Most artificial satellites launched into space so far orbit the Earth in a low Earth orbit (LEO) with altitudes of about 200–2000 km and representative periods of 1.5–2 h. Orbits of this type are typically used for remote sensing and surveillance missions but also for various communication constellations such as Globalstar and Iridium. The geostationary Earth orbit (GEO) represent another popular type of orbits that is commonly used for telecommunication and weather satellites. At a distance of roughly 42 000 km from the center of the Earth the orbital period just matches that of the Earth rotation and a satellite appears stationary relative to the surface of the Earth when placed in the equatorial plane. Highly elliptical orbits (HEOs) that stretch from a point close to the Earth up to distances of multiple Earth radii may serve as transfer orbits from LEO to GEO but are also employed for scientific missions exploring the magnetosphere or carrying astronomical telescopes. GNSS satellites themselves are mostly operated in medium altitude Earth orbits (MEOs) with periods near half a day and an orbital radius of about 25 000–30 000 km.

As illustrated in Fig. 32.1, LEO satellites equipped with a GNSS receiver and a zenith-pointing antenna can typically enjoy a GNSS signal coverage that is close to that of a terrestrial user. The received signal strengths are likewise similar, since the altitude of a LEO satellite is generally small compared to the overall distance of the GNSS satellites. It may be noted, though, that the line-of-sight vector extends to larger boresight angles. While terrestrial GPS users remain within a boresight angle of about 14° at all times, a satellite at 1500 km altitude may experience peak boresight angles of close

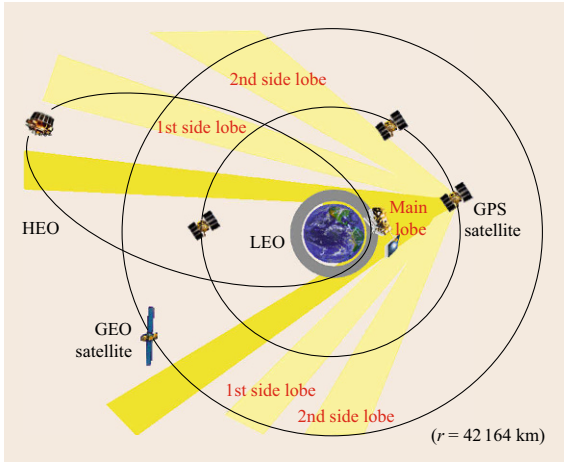

**Fig. 32.1** Schematic view of GNSS visibility conditions for LEO, HEO and GEO satellites

to 18°. Even though the transmit antenna gain may be reduced by up to 5 dB in such extreme cases, a LEO satellite always remains within the main lobe of the transmit antenna.

The situation is widely different, though, for HEO and GEO satellites, which even exceed the altitude of common GNSS satellites for most or all of their orbit. Here, GNSS signals can best be received when the transmitting GNSS satellite and the user are on opposite sides of the Earth (Fig. 32.1). For geostationary satellites, the distance from the transmitting GNSS satellite then amounts to almost 70 000 km. This results in large free-space losses and signal levels that are about 10 dB lower than for a terrestrial receiver. In combination with the limited beamwidth of the GNSS transmit antenna it becomes extremely challenging to simultaneously track the minimum of four GNSS satellites that would be required for an independent navigation fix.

While the problem will in part be alleviated by the future availability of multiple GNSS constellations that can be jointly tracked and used for navigation, the tracking of sidelobe signals is often proposed as an alternative. Sidelobes represent local maxima of the antenna gain pattern located at increasingly larger boresight angles. For GPS Block IIA and IIR satellites, first and second sidelobes occur near boresight angles of 30° and 55° but notable differences exist between the various antenna array types on top of strong azimuth variations (Fig. 32.2).

Various successful demonstrations of main and sidelobe signal tracking from spacecraft above the GPS constellation were made between 1997 and 2002 as part of the Falcon Gold experiment [32.9], the Equator-S [32.10] and AO-40 missions [32.11] as well as a nondisclosed GEO project [32.12]. More recently,

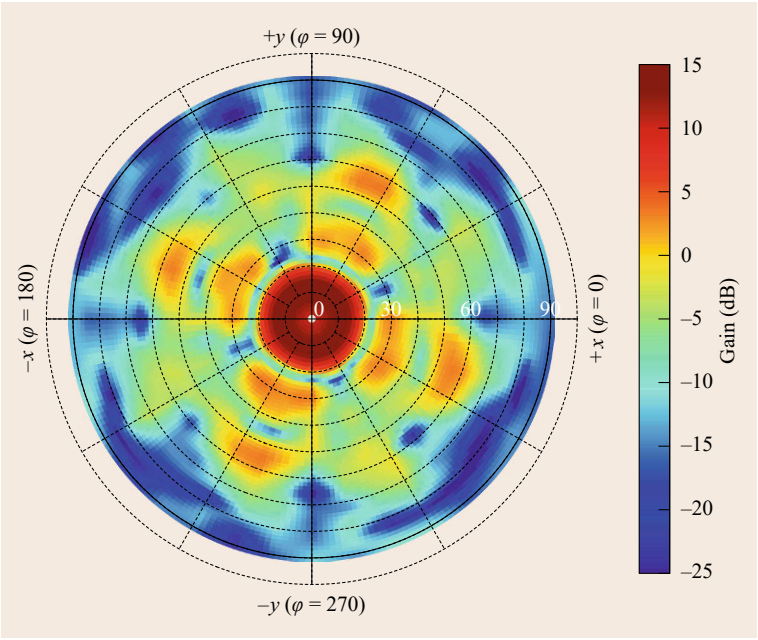

**Fig. 32.2** Gain pattern of GPS Block IIR-M transmit antenna on the L1 frequency. The polar plot shows the central main lobe as well as various sidelobes extending up to 60° (after [32.8])

successful sidelobe tracking has been demonstrated with the SGR-GEO receiver onboard the GIOVE-A (Galileo In-Orbit Validation Element) satellite [32.13] and the high-sensitivity navigator receiver on the Magnetosphere Multiscale Mission, MMS [32.14, 15]. It is evident, though, that neither the current GPS nor any other GNSS have been specifically designed with space applications in mind. However, the concept of a new Space Service Volume has been introduced along with the specification of the next generation GPS III satellites [32.16]. Here, minimum received signal levels, signal-in-space range errors and signal availability are addressed for spaceborne users covering altitudes of 3000–36 000 km.

Even though the early tests show that GNSS tracking at high altitudes is indeed feasible, the number of HEO and GEO missions proposing its use for navigation is still very low in view of the limited overall signal availability and performance. The remainder of this chapter is therefore limited to LEO missions where GPS is already widely employed today and new GNSSs that will be supported by the next generation of space receivers.

While link budgets and visibility conditions are generally favorable in such orbits, the tracking conditions are still quite different from those of a terrestrial or airborne user due to the high speed of the host platform. LEO satellites orbit the Earth with a representative velocity of 7.5 km/s and experience a line-of-sight range rate of up to 8.5 km/s when tracking a GNSS satellite (Fig. 32.3). At a wavelength of 0.2 m, a peak Doppler shift of ±45 kHz may thus be encountered that is almost ten times higher than for a static receiver on the ground. Likewise, much larger line-of-site accelerations (close to 15 m/s$^2$ or 75 Hz/s) are encountered in a circular low Earth orbit. Finally, the visibility period during which a GNSS satellite can continuously be tracked is typically limited to half an hour or less.

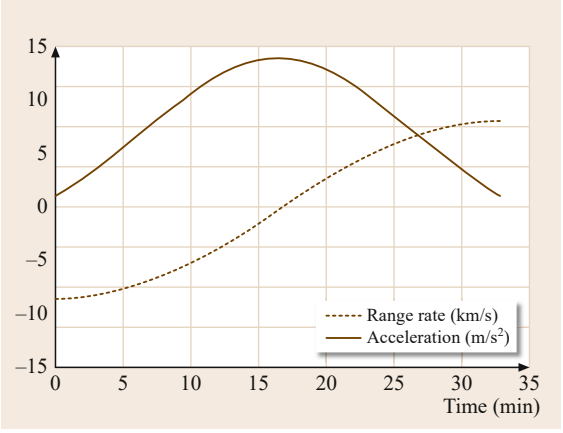

**Fig. 32.3** Representative line-of-sight range rate and acceleration for GNSS tracking from a LEO satellite

Spaceborne GNSS receivers need to cope with these conditions and require some adaptation to accommodate the higher signal dynamics and the rapidly changing set of visible satellites. As an example, particular care must be taken to accurately time-tag all observations. Even a microsecond offset would show

up as an along-track position error of about 1 cm. Furthermore, the tracking loops (Chap. 14) must be of adequate order to avoid steady-state errors due to line-of-sight accelerations. As a rule of thumb, third-order phase-locked loops (PLLs) have to be employed for carrier-tracking, while a carrier-aided first-order delay-locked loop (DLL) may be applied for tracking of the pseudorandom code. Concerning the initial signal search, the large range of possible Doppler results in a pronounced increase of the overall acquisition time compared to terrestrial receivers. When using a traditional sequential search, cold start times of up to 15 min may be required for GPS C/A code receivers in a low Earth orbit and even worse conditions would apply for Galileo E1 open service signals due to the increased code length and the more frequent bit transitions. To assist a rapid signal acquisition, a priori knowledge of the host vehicle position and velocity is therefore commonly employed. This may, for example, be obtained from a numerical or analytical orbit propagator along with a configurable set of orbital elements.

### 32.1.2 Spaceborne GPS Receivers

Even excluding the problems of high signal dynamics and specific visibility conditions, the design of spaceborne GNSS receivers (Fig. 32.4) poses notable challenges to their manufacturers. As for any kind of spacecraft electronics, a GNSS receiver intended for long-term operations in space needs to fulfill high reliability requirements despite the unique and partly hostile environmental conditions [32.17]. Key aspects that need to be taken care of in the design and premission verification of space hardware include the robustness against vibration during launch (which may cause physical damage to electrical and mechanical connections), the combined effect of temperature and vacuum (which limits heat dissipation and triggers outgassing of components), and finally space radiation.

The latter is of particular concern for the survivability in space and may affect space electronics in various ways. Ionizing radiation causes a gradual degradation and a continuously increasing power consumption, which ultimately limits the lifetime of the affected components. For satellites in low Earth orbit a total ionization dose (TID) tolerance of 10–20 krad is typically required, but substantially higher limits of up to 100 krad may apply for HEO and GEO missions. Single event upsets (SEUs) and single event latchups (SELs), on the other hand, represent an instantaneous failure of a component caused by the incidence of a high-energy particle. While SEUs (such as bit flips) represent a temporary error that can be overcome by a power cycling or reprogramming, a latchup destroys the affected circuitry on a permanent basis. In complementary metal oxide semiconductor (CMOS) devices, SEUs may arise from parasitic thyristors that are triggered by a short current spike upon incidence of a high-energy particle. Once activated, the thyristor acts as a persistent shortcut and may result in overheating unless the power supply is deactivated immediately [32.18]. Other than TID effects, which may in part be reduced by external shielding, SEUs and SELs require different means of compensation (redundancy, error detection and correction) or protection (rapid fuses, latchup immune semiconductor technology).

The various measures taken to ensure a high level of robustness against all aspects of the space environment will typically result in a higher mass and power consumption as well as a conservative performance of spaceborne GNSS receivers in comparison with their terrestrial counterparts. At the same time, the overall system costs are substantially higher due to the small manufacturing volume and the extensive test and validation effort required to guarantee the proper function in space.

