events while still protecting integrity. This was done by conservatively modeling the threat (from offline test data and RFI observations at Newark [31.46]) to determine the worst-case impact of several variations of refined monitor logic. The result was a validated means of tolerating the exclusion of two *jammed* reference receivers (out of four) for a brief period while still providing safe (albeit somewhat degraded) pseudorange corrections from the two *unjammed* ones. Since vehicles on the nearby roadway are almost always moving at speed, those with strong PPDs affect the revised LGF software but without bringing it to the *shutdown* point.

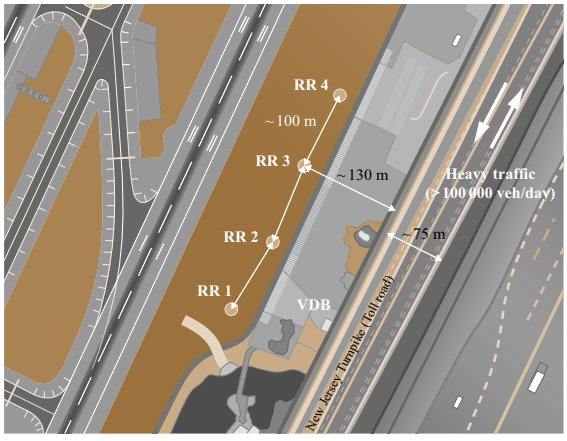

**Fig. 31.7** GBAS ground system siting at Newark Airport, NJ, USA. Note four reference receiver antennas in a line close to a busy freeway

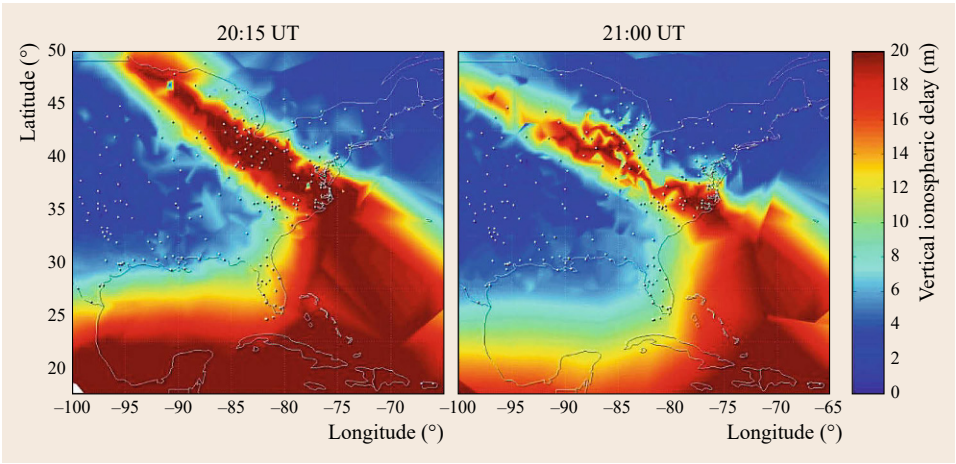

**Fig. 31.8** Large-scale ionospheric disturbance over CONUS on 20 November 2003 (after [31.51])

This experience with PPDs at Newark, along with other experiences of unintentional jamming affecting GBAS ground stations and aircraft (e.g., see [31.48] for the problems caused by an indoor GPS signal repeater broadcasting strong signals visible to landing aircraft), suggests changes in the way that future GBAS ground systems are fielded. First, if at all possible (though not possible at Newark), reference receiver antennas should be placed further away ($\approx 500$ m or more) from roadways with significant traffic, and they should be spread out further to prevent a single relatively weak jammer from affecting more than one reference receiver at a time. Future ground system designs will support larger antenna separations, but the limited real estate available for siting at many airports will remain a significant constraint.

### Ionospheric Spatial Decorrelation

Under normal conditions, the difference in ionospheric delay on smoothed pseudorange measurements made within 5–100 km of each other is a minor component of the total error budget for GBAS users and is conservatively bounded by the broadcast $\sigma_{vig}$ term used to compute $\sigma_{iono}$ in (31.8). In CONUS, the typical (1 s) spatial variation in zenith (i. e., vertical, at 90° elevation) ionospheric delay at the GPS L1 frequency is about 1 mm/km, and the value of $\sigma_{vig}$ used to bound ionosphere is 4 mm/km to add margin to cover days with high levels of ionospheric activity [31.49]. However, during strong ionosphere storms or other severe anomalies within the ionosphere, this value can grow much larger and can threaten GBAS user safety. Because each GBAS ground station views the ionosphere from one location on Earth and does not normally share information with other locations, an ionospheric anomaly can arrive at the vicinity of a ground station and potentially cause hazardous errors before it would be detected by GBAS ground and airborne monitoring.

The possibility of ionospheric spatial gradients large enough to be threatening was first discovered by analyses of Wide Area Augmentation System (WAAS) reference station data in 2002. In October and November of 2003, a very strong coronal mass ejection (CME) from the Sun created severe ionospheric anomalies that were noticed by WAAS and were analyzed after the fact by the continuously operating reference station (CORS) network of about 400 stations in CONUS at that time (now there are more than 1000 stations). Several years of WAAS and CORS observations in CONUS were collected and analyzed, with the result being a *threat model* that both describes the dynamics of these events from the GBAS viewpoint in simplified terms and provides bounding parameters on the variables in the model such that behavior outside the model is deemed to have negligible probability (see [31.50] for a general description of threat models and how they are used).