For illustration, Table 32.1 summarizes key parameters for a variety of spaceborne GNSS receivers in current use or planned for upcoming missions in the near future. A portfolio of different receivers and antennas is, furthermore, shown in Fig. 32.4. In a trade-off between performance requirements and system cost, single-frequency receivers are commonly preferred for all types of platform navigation and timing applications. Use of dual-frequency GPS receivers, in contrast, is limited to remote sensing and science missions demanding a highly accurate reconstruction of the spacecraft orbit.

With few exceptions, all receivers available and used in orbit so far have been limited to GPS tracking. Chipsets supporting new signals and constellations are only slowly emerging in parallel with the buildup of the new navigation systems. As an example, the European Space Agency (ESA) has initiated the development of the AGGA-4 Advanced GPS/GLONASS Application specific circuit (ASIC), which offers a total of 36 channels and enables tracking of GPS, GLONASS, Galileo and BeiDou open service signals with binary phase-shift keying (BPSK) and binary offset carrier (BOC) modulation [32.19]. It supercedes the AGGA-2 correlator chip employed in most European high-end space receivers so far and enables more compact multi-GNSS, multifrequency receiver designs.

The high cost and restricted capability of most spaceborne GNSS receivers has inspired various efforts

to employ commercial off-the-shelf (COTS) technology as an alternative to fully space qualified hardware. Here, advantage can be taken of latest advancements in receiver technology, which is particularly attractive for satellite projects aiming at a high level of miniaturization. Following the pioneering work of Surrey University [32.20] the use of COTS components and GNSS receiver boards has therefore become increasingly popular in low-budget science and technology missions. Even though a dedicated qualification program will always be required to gain adequate confidence in the proper function and survivability of a given device, the use of COTS technology may well represent a favorable trade-off between performance, cost and risks. As an example, a geodetic-grade PolaRx2 dual-frequency GPS receiver has been employed for precise orbit determination of the TET-1 technology demonstration satellite [32.21] and a Triumph triple-frequency multi-GNSS receiver has been selected for the Atom Clock Ensemble in Space (ACES) experiment [32.22] on board the International Space Station (ISS).

The use of miniaturized aeronautical GNSS receivers has also become of interest for numerous university-class nanosatellites and was first demonstrated successfully within the CanX-2 CubeSat project [32.23]. Besides technical considerations, it must be kept in mind, though, that common export regulations [32.24, 25] for dual-use goods inhibit a free trade of GNSS receivers unless confined to use below a height of 18 km (60 000 ft) and a speed of less than 515 m/s (1000 nm/h). This inhibits a plug-and-play use of standard GNSS receivers on satellites or ballistic vehicles irrespective of signal dynamics or environmental conditions.

## 32.2 Spacecraft Navigation

GNSS-based orbit determination of spacecraft makes extensive use of well-established concepts and algorithms for terrestrial and airborne navigation. Except in the early days of GPS, when Selective Availability was still in place, an undifferenced processing was generally employed both for real-time and offline processing. All considerations of the GNSS observation and positioning model discussed in Chaps. 19 and 21 are equally valid for spaceborne navigation. Pseudorange-based single-point positioning (SPP) and carrier-phase based precise point positioning (PPP, Chap. 25) techniques can likewise be employed to obtain the instantaneous location of a space vehicle from observations of an onboard GNSS receiver with corresponding levels of accuracy.

As a fundamental difference, though, the free motion of a spacecraft under the dominant gravitational attraction of the Earth is not entirely indeterministic and prone to sudden changes, but highly smooth and predictable. Knowledge of the forces acting on a spacecraft enables prediction of its future motion from the current position and velocity. Other than a purely kinematic SPP/PPP-type positioning, which makes no use of prior information on the spacecraft motion, a dynamical orbit determination exploits this knowledge to reduce the overall number of estimation parameters in the adjustment process. Dynamical models act as a constraint for the estimated position of the host vehicle, which reduces the sensitivity to errors or an unfavorable geometry of the GNSS observations. In addition, they enable a prediction of the spacecraft trajectory through outages and periods of limited GNSS tracking.

While a purely kinematic orbit determination (or point positioning) is of interest for selected applications such as investigations of the Earth's gravity field [32.26, 27], dynamic orbit determination concepts are most widely applied today in view of their obvious benefits for robustness and accuracy. In view of the high precision of GNSS observations (specifically that of carrier-phase measurements) it may, however, be challenging or even impossible to model the spacecraft motion with an equal level of accuracy. The concept of reduced dynamic orbit determination [32.5, 6] was therefore developed early on, which presents a natural compromise between the extremes of a purely kinematic and a purely dynamic processing (Fig. 32.5). Here, additional force model parameters (known as empirical or stochastic accelerations) are introduced on top of the deterministic trajectory model and estimated along with other orbit and measurement model parameters. These empirical parameters can be constrained to the expected uncertainties of the a priori force model and allow the adjusted trajectory to better adapt to the true motion as sensed by the GNSS measurements.

Depending on the specific application, orbit models of varying complexity and detail, different estimation concepts as well as different strategies for the incorporation of empirical parameters are employed in the orbit determination process. Real-time onboard navigation and ground-based precise orbit determination constitute two representative examples that will serve to illustrate typical mission needs and practical solutions. Even though the boundaries between low-latency and high-accuracy applications are gradually removed,

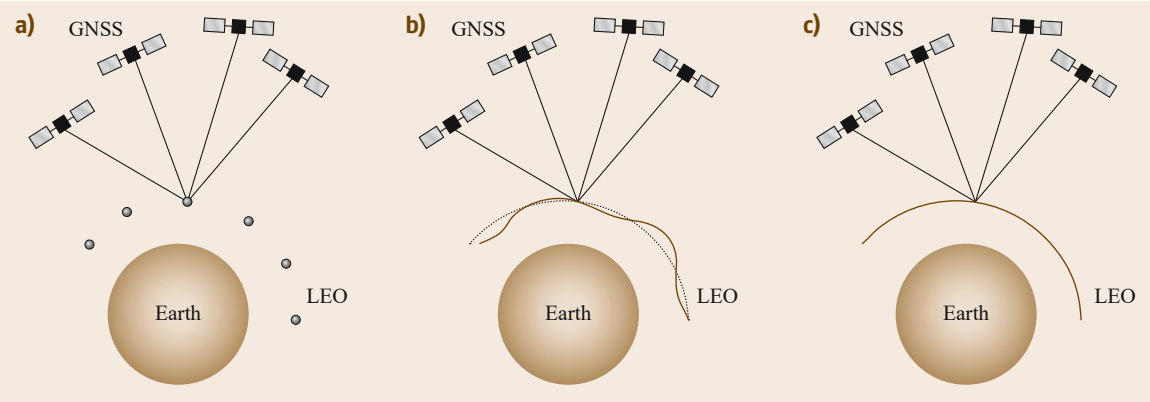

**Fig. 32.5a–c** GNSS-based precise orbit determination concepts for LEO satellites: (a) kinematic, (b) reduced dynamic, and (c) dynamic orbit determination

the two cases are well suited to highlight the relevant algorithms and concepts. Before going into a detailed discussion of these aspects, the modeling of spacecraft trajectories is reviewed that forms an integral part of any orbit determination process.

### 32.2.1 Trajectory Models

In its most general form, the orbital motion of a satellite as a function of time $t$ is described by a second-order differential equation

$$\frac{\mathrm{d}^2\boldsymbol{r}}{\mathrm{d}t^2} = \boldsymbol{a}(t, \boldsymbol{r}, \boldsymbol{v}, \boldsymbol{p}) \tag{32.1}$$

relating the change in position $\boldsymbol{r}$ to the acceleration $\boldsymbol{a}$, which in turn depends on time, position, velocity $\boldsymbol{v}$, and additional parameters $\boldsymbol{p}$. Equivalently, the equation of motion may be formulated as a first-order differential equation

$$\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t} = \boldsymbol{f}(t, \boldsymbol{y}) = \begin{pmatrix} \boldsymbol{v} \\ \boldsymbol{a} \end{pmatrix} \tag{32.2}$$

for the position-velocity (or state) vector $\boldsymbol{y} = (\boldsymbol{r}^\top, \boldsymbol{v}^\top)^\top$. With given initial conditions $\boldsymbol{y}(t_0) = \boldsymbol{y}_0$ and known accelerations $\boldsymbol{a}$, the state vector at any other time can then be determined from the analytical or, more commonly, numerical solution of this differential equation.

The equation of motion is complemented by the variational equations

$$\frac{\mathrm{d}}{\mathrm{d}t}(\boldsymbol{\Phi}, \mathbf{S}) = \begin{pmatrix} \mathbf{I} & \mathbf{I} \\ \frac{\partial \boldsymbol{a}}{\partial \boldsymbol{r}} & \frac{\partial \boldsymbol{a}}{\partial \boldsymbol{v}} \end{pmatrix} (\boldsymbol{\Phi}, \mathbf{S}) + \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \frac{\partial \boldsymbol{a}}{\partial \boldsymbol{p}} \end{pmatrix} \tag{32.3}$$

for the state transition matrix

$$\boldsymbol{\Phi}(t, t_0) = \frac{\partial \boldsymbol{y}(t)}{\partial \boldsymbol{y}(t_0)}\,, \tag{32.4}$$

which describes the dependence of the instantaneous state vector on the initial state, as well as the sensitivity matrix

$$\mathbf{S}(t) = \frac{\partial \boldsymbol{y}(t)}{\partial \boldsymbol{p}}\,, \tag{32.5}$$

which describes the dependence of the state vector on the force model parameters [32.28]. The partial derivatives provided by these matrices are required within the orbit determination process to establish the set of initial conditions and model parameters that best represents a given set of observations.

A variety of numerical integration methods for initial value problems are available in the open literature [32.28–30] and any of them can, in principle, be used for solving the equation of motion and the variational equations of a satellite orbit. However, there is hardly a single best method serving all applications needs. A key criterion for the selection of a suitable integration method is its order $n$, which characterizes the growth of errors in a single integration step. For an $n$th-order method the local truncation error is of order $\mathcal{O}(h^{n+1})$ in stepsize $h$ and the computed solution is such of similar accuracy as an $n$th-order Taylor approximation.

Single-step methods such as Runge–Kutta and extrapolation methods evaluate the derivative $\boldsymbol{f}$ in the equation of motion (32.1) at selected points within the interval $[t_i, t_i + h]$ to construct an approximation for the state $\boldsymbol{y}(t_i + h)$ from a given state $\boldsymbol{y}(t_i)$. Depending on the desired order an increasing number of function evaluations is required, which notably raises the computational effort of high-order methods. However, the increased effort is usually well compensated by the larger stepsizes that can be used. High-order methods are therefore preferable to cover large intervals

with a small total integration error. For stepsize control, approximations of different orders may be used to estimate the local integration error in a given step and to adjust the stepsize in accord with given accuracy requirements. Common implementations of these concepts include the Runge–Kutta–Fehlberg [32.31] methods as well as those of *Dormand* and *Prince* [32.29, 32].

Multistep methods compute a predicted value

$$\boldsymbol{y}(t_{i+1}) = \boldsymbol{y}(t_i) + \int_{t_i}^{t_i+h} \boldsymbol{p}_f(t)\mathrm{d}t \tag{32.6}$$

of the state vector at time $t_{i+1} = t_i + h$ from a polynomial approximation $\boldsymbol{p}_f(t)$ of the function $\boldsymbol{f}(t, \boldsymbol{y})$ at past epochs $t_i$, $t_{i-1}$, .... At the expense of storing information across multiple epochs, this concept ensures a high efficiency and facilitates the generation of high-order methods. As an added advantage, multistep methods enable a straightforward interpolation of the solution for dense output irrespective of the actual integration stepsize. Common classes of multistep methods include the Adams–Bashforth–Moulton method as well as Stoermer–Cowell and Gauss–Jackson methods. The latter types are particularly efficient for integrating the second-order formulation (32.1) of the equation of motion.