Figure 31.8 shows the ionospheric anomaly that generated the largest spatial gradients that have ever been discovered in CONUS or elsewhere in the middle latitudes (similar analyses have been done for Germany, Australia, and other locations). This occurred in the afternoon hours (local time) on 20 November 2003, during the period of coronal mass ejections mentioned above. In this figure, a zone of very high vertical ionosphere delay (in red) exists in between two zones of much lower delay (in blue). Thus, at the boundaries between the high and low-delay zones, very large spatial gradients occurred. The overall pattern of high delay moved roughly westward over time and eventually broke up into more irregular features, as shown in the plot for 21:00 Universal Time (UT) compared to 20:15 UT.

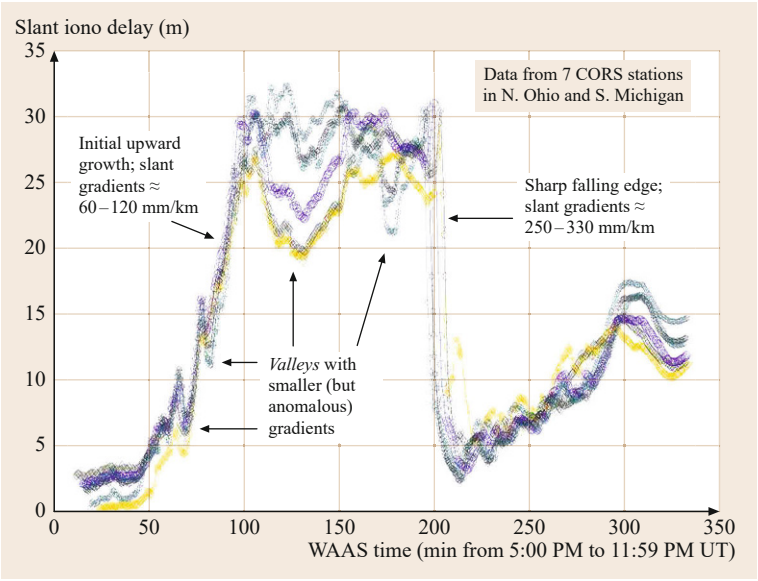

**Fig. 31.9** Change in ionospheric delay observed on SVN 38 at seven adjacent stations in CONUS on 20 November 2003 (after [31.51])

Figure 31.9 examines the event shown in Fig. 31.8 by plotting the slant ionospheric delay over time as observed by seven CORS reference stations located close to each other in Northern Ohio and Southern Michigan that are tracking the same GPS satellite (space vehicle number SVN 38). This shows the rapid rise in delay caused by the leading edge of the high-delay zone as it passed over. The resulting spatial gradients between these stations were very high (60–120 mm/km) compared to typical levels of 1–5 mm/km [31.49]. The observed ionospheric delays remained anomalous and unsteady during the period when the high-delay zone affected the measurements. When the trailing edge of this zone reached the measurements a little before 21:00 UT, a sudden, very large drop in delay appears at all seven stations, creating spatial gradients between the stations of as large as 330 mm/km. This same event caused gradients as large as 412 mm/km between other pairs of stations in Northern Ohio.

Based on observations of this event and several others that also created anomalous gradients (but not this severe), a threat model covering what was observed (and validated to be due to ionospheric events) was developed and is shown in Fig. 31.10 [31.51, 52]. This threat model provides bounds on the parameters of a simplified physical model of an ionospheric spatial gradient affecting a GBAS station and nearby users. This model, shown in Fig. 31.11, assumes that the gradient is generated by a constant, linear change in delay between high and low (or low and high) levels, and this gradient wedge is moving with constant speed relative to the ground. Example numbers that fall within the threat model bounds are shown in Fig. 31.11, but any

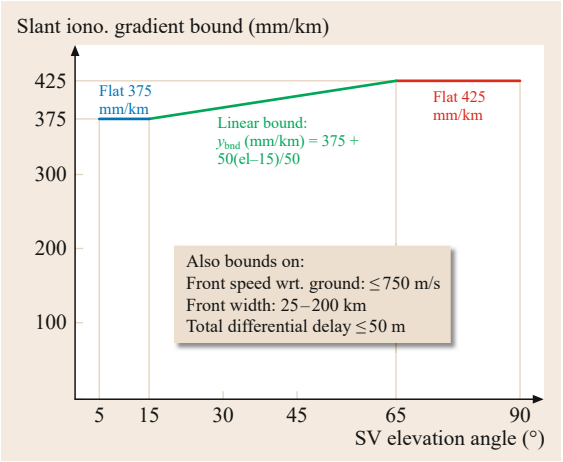

**Fig. 31.10** Ionospheric gradient threat model established for CONUS (after [31.51])

numbers falling within these bounds are deemed to be possible (credible); thus user integrity must be demonstrated against all permutations of parameters within the threat space.

Figure 31.10 shows the most critical threat model parameter, which is the maximum slant ionospheric spatial gradient as a function of satellite elevation angle. Based on observed data, it varies from 375 mm/km at low elevation angles to 425 mm/km at high elevation angles. Note that the latter number bounds the observed largest event of 412 mm/km with a small amount of margin for measurement error [31.52]. Other bounds are also listed, including the gradient propagation speed relative to the ground (no greater than 750 m/s, but smaller

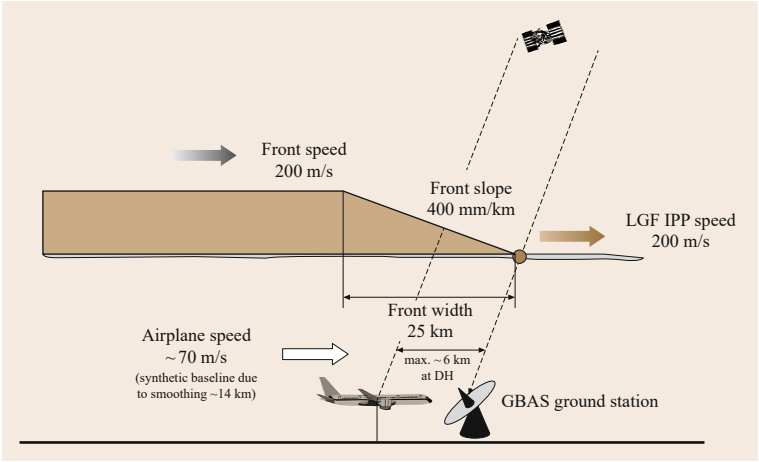

**Fig. 31.11** Simplified linear *wedge* model of ionospheric spatial gradient (after [31.51])

speeds are harder to detect and thus more threatening), the width of the zone in which the delay is changing (no less than 25 km), and a limit on the total differential delay (width times gradient) of 50 m. The limit on total differential delay means that some permutations of gradient and width that would otherwise fall within the threat model are eliminated because their product exceeds 50 m and thus are considered noncredible.

While the CONUS threat model is thought to cover all mid-latitude GBAS sites, regions outside CONUS should conduct their own data analyses to confirm that no larger gradients exist. If only smaller gradients are found, a less-conservative threat model bounded by these lower gradients could be used. However, because of the rarity of the events that cause extreme gradients and the low likelihood of observing very large gradients in a small geographic area, the use of the CONUS threat model of Fig. 31.10 is recommended for all mid-latitude regions that do not discover gradients exceeding it [31.53].

When the CONUS threat model is implemented as shown in Fig. 31.11 and then applied to GBAS, it is quickly evident that the worst-case user differential range error is very large. The (simplified) equation that relates ionospheric spatial gradients to user differential range error is given by [31.9, 49]

$$E_{\text{iono}} = F_{\text{PP}} \times g_{\text{v}} \times (x_{\text{air}} + 2t v_{\text{air}}) \,, \qquad (31.17)$$

where $E_{\text{iono}}$ is the resulting differential pseudorange error, $g_{\text{v}}$ is the ionospheric spatial gradient in vertical (zenith) terms, $t$ is the smoothing filter time constant (100 s for GAST-C GBAS), $x_{\text{air}}$ is the ground-to-user separation, and $v_{\text{air}}$ is the horizontal aircraft approach velocity (i. e., velocity of approaching the airport and the GBAS ground system). $F_{\text{PP}}$ is the standard ionospheric obliquity factor that converts between zenith and slant delay, but it is not needed here because gradients in the threat model are already expressed in *slant* ($g_{\text{s}}$) terms, where $g_{\text{s}} = F_{\text{PP}} \times g_{\text{v}}$.

Applying the maximum gradient ($g_{\text{s}} = 425\,\text{mm/km}$) with possible values of $x_{\text{air}}$ (6 km for very large airports) and $v_{\text{air}}$ (70 m/s is typical of jet aircraft) results in a (worst-case) differential error of 8.5 m on a single satellite, which is very large and would be difficult to handle with the existing VPL equations because these are compared to an alert limit of 10 m in the position domain (not the range domain). The vast majority of gradients approaching this size would be detected by one or more of the ground station monitors described in Sect. 31.3.3, such as the code-carrier divergence (CCD) monitor, that are sensitive to the time rate of change of ionospheric delay. However, it is possible for a gradient moving with respect to the ground to be counteracted by the motion of the satellite with respect to the ground, resulting in very little change of delay with time and thus very little to trigger the existing ground monitors.

Since very large differential range errors are possible and are not guaranteed to be detected by the ground station, a different technique for demonstrating the safety of Category I precision approaches under worst-case ionospheric conditions was needed. Two things resulted:

1. A relaxed requirement on the tolerable error limit (called TEL) based on the obstacle clearance surface (OCS) definitions for Category I precision approaches [31.54]
2. A new ground system integrity algorithm known as *geometry screening* that strategically inflates the broadcast VPL parameters (including the ephemeris decorrelation parameter $P$, $\sigma_{\text{vig}}$, and/or $\sigma_{\text{pr_gnd}}$) to ensure that any satellite geometries that could violate TEL are unavailable and thus cannot be used.

The procedures used to implement geometry screening in real time within GBAS ground systems are complicated and difficult to describe in simple terms. Detailed descriptions of two different approaches to the task are included in [31.55, 56]. The following summarizes the key steps in geometry screening:

1. Using the known set of approved satellites now and in the near future (e.g., the next 10 min), derive the set of possible user satellite geometries. This requires some assumptions on which subsets of satellites have been approved by the ground but may have been discarded (or unusable) by users (presumed to be approaching aircraft).
2. Using a simulation of the model in Fig. 31.11 with all possible satellite geometries, user approach geometries, and threat model parameters, determine the largest possible ionospheric-induced error in vertical user position (denoted as *MIEV*) for each possible user satellite geometry that would be deemed available by users (because the user VPL is below the normal Category I alert limit of 10 m). Note that MIEV also depends on the assumption of how many satellites can simultaneously be affected by the worst-case gradient (all combinations of two satellites are normally tested).
3. If MIEV exceeds TEL (about 28 m at the Category I approach threshold) for any possible user geometries, implement broadcast parameter inflation using trial increases of $P$, $\sigma_{vig}$, and/or $\sigma_{pr_gnd}$. Continue increasing a subset of these parameters until all possible user geometries become unavailable (VPL now exceeds the alert limit given the inflated broadcast parameters).