Multistep methods are most easily formulated when working with a fixed stepsize, but become increasingly complex when stepsize adjustments are desired. Also, a special starting scheme is required to establish the tableau of past function values upon initialization or restart of the integrator. Both aspects are readily covered by advanced implementations such as the variable-order and variable-stepsize Adams–Bashforth–Moulton method DDEABM of *Shampine* and *Gordon* [32.33] or the variable-step double-integration multistep integrator of *Berry* [32.34], which combines the efficiency of traditional multistep methods with the flexibility commonly attributed to single-step methods.

The choice of an integrator for orbit determination is largely tied to the type of estimation method used for the parameter adjustment as well as the interval between observations. Within a batch least-squares estimation the trajectory over the entire data arc is described by a single epoch state vector. Large stepsizes can be used to cover the entire data arc if the observations are sparse enough or if interpolation can be used to obtain the state at individual measurement epochs. Multistep methods appear best suited in this case and have been applied in various precise orbit determination packages such as GEODYN [32.35], NAPEOS [32.36], GIPSY-OASIS [32.37], or GHOST [32.38]. As an alternative, the Bernese software [32.39] makes use of the colocation method [32.30], which favorably combines the benefits of single- and multistep methods by constructing a Taylor approximation of the solution over a desired time step from the given initial conditions.

Real-time navigation in contrast will typically make use of low-order integration methods, since observations are processed in short intervals and since each measurement update in an extended Kalman filter mandates a restart of the trajectory integration [32.40]. This does not allow the exploitation of the large stepsizes supported by high-order methods and reduces their efficiency in this application. The well-known fourth-order Runge–Kutta (RK4) method provides a good compromise between accuracy and efficiency in this case and lends itself as a general purpose method for trajectory propagation in real-time navigation systems. As suggested in [32.29], the basic RK4 method can also be combined with the concept of Richardson extrapolation to obtain a fifth-order method requiring less function evaluations than a native fifth-order Runge–Kutta method. More significantly, however, the intermediate values computed in this process enable construction of an interpolating Hermite polynomial of consistent order [32.40]. This is particularly useful if high-rate orbit information is required for attitude and orbit control purposes or for geocoding of sensor data onboard the satellite [32.41].

Irrespective of the particular method chosen for the equation of motion, the quality of the dynamical model determines the accuracy of the orbit prediction over a given timespan or data arc. Again, a high-fidelity model is usually adapted in offline orbit determination, while simplicity may be favored in real-time navigation systems with limited computational resources or lacking access to auxiliary parameters such as Earth orientation angles or solar flux.

An overview of different accelerations acting on a satellite in low Earth orbit is given in Table 32.2 [32.28, 42, 43]. Similar to GNSS satellite orbits (Chap. 3), the motion of a LEO satellite is governed by the gravitational attraction of the Earth, even though the asphericity of the Earth gravity field has a much more pronounced effect at low altitudes. Generally speaking, the acceleration is described as the gradient $\boldsymbol{a}_{\mathrm{grav}} = \nabla V$ of the gravitational potential $V$, which is itself represented by a spherical harmonics expansion

$$V = \frac{GM_\oplus}{r} \sum_{n=0}^{\infty} \sum_{m=0}^{n} \frac{R_\oplus^n}{r^n} \bar{P}_{nm}(\sin\phi) \times \left[\bar{C}_{nm}\cos(m\lambda) + \bar{S}_{nm}\sin(m\lambda)\right] \tag{32.7}$$

in terms of geocentric distance $r$, latitude $\phi$ and longitude $\lambda$ as well as the gravitational coefficient ($GM_\oplus$) of

**Table 32.2** Representative values of accelerations acting on a LEO satellite

| Perturbation | Acceleration |
|---|---|
| Central gravity term | $8.5\,\mathrm{m/s^2}$ |
| Earth oblateness ($C_{2,0}$) | $15\,\mathrm{mm/s^2}$ |
| Aspherical gravity field | |
| $10\times10$ versus $C_{2,0}$ | $0.2\,\mathrm{mm/s^2}$ |
| $40\times40$ versus $10\times10$ | $30\,\mu\mathrm{m/s^2}$ |
| $100\times100$ versus $40\times40$ | $3\,\mu\mathrm{m/s^2}$ |
| Air Drag | $0.1\text{–}10\,\mu\mathrm{m/s^2}$ |
| Moon | $1\,\mu\mathrm{m/s^2}$ |
| Sun | $0.5\,\mu\mathrm{m/s^2}$ |
| Solid Earth tides | $0.5\,\mu\mathrm{m/s^2}$ |
| Solar radiation pressure | $50\,\mathrm{nm/s^2}$ |
| Ocean tides | $50\,\mathrm{nm/s^2}$ |
| General relativity | $20\,\mathrm{nm/s^2}$ |

the Earth and the normalized gravity field coefficients ($\bar{C}_{nm}$, $\bar{S}_{nm}$). The normalized Legendre polynomials $\bar{P}_{nm}$ and the trigonometric functions required for the evaluation of the gravitational potential and its gradient are best obtained through dedicated recurrence relations [32.44]. These offer a high level of computational efficiency and ensure the numerical stability required for use with models of high degree and order.

Gravity models in use today for satellite orbit prediction are themselves derived from geodetic satellite missions such as CHAMP, GRACE, GOCE and LAGEOS (see [32.45–47] and references therein). While some of these models are also augmented by surface gravity measurements to provide the highest possible resolution, the use of satellite-only models is generally fully adequate for satellite orbit modeling. The required degree and order depends on the envisaged modeling accuracy and may vary from $10\times10$ for simple onboard application to $150\times150$ for geodetic space missions with utmost accuracy requirements.

Aside from the Earth itself, a satellite is attracted by the Sun ($\odot$) and Moon ( ), to mention just the dominant solar system bodies. In a geocentric reference frame the associated third-body perturbation

$$\boldsymbol{a}_{\odot,\mathbb{C}} = \sum_{i=\odot,\mathbb{C}} GM_i \left( \frac{\boldsymbol{s}_i - \boldsymbol{r}}{\|\boldsymbol{s}_i - \boldsymbol{r}\|^3} - \frac{\boldsymbol{s}_i}{\|\boldsymbol{s}_i\|^3} \right) \tag{32.8}$$

is determined by the difference of the respective accelerations exerted on the satellite and the Earth itself. Here $GM$ and $\boldsymbol{s}$ denote the product of the gravitational constant and the perturbing body's mass as well as its geocentric position. The latter may be obtained from precomputed solar system ephemerides or analytical series expansions [32.28]. Given the proximity of a LEO satellite to the center of the Earth in comparison with the Sun-Moon distance, the two terms within the bracket in (32.8) are of almost similar magnitude and cancel except for a small tidal acceleration that grows almost linearly with the satellites distance from the Earth.

Among the nongravitational accelerations, atmospheric drag is often the most pronounced perturbation on a LEO satellite, particularly when considering altitudes of 350–500 km. The perturbing acceleration is always directed opposite to the satellite's velocity $\boldsymbol{v}_{\mathrm{rel}}$ relative to the atmosphere. This results in a continued loss of orbital energy and a change of the along-track position that grows essentially quadratically in time. Even a small drag acceleration can thus result in substantial orbital perturbations. Aside from the surface-to-mass ratio ($A/m$), the acceleration

$$\boldsymbol{a}_{\mathrm{Drag}} = -\frac{1}{2} C_{\mathrm{D}} \frac{A}{m} \rho \, \|\boldsymbol{v}_{\mathrm{rel}}\| \, \boldsymbol{v}_{\mathrm{rel}} \tag{32.9}$$

depends on the atmospheric density $\rho$, which may vary by several orders of magnitude within the relevant altitude range. Here, the drag coefficient $C_{\mathrm{D}}$ accounts for the dependence of the drag acceleration on the body shape. It can, in principle, be obtained from computational fluid dynamics (CFD) calculations for a known satellite structure [32.48, 49]. In the absence of such models, approximate values of 2.0–2.3 are commonly adopted as a starting point and refined drag coefficients are adjusted within the orbit determination.

In parallel with an increasing number of space missions, continuous effort has been made since the late 1960s to develop suitable physical and numerical models for the atmospheric density and its variation with time, location and other input parameters. Popular models used for satellite orbit modeling include the Jacchia models (Jacchia-70 and later refinements), the *mass spectrometer* and *incoherent scatter* models (MSIS-86, NRLMSIS-00 [32.50]) and the *drag temperature models* (DTM-2009 [32.51], DTM-2012). The individual models offer a typical accuracy of 10–30% [32.52]. Atmospheric density prediction thus constitutes a major source of uncertainty in the modeling of low-altitude satellite orbits.

Independent of orbital altitude, satellites are subject to a second type of nongravitational accelerations caused by the momentum transfer of absorbed and reflected photons. Similar to atmospheric drag, the resulting acceleration depends on the surface-to-mass ratio and is thus most pronounced for satellites with large solar panels. At a mean distance of one Astronomical Unit (1 AU$\approx$ 149.6 km) the solar flux amounts

to roughly 1367 $\mathrm{Wm}^{-2}$ and the Sun exerts a pressure of

$$P_\odot \approx 4.56 \cdot 10^{-6}\,\mathrm{Nm}^{-2} \tag{32.10}$$

on a surface that absorbs all incident radiation.

In the most simple form, solar radiation pressure (SRP) can be described by a so-called cannonball model, where the perturbing acceleration

$$\boldsymbol{a}_{\mathrm{SRP}} = -\eta\, C_\mathrm{R} \frac{A}{m} P_\odot \left(\frac{1\,\mathrm{AU}}{\|\boldsymbol{r}_\odot\|}\right)^2 \frac{\boldsymbol{r}_\odot}{\|\boldsymbol{r}_\odot\|} \tag{32.11}$$

is always directed opposite to the Sun direction and scales with the inverse square of the distance $|\boldsymbol{r}_\odot|$ from the Sun. Since satellites may move within the shadow of the Earth (or Moon) for at least part of their orbit, the factor $\eta$ is used to model the overall illumination. It varies between 1 in full Sun light and 0 in total eclipse. The solar radiation pressure coefficient

$$C_\mathrm{R} = 1 + \varepsilon \tag{32.12}$$

depends on the reflectivity $\varepsilon$ and takes into account that the impulse transfer is twice as high for a fully reflecting surface as compared to full absorption. Typical materials exhibit reflectivities ranging from 0.2 (solar panels) to 0.9 (coated mylar foil) and an average $C_\mathrm{R}$ value of 1.3–1.5 is commonly applied with the cannonball model. For a more refined modeling, individual surface properties and orientations relative to the Sun direction need to be handled in the form of a box-wing model or even a full-featured ray-tracing computation [32.53]. Due to remaining uncertainties in the actual surface properties, it is common practice, though, to adjust at least a single scaling factor (e.g., $C_\mathrm{R}$) of the radiation pressure model as a free parameter within the orbit determination process.

Aside from the major constituents of the force model (Earth gravity, lunisolar gravity, drag, and radiation pressure) introduced above, a multitude of smaller gravitational and nongravitational forces need to be taken into account for high-precision modeling of LEO satellite trajectories [32.28, 42, 43]. These include solid-Earth, pole and ocean tides [32.54], post-Newtonian corrections to the equation of motion [32.30], as well as Earth albedo and thermal radiation effects [32.53]. A detailed discussion of these perturbations and their modeling is beyond the scope of this text and interested readers are referred to the aforementioned text books and articles.