Implemented in this manner, geometry screening succeeds in protecting Category I GBAS users against worst-case ionospheric spatial gradients. Because of the conservatism involved in protecting each and every permutation of the threat combined with every possible user geometry, the result is significantly lower user availability. If geometry screening were not needed, GBAS Category I user availability would easily exceed 99% and might approach 99.9% at some airports. With geometry screening implemented based on the CONUS threat model and testing of all combinations of two satellites impacted at the same time, availability can fall below 99% for ground-to-approach-threshold separations of 1–3 km and below 98% for larger separations.

Given the lessons learned from GAST-C, the design of GAST-D GBAS to support Category II/III approaches implements several improvements to reduce the impact of anomalous ionospheric spatial gradients and improve the effectiveness of ground and airborne monitoring [31.57]. First, as mentioned above, GAST-D positioning is based on a 30 s smoothing time constant, which significantly reduces the possible differential range error per (31.17). Second, CCD monitoring is required in user equipment as well as within the ground system. This is advantageous because airborne users are moving relative to the ground and thus can detect gradients that the ground might be blinded to (and vice versa). Combined with the use of $D_V$ in the VPL calculations, this substantially increases the likelihood of detecting ionospheric divergence caused by anomalous spatial gradients.

Finally, GAST-D ground systems are required to implement new spatial gradient monitoring so as to guarantee that very large gradients that affect ground receiver will be detected regardless of any temporal *blinding* effects. To achieve this, differential carrier-phase test statistics between reference receiver antennas carefully sited to provide specific separations and directions of observability are needed. Several related algorithms have been proposed and are collectively called ionospheric gradient monitoring, or IGM [31.58, 59]. IGM is difficult to implement due to siting restrictions (see Sect. 31.3.6), small variations in reference receiver antenna errors that must be calibrated out to the extent possible, and the fact that even very large gradients only create small signatures over the short baselines used by IGM.

However, once IGM is implemented, it allows a large relaxation of the geometry screening required, and the remaining screening is done by each aircraft instead of within the ground system. Since each aircraft knows its own satellite geometry, the ground system need not cover all possible airborne geometries. That, combined with the reduced level of gradient that can escape undetected by IGM, leads to a significantly lower impact of geometry screening on precision-approach availability.

### 31.3.6 Equipment and Siting Considerations

Several aspects of ground system siting have already been discussed in previous sections. Siting focuses on choosing the best locations for the reference receiver antennas (to support monitoring while minimizing errors) and the VDB transmitter antenna (to cover the airborne user region with adequate, but not too strong, signal levels [31.8]). As noted above, reference receiver antenna siting follows these principles:

1. Where possible, separate the antennas by at least 100 m to minimize multipath error correlation among reference receivers, which weakens the ability of MRCC to mitigate individual receiver errors

(the residual correlation at each site should be estimated and accounted for).
2. Where short-baseline ionospheric gradient monitoring (IGM) is implemented to support GAST-D, antenna separations on the order of 150–300 m are needed [31.58, 59].
3. Where RF interference from nearby roadways or other sources is a threat, separate the antennas further to the degree possible to minimize the possibility of multiple receivers being affected simultaneously by the same interferer.

In addition, reference receiver antennas need to be located a sufficient distance away from nearby obstructions as to limit multipath errors to the bounding error models deemed acceptable from offline analysis. From years of trial-and-error and multipath error observations at several airports, siting guidelines to achieve this have been developed [31.60]. The concept of one or more *clear zones* that are free of significant multipath reflectors comes from the siting of ILS transmitters. An inner *clear zone* of perhaps 100–200 m in radius must be clear of all obstructions, including aircraft or other vehicles, while relatively small reflectors may be allowed in larger outer zones.

These guidelines take advantage of the use of multipath-limiting antennas, or MLAs, in GBAS ground systems. These devices go beyond normal GNSS antennas to establish a very strong roll-off between the gain pattern at low but positive elevation (where low-elevation satellites should be tracked) and low but negative elevation (which is the source of ground multipath). The first generation of MLA used in GBAS was a dual-element antenna with a helibowl facing toward zenith and a multi-element dipole for lower elevations that established the required gain roll-off. These two elements required two different receivers and *cross-over* software logic to combine their outputs into one *virtual* receiver for downstream GBAS processing [31.61]. The more-recent generation of MLAs uses a single multi-element dipole to track both high-elevation and low-elevation satellites [31.62], avoiding the need for two receivers per antenna and the resulting cross-over calibration. While not perfect, these antennas work very well in reducing both specular (single-reflection) and diffuse (multireflection) multipath to small levels that can be empirically measured and bounded by the broadcast $\sigma_{pr_gnd}$ as long as the above siting guidelines are followed.

One major advantage of GBAS siting with respect to ILS is that GBAS sites do not have to occupy specific locations near runway ends and that one GBAS ground station can support all runway ends. This benefit is limited by the need to find multiple *clear zones* and by the need to limit the separation between the geographic centroid of the reference receiver antennas and the landing thresholds of the multiple runways being covered. The effects of anomalous ionospheric spatial decorrelation, in particular, get worse with increased ground-to-user separation. While the *geometry screening* used to mitigate this threat for Category I approaches can support any separation, the resulting performance (availability) degradation becomes severe for separations greater than 4 or 5 km.

Finding sufficient space on airport property to site multiple reference receiver antennas while meeting both GBAS and external airport constraints is a challenge. At some airports, such as at Newark, the only possible locations may not meet all GBAS requirements. To account for this, GBAS can adjust several key performance parameters on a site-specific basis. One example is the broadcast $\sigma_{pr_gnd}$ values that bound the errors of ground-generated pseudorange corrections. Ideally, the same values (as a function of satellite azimuth and elevation) would be broadcast at all sites. However, sites with less-than-ideal multipath performance can adjust this model by broadcasting higher values in bins of azimuth and elevation where reference receiver multipath errors are greater (due to nonideal siting or any other cause). If the errors in certain bins are much higher than ideal, these bins can be *masked*, meaning that corrections are not broadcast for satellites that occupy these bins. *Masking* should only be applied to a small subset of azimuth bins at very low elevation angles (e.g., just above the 5° system elevation mask angle) to avoid significant user performance degradation.

### 31.3.7 Typical GBAS Errors and Protection Levels

Variants of GBAS that support Category I precision approaches are now fielded at many airports around the world. Most of these are at mid-latitude locations where ionospheric behavior is less severe and better understood, but several sites in equatorial locations (such as Rio de Janeiro, Brazil) have been fielded and are under study.

A good source for recent and near-real-time performance reporting from several GBAS installations is the William J. Hughes FAA Technical Center LAAS website [31.18]. The FAA Technical Center maintains its own LAAS ground station prototype at Atlantic City, NJ as well as providing data from commercial Honeywell SLS-4000 ground stations at Newark, NJ, Houston, TX, Moses Lake, WA, and Rio in Brazil. Using a web interface, it is possible to plot vertical and lateral user errors (based on a static *pseudo-user* antenna not far from the ground station) and vertical and

lateral protection levels at various distances from the ground system centroid and at the approach threshold for each runway supported by the system.

Figure 31.12 illustrates typical GBAS performance in CONUS by plotting vertical accuracy (measured by GBAS versus known from a survey) from the pseudo-user receiver sited near the Newark, NJ (EWR) and Houston, TX (Intercontinental, IAH) airport GBAS sites. These results are conservative because they are dominated by the error in the pseudo-user receiver, which is worse than a typical airborne receiver in that its antenna is on or near the ground and is not an MLA like the ground-station antennas. Even so, typical vertical accuracy is well within 0.5 m with only occasional excursions beyond 0.5 m. The magnitudes and patterns of errors at Newark and Houston are similar, suggesting that GBAS user performance is roughly the same for most mid-latitude locations. This level of nominal accuracy, combined with the *smoothness* of typical error variation (i. e., multipath-induced time correlation over a 150 s approach interval), provides approach guidance to aircraft that is objectively superior to that of ILS [31.63].

Both of these figures cover a week of measurements starting at midnight UT on 3 August 2014, and ending at midnight UT on 10 August 2014. The daily repetition of the pattern of errors is evident. This is due to multipath repeating every sidereal day (23 h 56 m), when the configuration of GPS satellites returns to the same locations in the sky. Since the position of the pseudo-user antenna relative to reflecting objects is also (mostly) fixed, multipath geometries approximately repeat every sidereal day and produce similar position errors. Significant exceptions to this rule occasionally appear. For example, an error spike just exceeding (negative) 1.5 m appears at Newark around 1600 Coordinated Universal Time (UTC) on 5 August that is not repeated on other days, and the same is true (with a smaller error) at Houston around 1600 UTC on 4 August. These unrepeated error spikes could have several causes but are most likely due to multipath from moving objects (including, possibly, aircraft moving near the pseudo-user antenna).

Figure 31.13 shows the computed GBAS vertical protection levels (VPLs) as estimated by the ground system at each of the runway ends supported by the Newark/EWR and Houston/IAH GBAS systems, respectively. Note that these plots cover only a single 24 h period of repeatable GPS satellite geometries on 3 August 2014. Because VPLs vary mostly with GPS satellite geometry, they will closely repeat from sidereal day to day.