Irrespective of the adopted modeling level and complexity, it frequently turns out that the real-world dynamics are not fully matched by the equation of motion. This is particularly obvious when working with high-precision observations such as GNSS and satellite laser ranging (SLR) measurements. It is therefore common practice to complement the deterministic a priori force model with empirical accelerations. These accelerations can then be adjusted within the orbit determination such as to best match the observations and the modeled trajectory under suitable constraints on the expected value and magnitude of the empirical parameters.

To facilitate their interpretation, empirical accelerations are typically parameterized in an orbital frame aligned with the radial ($\boldsymbol{e}_\mathrm{R}$), along-track ($\boldsymbol{e}_\mathrm{T}$) and cross-track ($\boldsymbol{e}_\mathrm{N}$) direction

$$\boldsymbol{a}_{\mathrm{emp}} = a_\mathrm{R}\boldsymbol{e}_\mathrm{R} + a_\mathrm{T}\boldsymbol{e}_\mathrm{T} + a_\mathrm{N}\boldsymbol{e}_\mathrm{N}\,. \tag{32.13}$$

In the most simple form, the individual components $a_i$ ($i = \mathrm{R}, \mathrm{T}, \mathrm{N}$) are treated as constants over a certain time of applicability. Alternatively, additional *once-per-rev* terms may be considered to account for perturbations that exhibit a harmonic variation with the orbital period. The resulting accelerations can then be described as

$$a_i = a_{i,0} + a_{i,\mathrm{c}} \cos u + a_{i,\mathrm{s}} \sin u\,, \tag{32.14}$$

where $u$ denotes the argument of latitude.

### 32.2.2 Real-Time Navigation

Use of GPS (or, more generally, GNSS) receivers onboard LEO satellites has become increasingly popular, since it offers position, velocity and timing information onboard a spacecraft and can therefore contribute to an increased autonomy. Common applications of GNSS-based orbit information include attitude control, geocoding of payload data, autonomous instrument and spacecraft operations as well as orbit control:

- Earth observation (EO) missions commonly require alignment of their instruments (e.g. cameras, altimeters, or light detection and ranging (LIDAR) sensors) with the nadir direction and the ground track. While star cameras provide highly accurate measurements of the spacecraft orientation, the resulting information is naturally referred to a celestial reference frame. Knowledge of the instantaneous position and velocity is thus required to refer the measured attitude to an orbital frame aligned with the nadir and flight direction [32.41]. Onboard position and velocity knowledge with accuracies of about 10 m and 1–10 cm/s is commonly required in EO mission specifications for attitude control support.
- Geocoding refers to the association of spacecraft instrument data (such as pixels within a camera image) with the corresponding geographic location.

Traditionally, it is performed on the ground after determining the spacecraft position (and attitude) with adequate accuracy. Onboard geocoding of payload data (or at least onboard orbit determination) reduces the necessary data processing within the mission control center and supports a direct downlink of preprocessed image products to users in remote locations. Since local terrain models that would be required for a rigorous geocoding are mostly substituted by approximate geoid models in onboard applications, orbit information at the 10 m level is generally compatible with the overall accuracy requirements.

- Onboard position information can further be used to perform autonomous instrument and spacecraft operations. Instead of time-tagged activation, a synthetic aperture radar (SAR) or other sensor may be activated once a required orbital position is reached [32.55]. In this way, the limitations of ground-based mission planning and the dependence on predicted orbit information can be overcome. Similar considerations apply for the operations of the satellite itself. As an example, the spacecraft may autonomously reorient itself and activate its transmitters for performing a data dump once it enters the visibility range of a ground station. Depending on the specific application, onboard orbit information with an accuracy at the 10–1000 m level will be required.
- Last, but not least, orbit information provided by a GNSS sensor can be used to autonomously control the orbital motion (such as the ground track or the equator crossing time) of a remote sensing satellite and to compensate orbit changes causes by atmospheric drag or other natural orbital perturbations [32.56]. A 10–100 m position knowledge is generally adequate for orbit control of individual satellites or a loose constellation. However, the maneuver planning cannot be based on instantaneous position and velocity measurements alone but requires a proper averaging and monitoring of orbital elements variations over timescales of multiple orbits or days.

The above discussion demonstrates that the standard positioning service (SPS) or open service (OS) performance of common GNSSs is fully adequate for the majority of onboard applications related to spacecraft and instrument operations. Even though the desired accuracy can, in principle, be delivered by a standalone GNSS receiver in low Earth orbit, a complementary navigation filter is usually foreseen to ensure proper robustness and continuity of the navigation information. This filter employs a dynamical model to reduce the inherent measurement noise, to provide orbit information between consecutive measurement epochs and to predict the orbit across periods of limited GNSS tracking. A reduced number of visible GNSS satellites may, for example, be encountered near the poles or during nonzenith pointing orientation of a spacecraft.

Depending on the overall system and redundancy concept, a navigation filter may reside inside the satellite's onboard processor or the GNSS receiver itself. While the former approach offers a great flexibility in the choice of receivers and facilitates handover between prime and backup units, a navigation system inside the GNSS receiver is often advantageous in terms of interfaces and the transferred amount of data. Filtered navigation solutions (of varying accuracy) are already provided by a variety of GNSS receivers (e.g., MosaicGNSS and Topstar3000, Lagrange; Table 32.1) designed specifically for spacecraft operations and platform support.

Generically speaking, a real-time navigation system employs an orbit propagator to predict the satellite orbit and the associated covariance between consecutive GNSS observations. These observations are then processed in a Kalman filter that blends the predicted state with the new measurement information. With each filter update, a new estimate of the current spacecraft position is thus obtained.

Even though the use of alternative filter concepts has occasionally been suggested for GNSS-based onboard navigation, the use of an extended Kalman filter (Sect. 22.5) is most common and fully adequate for the purpose. For typical time steps (of 1–30s), proper initial conditions and a reasonably accurate force model, a real-time navigation filter operates close to linearity. As such, filter concepts for highly nonlinear problems (e.g., the unscented or sigma-point *Kalman* filter, UKF [32.57]) do not offer relevant advantages that justify the increased computational effort within this type of application.

In the context of satellite orbit determination, the filter state $\boldsymbol{x} = (\boldsymbol{y}^\top \boldsymbol{p}^\top \boldsymbol{q}^\top)^\top$ is composed of the position-velocity vector $\boldsymbol{y}$ as well as other parameters that need to be adjusted within the estimation. These comprise force model parameters $\boldsymbol{p}$ (such as drag and radiation pressure coefficients or empirical accelerations) as well as measurements model parameters $\boldsymbol{q}$ (such as clock offsets and biases).

As discussed in Sect. 22.5, the extended Kalman filter is a recursive estimation scheme, which is continuously repeated as new observations are processed. Given the estimated filter state $\hat{\boldsymbol{x}}_{i-1|i-1}$ and its covariance $\mathbf{P}_{i-1|i-1}$ at epoch $t_{i-1}$, the corresponding values at the following epoch $t_i$ are obtained through combination of

a time-update step and a subsequent measurement-update step.

Based on the given position, velocity, and force model parameters at time $t_{i-1}$, the trajectory is first propagated by numerical integration of the equation of motion (32.2) to obtain the spacecraft state vector $\boldsymbol{y}_i$ at the subsequent measurement epoch $t_i$. The remaining filter parameters $(\boldsymbol{p}, \boldsymbol{q})$ are likewise propagated to the new epoch using the corresponding stochastic process models. Empirical accelerations, for example, may be treated as exponentially correlated random variables [32.58], in which case the predicted value

$$\boldsymbol{a}_{i|i-1} = \mathrm{e}^{\frac{t_i - t_{i-1}}{\tau}} \boldsymbol{a}_{i-1|i-1} \tag{32.15}$$

results from an exponential damping in accord with the correlation timescale $\tau$. For bias parameters, in contrast, constancy can be assumed and the propagated parameter matches the value at time $t_{i-1}$.

Complementary to the state propagation, the state transition matrix $\boldsymbol{\Phi}_{i|i-1} = \partial \boldsymbol{x}_i / \boldsymbol{x}_{i-1}$ for the combined filter state is formed. It comprises the state transition and sensitivity matrices of the position-velocity vector (which follow from the numerical integration of the variational equations (32.3)) as well as (less computationally intensive) blocks for the remaining estimation parameters. Overall, the time-update step of the extended Kalman filter yields the predicted state vector $\boldsymbol{x}_{i|i-1}$ along with the corresponding covariance matrix

$$\mathbf{P}_{i|i-1} = \boldsymbol{\Phi}_{i|i-1}\, \mathbf{P}_{i-1|i-1}\, \boldsymbol{\Phi}_{i|i-1}^{\top} + \mathbf{Q}_i \,, \tag{32.16}$$

where $\mathbf{Q}_i$ denotes the covariance increase due to process noise in the dynamical model.

Based on the difference between the actual measurements $z_i$ and the modeled observations $\boldsymbol{g}(\boldsymbol{x}_{i|i-1})$ an improved estimate

$$\hat{\boldsymbol{x}}_{i|i} = \hat{\boldsymbol{x}}_{i|i-1} + \mathbf{K}_i \left( z_i - \boldsymbol{g}(\hat{\boldsymbol{x}}_{i|i-1}) \right) , \tag{32.17}$$

of the state at time $t_i$ is obtained within the measurement-update step. The Kalman gain

$$\mathbf{K}_i = \mathbf{P}_{i|i-1} \mathbf{G}_i^{\top} (\mathbf{W}_i^{-1} + \mathbf{G}_i \mathbf{P}_{i|i-1} \mathbf{G}_i^{\top})^{-1} \,, \tag{32.18}$$

which provides a linear mapping of the innovation $z - \boldsymbol{g}$ to the state domain depends on the measurement covariance $\mathbf{W}_i^{-1}$, the Jacobian $\mathbf{G} = \partial \boldsymbol{g}(\boldsymbol{x}) / \partial \boldsymbol{x}$ of the observation model as well as the predicted state covariance $\mathbf{P}_{i|i-1}$. It is furthermore used to obtain the postmeasurement-update covariance

$$\mathbf{P}_{i|i} = (\mathbf{I} - \mathbf{K}_i \mathbf{G}_i)\, \mathbf{P}_{i|i-1} \tag{32.19}$$

of the estimated state, where $\mathbf{I}$ denotes the identity matrix. Together, $\boldsymbol{x}_{i|i}$ and $\mathbf{P}_{i|i}$ provide the necessary information for the subsequent cycle of the extended Kalman filter.

Concerning the practical use of (32.19), it is noted that symmetry and positive semidefiniteness of the resulting matrix may not be guaranteed in numerical computations with limited precision. This may result in a hard-to-identify source of filter divergence. More robust formulations of the filter equations (such as the UD-factorization [32.59] with upper diagonal factor U and diagonal factor D) have therefore been developed and are generally preferred in actual flight software.

The specific concepts and algorithms employed in a real-time onboard navigation system depend largely on the desired accuracy but also on considerations of processor load as well as software complexity, reliability and verification. In the most simple case, kinematic position fixes of a GNSS receiver are processed as observations within a Kalman filter estimating only the instantaneous position and velocity. The approach is well suited for use inside an onboard processor and can be employed in combination with arbitrary GNSS receivers. It requires a minimalistic measurement model and decouples the navigation filter from the intrinsic details of GNSS-based positioning. In particular, no clock-offset parameter needs to be estimated in the filter and no explicit knowledge of the GNSS satellite positions is required for the processing. Sample implementations of a GNSS-position filter are described in [32.28] and [32.41], where representative accuracies of 5 m have been achieved with a single-frequency GPS receiver. Even though the filter yields a smooth and predictable trajectory, it can only partly compensate for errors in the employed position measurements, which are affected by uncompensated ionospheric path delays and the limited precision of the broadcast ephemeris errors. Also, the simple navigation filter is unable to process observations when less than four GNSS satellites are tracked and the receiver is no longer able to provide a kinematic position solution.

Advanced real-time navigation systems will therefore process raw pseudorange and, optionally, carrier-phase observations within the measurement-update step. For pseudorange-only processing, the observation model is essentially the same as that of a standalone GNSS receiver. It comprises the modeling of the light-time corrected geometric distance between the receiver and the GNSS satellite based on broadcast ephemerides as well as receiver and GNSS satellite clock offsets (including relativistic clock corrections) and relevant group delays. Tropospheric corrections are obviously of no concern at orbital altitudes but ionospheric path delays need to be considered through a model of the

individual path delays unless a ionosphere-free linear combination of dual-frequency observations is employed. The *Klobuchar* model [32.60] used in terrestrial receivers is of limited value for use in low Earth orbit, since the peak electron density is typically at or even below the altitude of the receiver. As an alternative, the *Lear* model [32.61] may be employed, which describes the slant delay at elevation $E$ as the product $I = I_0 m(E)$ of the vertical path delay $I_0$ and a dedicated mapping function

$$m(E) = \frac{2.037}{\sqrt{\sin^2 E + 0.076} + \sin E} \,. \tag{32.20}$$

The vertical delay itself is rarely known in advance and may vary rapidly along the orbit. It should therefore be incorporated into the filter state and estimated together with other dynamical and measurement model parameters.

Pseudorange-based Kalman filters are commonly adopted for navigation systems inside a spaceborne GNSS receiver. They offer a reasonable compromise between robustness, accuracy and software complexity. For highest accuracy, however, the processing of carrier-phase observations is indispensable. The use of phase measurements requires the incorporation of bias parameters that need to be estimated in the filter state and (re)initialized, whenever a new satellite is allocated to a tracking channel or whenever a cycle slip is encountered. Outlier identification and rejection in a spaceborne carrier-phase navigation filter is often more difficult than in terrestrial applications (among others, due to rapid position changes and variations in the ionospheric path delays, but also due to limited computational resources) and often considered a potential risk for the overall reliability and robustness. Only limited flight experience is therefore available at present.

Following [32.62], the accuracy of a dual-frequency GPS navigation filter can be improved from roughly 1 m to 0.5 m (3-D root mean square [RMS] position error) when incorporating carrier-phase measurements in addition to code observations. The adopted filter design utilizes a fidelity force model including Earth gravity (up to degree and order 70) and lunisolar perturbations as well as drag and solar radiation pressure. Remaining force model deficiencies are compensated by empirical accelerations that are adjusted within the filter. Overall, the filter state

$$\boldsymbol{x} = (\boldsymbol{r}^\top \, \boldsymbol{v}^\top \, C_\mathrm{D} \, C_\mathrm{R} \, \boldsymbol{a}_\mathrm{emp}^\top \, cdt \, \boldsymbol{b}^\top)^\top \tag{32.21}$$

incorporates the host satellite position $\boldsymbol{r}$ and velocity $\boldsymbol{v}$, the drag and radiation pressure coefficients ($C_\mathrm{D}$, $C_\mathrm{R}$), empirical accelerations $\boldsymbol{a}_\mathrm{emp}$, the receiver clock offset $cdt$ and a vector of biases $\boldsymbol{b}$ representing the carrier-phase ambiguities of all tracking channels. For a representative 12-channel GNSS receiver, a 24-dimensional estimation state is thus obtained.

Evidently, the factor-of-two performance gain achieved by the incorporation of carrier-phase observation in addition to pseudoranges does not reflect the inherent precision of the respective measurements. In fact, the achievable real-time navigation performance is mostly limited by the quality of broadcast ephemerides, which exhibit representative signal-in-space range errors (SISRE) of 0.3 m (GPS Block IIF) to 1.2 m (GPS Block IIa) [32.63]. While the adjustment of bias states in the navigation filter can partly help to compensate the impact of slowly varying broadcast orbit errors [32.62], the broadcast clock quality remains a limiting factor for the performance of GNSS real-time navigation systems. For comparison, an onboard orbit determination accuracy of 0.1 m has successfully been demonstrated in the Doppler orbitography and radiopositioning integrated by satellite (DORIS) immediate orbit onboard determination (DIODE) system of the JASON-2 satellite, which employs Doppler measurements from ground-based radio beacons [32.64]. It can be shown, though, that a similar accuracy is readily achievable in GNSS-based navigation systems when using real-time clock corrections [32.62, 65]. These may, for example, be provided through dedicated communication links as in NASA's tracking and data relay satellite system (TDRSS) augmentation service for satellites (TASS [32.66]) or via dedicated GNSS services such as the Quasi-Zenith Satellite System (QZSS) centimeter level augmentation service [32.67] and the proposed Galileo commercial service.

Aside from dual-frequency pseudorange and carrier-phase observations, the filter concept described above can also be applied with a ionosphere-free combination of single-frequency observations. The GRAPHIC (group and phase ionospheric correction) concept was first proposed by *Yunck* [32.68] and has since then been employed for a variety of space missions with single-frequency GPS receivers. It makes use of the fact that ionospheric path delays affect code and phase measurements with opposite sign and cancel (to first order) when forming the arithmetic average

$$o_{\mathrm{GPH}(p,\varphi)} = \frac{1}{2}(p + \varphi) \tag{32.22}$$

of the measured pseudorange ($p$) and the corresponding carrier-phase measurement ($\varphi$). Due to the unknown carrier-phase ambiguity, the GRAPHIC observation is a biased measurement but exhibits only half the

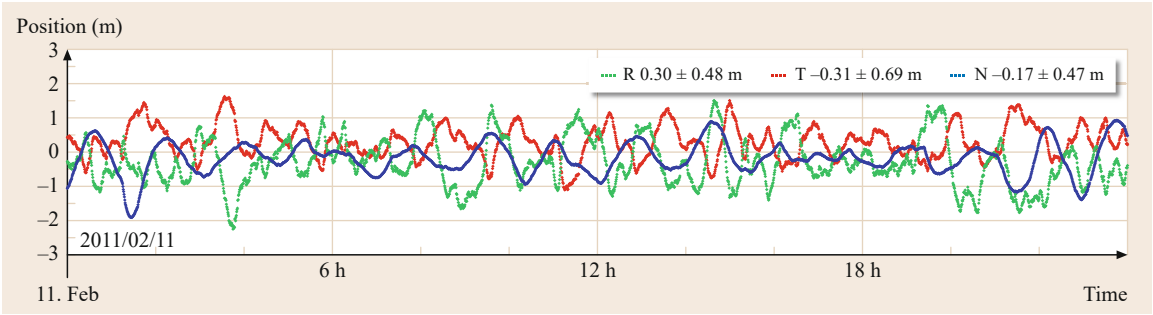

**Fig. 32.6** Real-time navigation performance of the Phoenix-XNS navigation system on board the PROBA-2 satellite in radial (R), along-track (T) and cross-track (N) direction

noise level of the pseudorange measurement. Similar to the ionosphere-free carrier-phase combination, the GRAPHIC measurement can be processed in a Kalman filter that adjusts the relevant ambiguities along with other estimation parameters.

As an example of an actual flight application, the performance of the Phoenix extended navigation system (XNS) on board the PROBA-2 spacecraft of the European Space Agency (ESA) is shown [32.69]. The XNS software is integrated into a miniaturized 12-channel GPS receiver and processes GRAPHIC observations based on L1 C/A code and phase measurements. As illustrated in Fig. 32.6 a steady-state accuracy of about 1.1 m (3-D root mean square (RMS) position error relative to a ground based precise orbit determination result) has been demonstrated in actual flight tests and an even better performance of about 0.7 m could be achieved in postflight analyses through use of current Earth orientation parameters and a refined filter tuning.

### 32.2.3 Precise Orbit Determination

Precise orbit determination (POD) commonly refers to estimation of a satellite's position and velocity with the highest possible accuracy. Other than real-time onboard navigation, POD is performed on the ground and can thus make use of the most elaborate processing schemes, powerful computer infrastructure, and the best available auxiliary data. Traditionally, latency is of less concern than quality. Delivery times up to several weeks are often accepted for the best and final POD solutions.

In much the same way as tracking systems and modeling techniques have been refined over the past decades, the notion of precision has likewise changed by several orders of magnitude. GNSS observations (as well as other techniques such as SLR or DORIS) enable orbit determination accuracies at the subdecimeter level on a routine basis and a 1 cm 3-D RMS position accuracy is within reach of the most advanced POD approaches. Along with that, processing times have decreased dramatically and high-quality orbit determination results can today be delivered with latencies of several hours and less.

The quest for ever-improved POD accuracies (Table 32.3) is mainly driven by the overall objectives and the specific instrumentation of scientific space missions:

- Synthetic aperture radar (SAR) missions commonly require position accuracies close to the instrument resolution (approx. 1 m) for SAR image generation [32.72]. These values mainly drive the need for near-real-time orbit determination. A (sub)decimeter accuracy, in contrast, is required for the less time-critical interferometric processing of images collected during repeated passes over the same scene as well as high-precision radar ranging applications [32.73].
- Altimeter missions determine the mean sea level from the known satellite position and measurements of its height above the ocean surface (Fig. 32.7a). For climatology, the sea level must be monitored with centimeter to millimeter level accuracy over decades, which requires a corresponding quality of the orbit determination [32.70]. Uncertainties of less than 1–2 cm in radial direction are therefore commonly required for altimeter missions [32.74].
- GNSS radio occultation (RO) missions (Chap. 38) monitor the troposphere by measuring the signal delay and the associated bending of the signal path when a GNSS signal traverses the Earth's atmosphere (Fig. 32.7b). The bending angle can be inferred from the difference of the observed Doppler shift and that of a fictitious straight-line signal. Knowledge of the along-track velocity with an uncertainty of less than 0.05–0.2 mm/s is therefore required [32.75]. This is roughly equivalent to a 5–20 cm position knowledge.
- For gravity missions, such as GOCE and GRACE, varying accuracy requirements arise from mission

**Table 32.3** POD requirements of selected science missions (R,T,N: radial component, along-track, cross-track component; 3-D: total error)

| Mission | Type | Near-real-time | Final |
|---|---|---|---|
| GOCE | Gravity | 0.5 m 3-D | - |
| TerraSAR-X | search and rescue (SAR) | 1 m 3-D | 10 cm 3-D |
| Sentinel-1 | SAR | 10 cm 3-D | 5 cm 3-D |
| Sentinel-2 | Optical | 1 m 3-D | - |
| Sentinel-3 | Altimetry | 8 cm R | 2 cm R |
| Jason-1/2 | Altimetry | - | 1.5 cm R |
| Metop-A | radio occultation (RO) | 0.1 mm/s T | |

and instrument operations (e.g., a subnanosecond time synchronization of two spacecraft within a formation). Furthermore, purely kinematic positioning solutions with accuracies of a few centimeters are commonly requested to support an independent recovery of low-degree and order components of the gravity field from the observed spacecraft motion.

In order to meet the most stringent accuracy requirements, GNSS-based precise orbit determination combines sophisticated dynamic models with the concepts of carrier-phase-based precise point positioning (PPP; Chap. 25). Even though double-differencing with respect to ground-based reference stations has been employed in early POD concepts (namely before the abandoning of selective availability in GPS), undifferenced approaches are almost exclusively employed today.