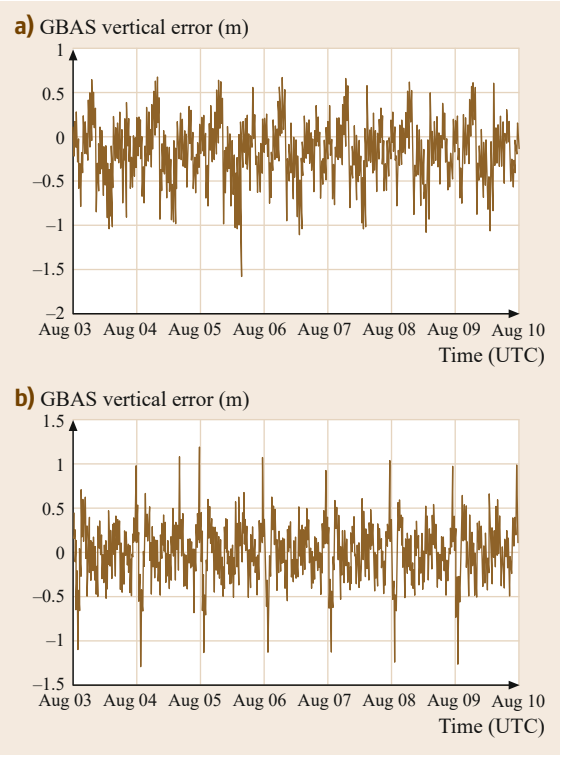

**Fig. 31.12a,b** GBAS vertical accuracy at Newark (a) and Houston (b) from 3–10 August 2014

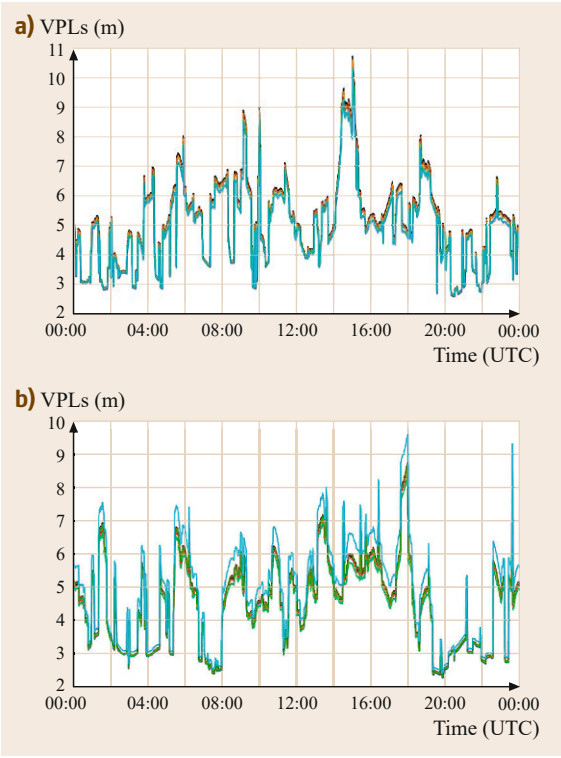

**Fig. 31.13a,b** GBAS vertical protection levels (VPLs) at Newark (a) and Houston (b) on 3 August 2014

The variation in VPL seen in these figures results partly from changes in the quality of the satellite geometry for positioning as measured by weighted vertical dilution of precision, or VDOP (Chap. 1) and partly from the deliberate inflation of $\sigma_{vig}$ as part of *geometry screening* to protect against worst-case ionospheric gradients (Sect. 31.3.5). VPL values above 7–8 m generally indicate the presence of significant $\sigma_{vig}$ inflation, which occasionally leads to brief losses of Category I precision approach availability when VPL grows to exceed the 10 m Category I VAL. As shown in Fig. 31.13a, this occurred at Newark/EWR for a brief period around 15:00 UTC for all five runway ends supported by GBAS. Since the degree of $\sigma_{vig}$ inflation is driven by satellite geometry rather than any particular knowledge of the ionospheric state, this condition will typically persist day after day until the satellite constellation itself changes (e.g., an unhealthy satellite is brought back into service).

### 31.3.8 Existing GBAS Ground Systems and Airborne Equipment

As noted above, GBAS ground and airborne equipment that supports Category I precision approaches has been certified and available for several years. The most prominent GBAS ground system on the market is the Honeywell *SmartPath* SLS-4000, which has been fielded at several sites in the US and Europe as well as Rio de Janeiro in Brazil and which generated the data shown in the previous section [31.64]. Other GBAS ground systems include the Thales DGRS 610/615 Reference Station and the NPPF Spektr LCCS-A-2000, which has been fielded at many airports within Russia [31.65].

On the airborne side, the first equipment to be approved for use with GBAS was the Rockwell Collins GLU-925 multimode receiver (MMR), which combines GPS/GBAS (sometimes denoted as *GLS* for *GPS-based landing system*) with ILS and microwave landing system (MLS) receiver components in order to support all sources of precision-approach guidance within a single unit [31.66, 67]. Honeywell (RMA-55B) and Thales (TLS-755) now also offer MMRs that are GPS- and GBAS-capable. Current equipment has only been approved for Category I precision approach, but the developing standards for GAST-D GBAS mentioned earlier provide a pathway to upgrade this equipment to Category II/III approach capability.

## 31.4 Augmentation via Ranging Signals Pseudolites

### 31.4.1 Origins and Use in Local-Area DGNSS

*Pseudolites* are terrestrial devices that transmit GPS or GNSS-like signals to nearby users in order to either enhance the performance of GNSS satellite users or completely replace the need for satellites. One of the first uses of pseudolites was to support the testing of GPS and user equipment functions during the very early days of GPS (the late 1970s), when no or very few satellites were in orbit [31.68]. By the early 1990s, as GPS user equipment became smaller and more portable, small and lightweight pseudolites also became practical and became a key component of early DGNSS systems.

One prototype DGNSS system aimed at providing centimeter-level accuracy (via carrier-phase DGPS) and integrity sufficient to support Category II/III landings was known as the integrity beacon landing system, or IBLS [31.3]. The layout of IBLS is shown in Fig. 31.14. Its most unique feature is the use of a pair of pseudolites (*integrity beacons*) sited along each approach path. These pseudolites broadcast weak, carrier-only GPS-like signals (received on antennas mounted on the bottom of the aircraft) that create a *bubble* through which each approaching aircraft flies. The rapid change in aircraft-to-bubble geometry created by this allows the aircraft to reliably resolve carrier-phase integer ambiguities to both the pseudolites and the GPS satellites. Carrier-phase receiver autonomous integrity monitoring (RAIM) at the aircraft is the primary source of integrity monitoring [31.69]. The nearby ground system provides pseudorange and carrier-phase corrections for both satellites and pseudolites but is not responsible for the degree of integrity monitoring described above for GBAS. The quality of pseudorange measurements can be much weaker as well – the primary need for

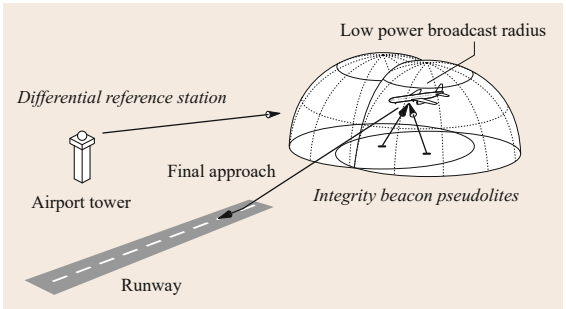

**Fig. 31.14** Integrity beacon landing system (IBLS) concept diagram

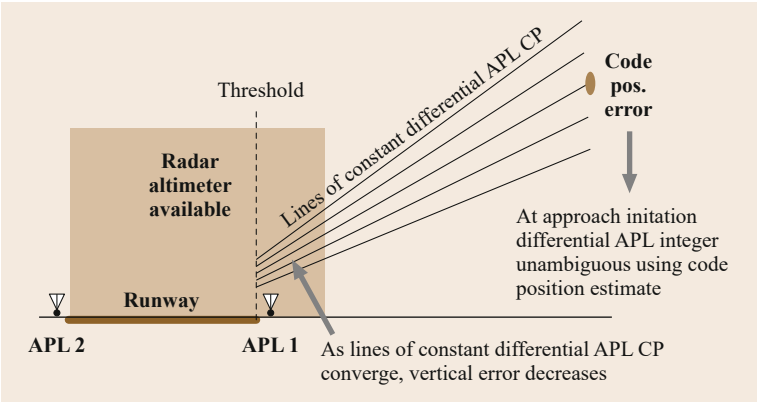

**Fig. 31.15** Intrack airport pseudolite (APL) concept diagram (after [31.10])

pseudorange accuracy is to ensure the reliability of the carrier-phase integer ambiguity resolution procedure.

While IBLS worked very well and was demonstrated by multiple aircraft flight tests in the early 1990s [31.3], its requirements for pseudolites along each approach direction (analogous to ILS) and its focus on verifying integrity at the aircraft rather than within the ground system made it unpopular with the FAA and other civil navigation service providers. The IBLS concept was modified to address these concerns in what was known as the *Intrack airport pseudolite* (*APL*) *landing system* that was demonstrated at Moffett Field Naval Air Station in the late 1990s. The Intrack airport pseudolite (APL) concept is illustrated in Fig. 31.15. It includes two pseudolites placed at both ends of each runway, but both runway ends are served rather than just one (approaches are supported from either direction). The pseudolites transmit GPS-like pseudorange and carrier-phase signals on unused PRN codes. Approaching aircraft can employ algorithms similar to those in IBLS but do not expect to resolve integer ambiguities. Instead, if *floating* integer values are utilized, the orientation of the two pseudolites along the direction of approach results in improved vertical position accuracy and integrity (where it is most needed), while lateral accuracy and integrity are unaffected. Airborne RAIM is included in this concept, but unlike IBLS, the focus of integrity monitoring is within the ground system that provides differential corrections.

While the Intrack-APL approach requires fewer pseudolites than does IBLS, the need for two pseudolites per runway was seen as excessive for a system that was to serve all runways and to be much easier to site than ILS. The advent of the specialized, multipath-resistant ground system antennas or *MLAs* as described above provided improved pseudorange accuracy and reduced the need for the improvements provided by the Intrack APL layout [31.61, 62]. As a result, the role of pseudolites in GBAS became that of an additional GPS-like ranging signal broadcast from the ground that was designed to fill in for occasional gaps in GPS satellite coverage. By the early 2000s, even this level of pseudolite augmentation seemed unnecessary, which is why pseudolites are not a feature of today's fielded GBAS systems.

### 31.4.2 New-Generation Pseudolite Systems for Commercial Applications

In recent years, pseudolite systems designed to more heavily augment (or even replace GNSS) satellites have been developed, particularly for applications where sky visibility is significantly restricted. Open-pit mining is one such application, as equipment operating on the floor of a deep mine is far below the ground's surface and may be unable to see a sufficient number of satellites above the walls of the mine to support accurate positioning.

One pseudolite system developed by Novariant, Inc. to address this scenario is known as *Terralite XPS* and is described in [31.2]. It transmits its own XPS ranging signals in the X-band, between 9.5 and 10 GHz, to avoid interfering with L-band and other commercial transmissions in industrial, scientific and medical (ISM) bands. The combination of XPS signals from multiple pseudolites and at least some L1 and L2 signals from GPS satellites supports three-frequency carrier-phase differential GNSS positioning with accuracies on the order of 10–30 cm. As with the pseudolite systems previously discussed, a differential reference station is needed to provide corrections (raw measurements, in this case) for the L1, L2, and XPS signals received at the reference station to all users. Integrity monitoring is provided within the reference station (along the lines of GBAS) to improve positioning robustness. The number of pseudolites fielded in and around the mine can be adjusted to achieve the needed visibility in the depths of the mine.

In the last several years, pseudolite systems designed to operate mostly or completely independently of GNSS satellites have been introduced. One example has been developed by Locata Corp. of Australia. It is based on individual *LocataLites* that are combined within a network (*LocataNet*) that synchronizes itself wirelessly, which in principle avoids the need for a traditional reference station. The LocataLites transmit on two separate frequencies in the 2.4–2.4835 GHz ISM band, with each frequency being transmitted on two PRN codes. While a LocataNet constructed of multiple LocataLites can be combined with GPS satellites, it is also capable of operating independently in places where GPS satellites are not available, such as indoors [31.70, 71].