Except for troposheric path delays, which are of no concern at orbital altitudes, the GNSS observation model for LEO orbit determination considers the same terms and corrections as introduced in Chap. 19 for terrestrial and airborne applications. This includes the light-time modeling, relativistic clock and range corrections, phase center offsets and variations of the GNSS satellite and the receiving antenna, group and phase delays as well as phase wind-up effects. Since the dynamical model describes the motion of the center-of-gravity (COG) of a space vehicle, proper knowledge of its attitude and the location of the antenna reference point relative to the COG is a vital prerequisite for precise orbit determination. Given the fact that LEO satellites move by more than 7 m within a millisecond, a proper time-tagging of all measurements and a careful distinction between receiver time and GNSS system time (or the respective fundamental time scale used in the equation of motion) is, furthermore, required.

Most software packages for GNSS processing and LEO orbit determination (such as GEODYN [32.35], NAPEOS [32.36], or GHOST [32.38]) make use of a weighted least squares estimation scheme to adjust dynamical orbit parameters and GNSS observation model parameters within the orbit determination. While details vary among the different software implementations and configurations, a representative estimation parameter vector

$$\boldsymbol{X} = (\boldsymbol{T}^\top \boldsymbol{Y}^\top \boldsymbol{B}^\top)^\top \tag{32.23}$$

will comprise a vector

$$\boldsymbol{T} = (cdt_1, \ldots, cdt_{n_T})^\top \tag{32.24}$$

of receiver clock offset parameters for a total of $n_T$ measurement epochs, the dynamical model parameters

$$\boldsymbol{Y} = (\boldsymbol{r}^\top, \boldsymbol{v}^\top, C_\mathrm{D}, C_\mathrm{R}, \boldsymbol{a}^\top_{\mathrm{emp},1}, \ldots, \boldsymbol{a}^\top_{\mathrm{emp},n_\mathrm{A}})^\top \,, \tag{32.25}$$

which include the initial position and velocity vector (or equivalently a vector of six initial orbital elements), the drag and radiation pressure parameters, as well as a vector of empirical accelerations for a total of $n_\mathrm{A}$ intervals, and, finally, a vector of (float-valued) carrier-phase ambiguities

$$\boldsymbol{B} = (b_1, \ldots, b_{n_B})^\top \tag{32.26}$$

for a total of $n_B$ passes of continuous carrier-phase tracking.

Considering a 30 s sampling rate, approximately 3000 clock offset parameters have to be adjusted for a one-day data arc when processing observations of a single constellation. In a multi-GNSS orbit determination constellation-specific clock offsets or intersystem biases need to be adjusted at each epoch, which results in an associated increase in the total number of estimation parameters [32.76]. The number of empirical acceleration parameters employed in a LEO orbit determination depends on the quality of the dynamical model and may range from a small number of one-per-rev parameters in a highly dynamical POD configuration to a large set of piecewise constant accelerations in a reduced-dynamic approach. Considering, for example, one set of accelerations in radial, along-track and cross-track direction per 10 min interval (i. e., roughly 1/10th of the orbital period) about 500 acceleration parameters need to be adjusted in a 24 h orbit determination arc. The number of ambiguity parameters, finally, depends on the total number of satellites in a constellation and the number of orbital revolutions (assuming that each GNSS satellite is tracked once per orbit). Some 500 parameters per day are typically required for GPS-only tracking unless the dataset is affected by frequent cycle slips. For future multi-GNSS POD applications, the number of estimation parameters will again increase in accord with the amount of tracked satellites and constellations.

Given the large number of estimation parameters, the direct solution of the full normal equations using Gauss elimination, LU-decomposition, or Cholesky factorization would become fairly computation intensive. It may be noted, though, that the normal equations matrix (Fig. 32.8) is dominated by a sparse diagonal matrix related to the clock-offset parameter vector $\boldsymbol{T}$. This matrix can easily be inverted, which enables a pre-elimination of the respective parameters and yields

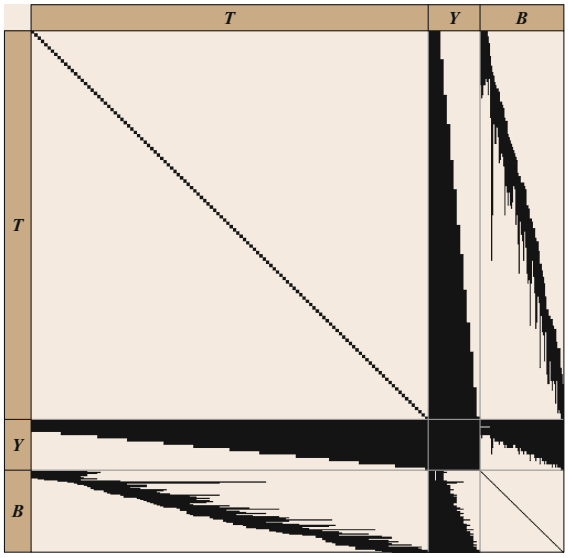

**Fig. 32.8** Representative structure of normal equations for GNSS-based precise orbit determination of a LEO satellite. *Light brown areas* denote cells with zero values

a reduced set of normal equations for the remaining dynamical ($\boldsymbol{Y}$) and ambiguity ($\boldsymbol{B}$) parameters and enables an efficient solution of the overall normal equations [32.77].

The estimation of piecewise-constant empirical accelerations is illustrated in Fig. 32.9, which shows the along-track accelerations required in addition to the a priori force model to best fit the GPS observations of the TerraSAR-X satellite during a one-day data arc in 2007. The acceleration is assumed to be constant within each 10 min interval. The observation residuals exhibit a standard deviation of about 7 mm for the ionosphere-free L1/L2 carrier-phase combination, which corresponds to a noise level of about 2 mm for the individual single-frequency phase observations. To achieve this goodness of fit, systematic phase pattern variations of the employed choke ring antenna (Fig. 32.4) have been corrected through a phase center variation (PCV) map (Fig. 32.10) derived from an inflight calibration.

Given the fact that GNSS-based precise orbit determination is itself one of the most accurate (and certainly the most widely used) techniques for measuring the position of a LEO satellite in space, it is inherently difficult to validate the performance that can actually be achieved. Other than in terrestrial PPP applications, where the analysis of time series for static monitoring stations enables a direct assessment of the positioning performance, there is hardly any truth standard for the motion of a space vehicle. Nevertheless, a variety of internal and external quality measures can be utilized

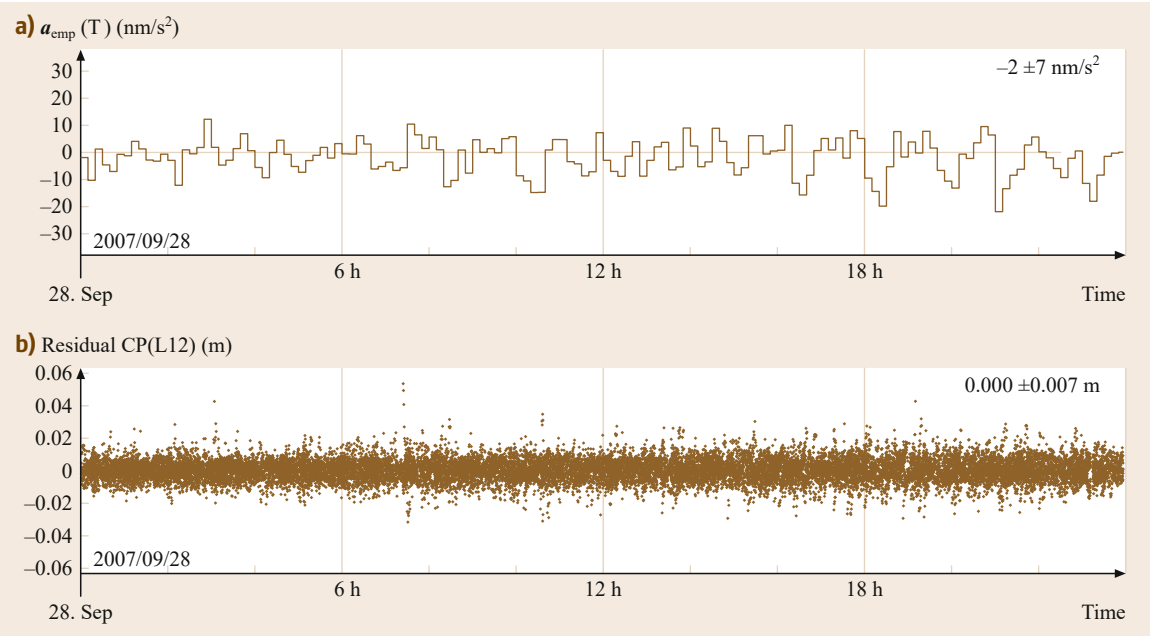

**Fig. 32.9a,b** Example of empirical accelerations compensating the difference between true and modeled dynamics for the TerraSAR-X satellite **(a)** and resulting carrier-phase residuals **(b)**

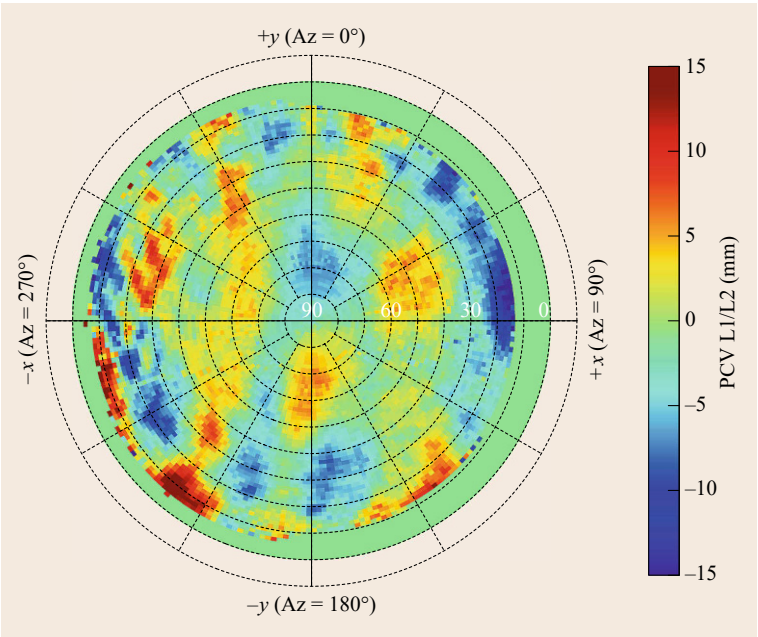

**Fig. 32.10** Phase center variations of TerraSAR-X POD antenna

to characterize the accuracy of a precise orbit determination solution. These provide good confidence that the specified performance (Table 32.3) can in fact be reached and even superseded.

In the absence of external comparison methods the achievable orbit determination quality can be assessed through various types of (self-)consistency checks. Within interagency comparisons the sensitivity of the resulting solution to the employed algorithms, processing standards and auxiliary data products can be evaluated using different software tools for a common dataset. Even though all solutions are based on the same

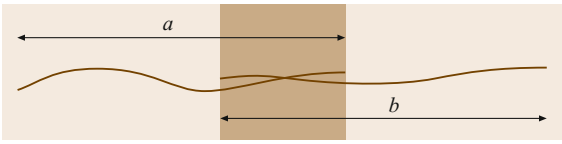

**Fig. 32.11** Overlap comparisons provide a measure of the self-consistency of two different orbit solutions $(a, b)$ within the common part of the data arc

**Fig. 32.12** Satellite laser ranging station of the Zimmerwald observatory (courtesy of Astronomisches Institut der Universität Bern)

GNSS observations, the resulting orbit solutions will hardly be identical due to different processing schemes and the resulting differences provide a fair measure of the overall accuracy. As an example, a 5 cm 3-D RMS consistency has been demonstrated for Metop-A orbit determination results obtained by five institutions using different software packages and different levels of dynamic versus reduced dynamic processing [32.78].