## 31.5 Outlook

This chapter has summarized the key aspects of ground-based augmentation systems. The GBAS architecture is described in detail as an example of local area differential GNSS (LADGNSS) augmentation systems. Although most LADGNSS systems do not need to meet the integrity and reliability (continuity and availability) requirements of civil aviation as supported by GBAS, the hardware and software components of GBAS are good illustrations of what is possible with LADGNSS.

Fielding pseudolites to augment or even replace GNSS satellites has significant advantages for applications where GNSS-equipped users do not have a full and clear view of the sky. The advent of multiple GNSS constellations makes it possible to receive sufficient satellite signals even in obstructed locations, but there will likely remain scenarios where pseudolite augmentation remains worthwhile.

*Acknowledgments.* The author would like to thank the many people in government, academia, and industry who have contributed to the development of GBAS. The author would especially like to note the support of Per Enge and Todd Walter of Stanford, Boris Pervan of the Illinois Institute of Technology, Jiyun Lee of KAIST, John Warburton of the FAA William J. Hughes Technical Center, Tim Murphy and Matt Harris of Boeing, and Mats Brenner and Bruce Johnson of Honeywell. The research support of the US Federal Aviation Administration (FAA) over many years is greatly appreciated.

# 32. Space Applications

Oliver Montenbruck

Signals transmitted by global navigation satellite system (GNSS) satellites are not confined to the surface of the Earth but can likewise be used for navigation in space. Satellites in low Earth orbits, in particular, benefit from a similar signal strength and experience a full-sky visibility. On the other hand, the harsh space environment, long-term reliability requirements and the high dynamics of the host platform pose specific challenges to the design and operation of space-borne GNSS receivers. Despite these constraints, satellite manufacturers and scientists have early on started to exploit the benefits of GNSS technology. From the first flight of a Global Positioning System (GPS) receiver on Landsat-4, GNSS receivers have evolved into indispensable and ubiquitous tools for navigation and control of space vehicles.

Following a general introduction, the chapter first describes the specific aspects of GNSS signal tracking in space and highlights the technological challenges of space-borne receiver design. Subsequently, the use of GNSS for spacecraft navigation is discussed taking into account both real-time navigation and precise orbit determination. Relevant algorithms and software tools are discussed and the currently achieved performance is presented based on actual missions and flight results. A dedicated section is devoted to the use of space-borne GNSS for relative navigation of formation flying satellites.

The chapter concludes with an outlook on special applications such as spacecraft attitude determination, GNSS tracking of ballistic vehicles as well as GNSS radio science.

32.1 **Flying High** ..... 933
32.1.1 GNSS Tracking in Space ..... 934
32.1.2 Spaceborne GPS Receivers ..... 936

32.2 **Spacecraft Navigation** ..... 938
32.2.1 Trajectory Models ..... 939
32.2.2 Real-Time Navigation ..... 942
32.2.3 Precise Orbit Determination ..... 946

32.3 **Formation Flying and Rendezvous** ..... 951
32.3.1 Differential Observations and Models ..... 952
32.3.2 Estimation Concepts ..... 954
32.3.3 Ambiguity Resolution ..... 955
32.3.4 Flight Demonstrations ..... 955

32.4 **Other Applications** ..... 957
32.4.1 Attitude Determination ..... 957
32.4.2 Ballistic Missions ..... 958
32.4.3 GNSS Radio Science ..... 959

## 32.1 Flying High

Global navigation satellite systems such as GPS, GLONASS, Galileo and BeiDou are primarily designed to offer a worldwide positioning and timing service for ground-based, maritime and airborne users. It is obvious, though, that navigation signals transmitted from the high-altitude GNSS satellites are not just confined to the surface of the Earth and its atmosphere but spill widely into space and can likewise be received by Earth orbiting satellites.

Compared to conventional ground-based tracking systems, the use of GNSS receivers offers a wide range of benefits for spacecraft operations [32.1, 2]. GNSS tracking can provide an almost continuous coverage and is not limited to short contacts with a ground station. It offers high accuracy at favorable overall system cost and, most notably, enables an increased autonomy by providing navigation information on board a spacecraft rather than generating this information in an offline orbit determination process [32.3].

The potential benefits soon led to first experiments and flight applications of spaceborne GPS receivers. As early as 1982, a time when GPS comprised a mere five active satellites, the flight of the GPSPAC system on board Landsat-4 demonstrated the feasibility of GPS

signal tracking in space and applied such measurements for real-time navigation of the host satellite [32.4]. A decade later, but still well before the buildup of the nominal GPS constellation, the use of a six-channel dual-frequency receiver on board the TOPEX/Poseidon satellite opened the era of GPS-based geodetic-grade orbit determination [32.5, 6]. Extending the use of GPS beyond pure navigation applications, spaceborne radio occultation measurements could first be collected within the GPS/MET experiment on board MicroLab-1 in 1996 [32.7].

The present section discusses the specific constraints of GNSS signal tracking from a spaceborne platform. The visibility and link budgets as well as the signal dynamics experienced in various types of user orbits are first described. Subsequently, the impact of such conditions on the design of spaceborne GNSS receivers is described and an overview of present and upcoming receiver technology is provided.

### 32.1.1 GNSS Tracking in Space