As an alternative, overlap comparisons are frequently used for quality control and performance assessments. Orbit determination solutions using different data arcs will usually differ when comparing epochs in the common overlap region (Fig. 32.11). Such differences are most pronounced near the start and tail of each POD solution and can be used as an overall quality measure. Overlap comparisons provide a good performance indicator in a highly dynamic orbit determination, but tend to be less representative of the true accuracy in a reduced dynamic approach. Here the solutions are strongly driven by the observations and tend to align to each other in the overlap region. For a more significant POD assessment, other validation methods are therefore desired, which are based on independent measurement systems of comparable accuracy or precision.

Among the external validation techniques, satellite laser ranging (SLR) represents probably the most universal and widely used method for assessing the quality of GNSS-based precise orbit determination solutions. SLR measures the turnaround time of short laser pulses and provides a highly precise and unambiguous measure of the distance between a satellite and the SLR station. The use of SLR stations (Fig. 32.12) for scientific space missions is coordinated by the International Laser Ranging Service (ILRS, [32.79]), which supervises the operation of 40–50 stations around the world and ensures a priority-based tracking of individual satellites.

As a fully passive system, a laser ranging reflector can easily be accommodated on the host satellite and is widely used in geodetic space missions. Even though SLR observations can also be used for orbit determination as a standalone measurement type or in combination with other observations, the available number of measurements is generally substantially lower than that of GNSS due to the sparse ground network and the much higher operational effort. For satellites equipped with geodetic-grade GNSS receivers it is therefore of primary interest as an independent validation tool. An example of SLR residuals relative to GNSS-based orbit solutions is shown in Fig. 32.13 for the GOCE gravity mission. Reduced-dynamic orbits for this mission have been computed by the Astronomical Institute of the University of Bern (AIUB) from dual-frequency GPS observations of the Lagrange receiver [32.80]. The SLR residuals exhibit a standard deviation of 1.5 cm and a mm-level bias, which demonstrates an excellent consistency of both tracking techniques and a GPS POD accuracy of about 2–3 cm.

Similar POD performances have been reported for the Jason-1 and -2 satellites. In addition to GPS and SLR, these satellites are also equipped with a DORIS (Doppler orbitography and radiopositioning integrated by satellite) receiver, that provides Doppler measurements relative to a global ground station network. DORIS observations can be used for independent or combined POD solutions and an excellent consistency is obtained for all three techniques, which demonstrates a 3-D accuracy of 2–3 cm [32.81]. For the radial component of the Jason orbits, which is of primary interest for altimetry, an accuracy of 7–9 mm has been determined in the comparison of GPS-based POD solutions with SLR observations, SLR/DORIS orbits and altimeter crossovers [32.82].

While the accuracies discussed above are certainly remarkable and largely fulfill present-day requirements, continuous effort is made to further reduce the error level of GNSS-based LEO orbit determination solutions. A joint adjustment of GNSS satellite orbits and multiple LEO satellites in a common orbit determination process with full ambiguity fixing is often considered as a means for improving both the overall accuracy and the reference frame tie, but has not been conducted so far in view of the excessive com-

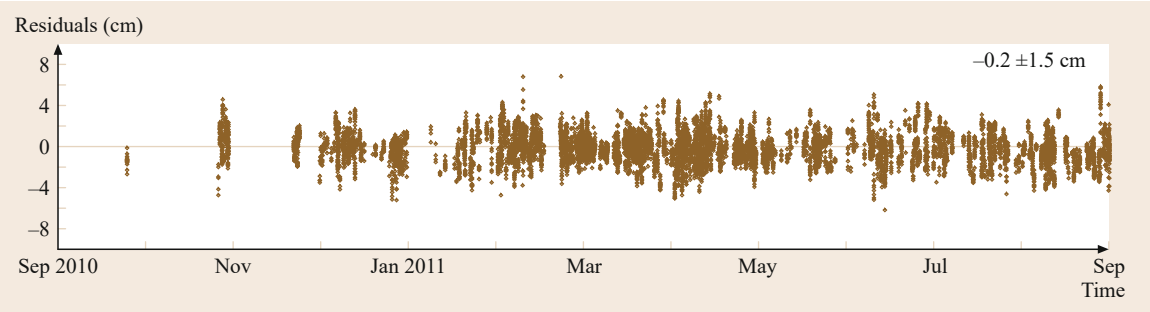

**Fig. 32.13** SLR residuals of Astronomical Institute of the University of Bern (AIUB) precise orbit determination solutions for the GOCE satellite (September 2010–August 2011)

putational effort. However, single-receiver ambiguity fixing concepts that are likewise employed in modern PPP concepts (Sect. 25.3.4), have been shown to provide a favorable alternative. Various approaches have been proposed that make use of dedicated GNSS clock products (so-called integer clocks [32.83]) or phase bias products [32.84] to convey the underlying network information but avoid the explicit use of ground-station observations within the POD process. Single-receiver ambiguity fixing has been shown to improve both the absolute and the relative accuracy of LEO satellite orbits in sample applications to the GRACE and Jason satellites [32.83, 84]. It also appears as a particularly promising technique for precise orbit determination of loose constellations with multiple satellites at baselines of hundreds to thousands of kilometers.

Complementary to accuracy, the timeliness of POD solutions is of growing interest in many remote sensing missions to enable a rapid release of science products and a quick-look data analysis. For GNSS-based precise orbit determination, the availability of sufficiently accurate low-latency GNSS orbit and clock data has long been a bottleneck in the generation of rapid POD solutions. Various institutions have therefore established independent ground networks and services (such as JPL's global differential GPS (GDGPS, [32.66]) system or ESA's ground support network (GSN, [32.85])) to meet the reliability and latency needs of dedicated space missions. More recently, similar products have also become publicly available as part of the International GNSS Service (IGS) real-time service (RTS, [32.86]). Even though the IGS does not offer a formal service guarantee, its products benefit form a large and highly redundant network infrastructure and are provided free of charge to its users. As shown in various studies [32.87, 88], advanced (near-)real-time GNSS orbit and clock products can nowadays be used to generate near-real-time LEO POD solutions that exhibit only a minor performance degradation compared to their final counterparts.

## 32.3 Formation Flying and Rendezvous

As discussed in the preceding sections, spaceborne GNSS receivers and PPP-style processing techniques have found a wide range of applications for the navigation of individual spacecraft. Depending on the level of effort and the algorithms involved, accuracies ranging from a few meters in real-time single-point positioning to several centimeters in precise orbit determination may be achieved. It has long been realized, though, that differential GNSS (DGNSS) would be a powerful tool for relative navigation of multiple spacecraft. Similar to terrestrial applications, various forms of common errors (such as ionospheric path delays as well as GNSS orbit and clock errors) are partly or fully eliminated when working with differential measurements over short baselines. Also, carrier-phase ambiguities can more easily be resolved among nearby spacecraft than in space-to-ground baselines, which require a detailed consideration of atmospheric path delays. Carrier-phase-based differential navigation of orbiting spacecraft can therefore offer an order-of-magnitude increase in (relative) accuracy compared to absolute GNSS positioning techniques (Fig. 32.14). Furthermore, high-precision relative navigation can also be achieved in real-time applications due the reduced dependence on GNSS ephemeris information.

Applications that can directly benefit from GNSS-based relative navigation include spacecraft formation flying as well as orbital rendezvous with cooperative targets. While formation flying aims at a long-term op-

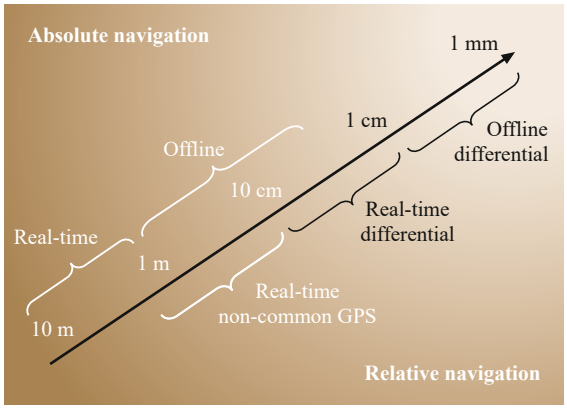

**Fig. 32.14** Comparison of absolute and relative positioning accuracies achievable in spaceborne GNSS navigation (after [32.89])

eration of two or more spacecraft in close proximity to achieve an advanced mission goal (such as gravimetry or interferometry [32.90]), rendezvous is usually a short-term activity but covers a wider range of relative distances. Accurate knowledge of the relative position and velocity is a prerequisite for both types of missions to properly control the motion of all participating spacecraft in accordance with the overall mission concept and the safety requirements [32.91]. Furthermore, precise relative orbit determination is often essential for achieving the primary science goals of a formation flying mission. In all cases GNSS recommends itself as an attractive navigation sensor in view of its performance, cost and onboard availability. Relative GPS has indeed helped to realize a variety of ambitious space missions, some of which will be highlighted in Sect. 32.3.4.

In accordance with earlier considerations, the subsequent discussion focuses on relative navigation in low Earth orbit, which offers the best GNSS visibility and coverage conditions. Even though formation flying and rendezvous are also discussed for high-latitude and even deep-space missions, such missions will typically make use of other types of radiometric or optical navigation sensors.

### 32.3.1 Differential Observations and Models

Spaceborne relative navigation using GNSS builds on well established differential GNSS processing concepts and combines these with knowledge of the (relative) orbital motion of the involved spacecraft [32.89].

Either single- or double-difference observations are most widely employed for spaceborne relative navigation (Fig. 32.15), even though it is also possible to take advantage of common error cancellation in properly formulated undifferenced navigation schemes [32.92]. In either case, proper synchronization of measurements collected by receivers on individual spacecraft in a formation is a prerequisite for high-accuracy processing. Due to the high velocity of LEO satellites, even a subtle 1 μs epoch difference would show up as a 7 mm offset in the along-track component of the relative position. This raises the need for continuous clock steering within the employed GNSS receivers (Table 32.1) and poses specific constraints on the hardware selection for formation flying missions.

Considering the relevant contributions to the pseudorange and carrier-phase model introduced in Chap. 19, the single-difference $(\Delta(\cdot)_{ab} = (\cdot)_b - (\cdot)_a)$ observations for two LEO spacecraft $a$ and $b$ tracking a common GNSS satellite $s$ can be described as

$$\begin{aligned}\Delta p^s_{ab} &= \left\|\boldsymbol{r}^i - \boldsymbol{r}_b\right\| - \left\|\boldsymbol{r}^i - \boldsymbol{r}_a\right\| + c\Delta dt_{ab} + \Delta I^s_{ab} \,,\\ \Delta\varphi^s_{ab} &= \left\|\boldsymbol{r}^i - \boldsymbol{r}_b\right\| - \left\|\boldsymbol{r}^i - \boldsymbol{r}_a\right\| + c\Delta dt_{ab} - \Delta I^s_{ab}\\ &\quad + (\lambda\Delta N_{ab} + \Delta\delta_{ab}) + \lambda\Delta\omega_{ij} \,.\end{aligned} \tag{32.27}$$

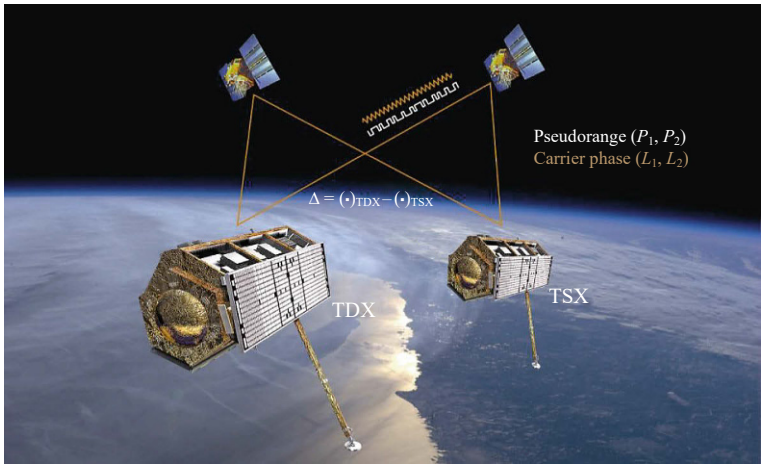

**Fig. 32.15** Differential GPS observations for relative navigation in the TanDEM-X formation flying mission. Artist's drawing (courtesy of P. Kuss based on images of DLR/NASA)

Here $\boldsymbol{r}^s$ and $\boldsymbol{r}_i$ $(i = a, b)$ denote the antenna position of the GNSS and LEO satellites at the signal transmission and reception time respectively, while $\Delta dt_{ab}$ is the single-difference of the receiver clock offsets. Differential ionospheric path delays $\Delta I^s_{ab}$, if applicable, affect both code and phase observations but in an opposite manner, whereas differential phase ambiguities $\Delta\lambda N_{ab}$, receiver phase biases $\Delta\delta_{ab}$ and wind-up effects $\Delta\omega_{ab}$ are only present in the carrier-phase observation model.

Single differencing between two receivers rigorously eliminates GNSS clock offset uncertainties, which constitute a primary error source in single-spacecraft real-time navigation. The impact of GNSS position errors (and, equivalently, user position errors) on the computed relative position scales with the ratio of the baseline and the GNSS satellite distance and is thus attenuated by a factor of 100–10 000 in common formation flying missions. Even in onboard applications with representative broadcast ephemeris errors and absolute position uncertainties at the 1 m-level, the impact of such errors on the relative navigation remains below the carrier-phase noise for formations of up to 20 km separation.

The magnitude of differential ionospheric path delays for two orbiting receivers depends largely on the spacecraft separation but also on the total electron content above the spacecraft. While various efforts have been made to employ model-based ionosphere corrections in spaceborne relative navigation, only very limited practical knowledge of the differential ionosphere at orbital altitude and its variation with spacecraft separation is yet available from actual space missions. In the absence of more accurate models, differenced versions of the *Lear* model [32.61] presented in Sect. 32.2.2 have been employed to extend the range of single-frequency relative navigation [32.93] or to assist dual-frequency ambiguity resolution in long-baseline applications [32.94].

For the most common altitude range of 400–800 km, between 10 and 50% of the terrestrial vertical total electron content (VTEC) may be expected above a LEO satellite. During a phase of close proximity, differential ionospheric effects exceeding a few millimeters have been observed at baselines of more than about 10 km [32.95] for the GRACE satellites in late 2005. This supports the common conception that single-frequency relative navigation neglecting ionospheric errors is adequate for narrow formations with baselines of less than a few km. On the other hand, a rigorous elimination of ionospheric errors through dual-frequency linear combinations is clearly required for precise relative navigation at baselines of a few hundreds of kilometers as employed in the routine operations of the GRACE mission.

Similar to single-satellite precise orbit determination, dynamical models of the spacecraft motion in a relative navigation process are necessarily referred to the respective centers of gravity. Proper knowledge of the GNSS antenna phase-center relative to the center of gravity and concise information on the orientation of the spacecraft in space is therefore required for lever-arm correction in the observation modeling. However, GNSS antennas on board a spacecraft are commonly affected by phase-pattern distortions, which are caused by the near-field environment and hard to assess in pre-flight testing on ground. These distortions may reach a level of several millimeters even for geodetic-grade choke ring antennas (Fig. 32.10). An inflight calibration of absolute or relative antenna phase patterns is therefore essential to fully exploit the accuracy of differential GNSS carrier-phase observations in demanding formation flying applications [32.96].

Finally, differential phase wind-up effects $\Delta\omega_{ab}$ need to be considered in the most general case of a measurement model for differential carrier-phase observations in spacecraft relative navigation. Such effects show up whenever the boresight axes of the receiving antennas are not aligned with each other and do not coincide with the instantaneous rotation vector of the host spacecraft [32.97]. This situation is commonly encountered in rendezvous and proximity operations with specific constraints on the relative pose of the involved vehicles but mostly avoided in remote sensing formation flying missions with parallel alignment of all spacecraft.

While the use of receiver-receiver differences immediately simplifies the GNSS measurement model for a pair of formation flying spacecraft and helps to reduce or even fully eliminate common errors, it is less straightforward to apply the same concept to the relative dynamics. Considering a purely Keplerian motion (i. e., assuming a point-mass Earth), near-circular orbits, and close proximity, the relative motion of two spacecraft can be described by the Hill–Clohessy–Wiltshire equations [32.42] as a superposition of periodic oscillations in radial, along-track and cross-track direction as well as a linear drift in the along-track axis that is proportional to the mean radial separation. Since both spacecraft experience almost the same perturbations due to the asphericity of the Earth and the lunisolar gravity, it is tempting to neglect the resulting differential accelerations in the description of the relative motion. Even though such simplifications are adequate for conceptual studies of formation flying or orbit control purposes, they are not well suited to describe the relative dynamics at a level of accuracy compatible with GNSS carrier-phase observations. Also, drag and solar radiation pressure forces are unlikely to match exactly

for both spacecraft even in case of a similar design (e.g., due to different fuel loading or attitude). It is therefore advisable to employ a rigorous description of the orbital motion, which explicitly models all perturbations acting on the individual spacecraft.

Considering a dual-spacecraft formation, a combined state vector $\boldsymbol{y} = (\boldsymbol{r}_\mathrm{a}^\top \boldsymbol{v}_\mathrm{a}^\top \Delta\boldsymbol{r}_\mathrm{ab}^\top \Delta\boldsymbol{v}_\mathrm{ab}^\top)^\top$ can be formed from the absolute position and velocity of one spacecraft (here $a$) as well as the relative position and velocity of the two spacecraft. The corresponding equation of motion is given by

$$\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t} = \begin{pmatrix} \boldsymbol{v}_\mathrm{a} \\ \boldsymbol{a}_\mathrm{a} \\ \Delta\boldsymbol{v}_\mathrm{ab} \\ \Delta\boldsymbol{a}_\mathrm{ab} \end{pmatrix} \tag{32.28}$$

and requires modeling of the absolute acceleration for the reference satellite as well as the relative acceleration acting over the baseline of the formation. Depending on the separation of the two spacecraft, the relative acceleration model may employ some simplifications (such as a neglect of higher-order gravity field terms) but would nominally correspond to the difference of the absolute acceleration models for the two spacecraft. In addition, it may incorporate relative empirical accelerations that are typically required to compensate small deficiencies in the a priori model of the relative dynamics. On the other hand, (32.28) is computationally equivalent to the combination of the single-satellite states provided that the individual equations of motion are jointly integrated with a common stepsize. The latter approach is often preferred in practice, because it ensures a fully symmetric treatment of all spacecraft and can easily be generalized to multisatellite formations.

### 32.3.2 Estimation Concepts

The navigation problem for two or more spacecraft in a formation can be formulated in a variety of manners. The specific choice of estimation parameters may vary widely among different implementations and does not necessarily match the formulation of the dynamical state vector used in the equation of motion. Depending on the mission and application needs, a navigation process may be confined to the estimation of the relative state vector of a pair of satellites [32.98, 99], the absolute state of one spacecraft while keeping the state of the reference spacecraft fixed [32.100], or the absolute states of all individual members of the formation [32.101, 102]. In either case, knowledge of the relative motion is primarily derived from differential GNSS (carrier-phase) observations, while information on the absolute motion of the entire ensemble is, optionally, provided from undifferenced single-satellite observations.

As discussed above, uncertainties in the absolute position of the reference spacecraft derived from a POD solution or a real-time navigation process are generally small enough to have negligible impact on the relative observation model. For all practical purposes it is therefore appropriate to keep the orbit of the reference satellite fixed at its a priori value and confine the estimation to the relative motion for each pair of satellites. In this way, the total number of estimation parameters can be minimized and the multisatellite adjustment can be partitioned into distinct estimation problems for the individual baselines.

In accord with the discussion of single-satellite navigation, extended Kalman filters are typically used for real-time onboard navigation systems, whereas the use of batch least-squares estimation techniques is confined to offline processing aiming at utmost accuracy. It may be noted, though, that an extended Kalman filter (EKF) filter/smoother approach has also been preferred by [32.99] for the precise baseline reconstruction of dual-spacecraft formations such as GRACE or TanDEM-X. Benefits of the EKF design in this application include a notably reduced dimension of the estimation state and the possibility to resolve carrier-phase ambiguities on an epoch-by-epoch basis.

By way of example, the estimation state vector adopted in this particular relative navigation filter comprises the relative position $\Delta\boldsymbol{r}$ and velocity $\Delta\boldsymbol{v}$, relative drag and radiation pressure coefficients ($\Delta C_\mathrm{D}$, $\Delta C_\mathrm{R}$), relative empirical accelerations $\Delta\boldsymbol{a}_\mathrm{emp}$ and the differential receiver clock offset $c\Delta dt$, where spacecraft-related indices $(\cdot)_\mathrm{ab}$ have been dropped for the ease of notation. For dual-frequency processing a differential ionospheric path delay $\Delta I^s$ as well as float-valued single-difference carrier-phase ambiguity parameters $\Delta A_j^s = \Delta N_j^s + \Delta\delta_j$ on both signal frequencies ($j = 1, 2$) are, furthermore, adjusted for each tracked satellite $s = (1, \ldots, n)$. Overall, a 48-dimensional estimation vector is thus obtained for a 12-channel, single-constellation GNSS receiver. For single-frequency processing, the channel-wise ionospheric delays are replaced by a single vertical path delay parameter, which is used along with the Lear mapping function to compensate the differential path delays. Furthermore, only a single set of ambiguity parameters needs to be adjusted, which reduces the estimation state to 25 parameters.

The choice of estimation parameters illustrated here is representative for a single-baseline filter but in no way unique. Alternative parameterizations are discussed in the literature given above for different formulations of the relative navigation problem. In particular, the extension of a traditional POD concept for

precise baseline estimation using least-squares estimation is discussed in [32.100].

### 32.3.3 Ambiguity Resolution

Similar to other carrier-phase-based positioning applications, the resolution of integer ambiguities represents a key to utmost accuracy in spaceborne relative navigation. It effectively converts the ambiguous carrier-phase observations into low-noise pseudoranges and thus enables a mm-level relative positioning. While relative navigation solutions using float-ambiguity estimation are typically confined to accuracies in the 0.5–1 cm range, an up to ten times better performance has indeed been demonstrated for ambiguity-fixed solutions [32.99, 100].

A detailed presentation of carrier-phase ambiguity resolution and validation is given in Chap. 23. The present discussion is therefore confined to specific and practical aspects of ambiguity resolution in GNSS-based relative navigation of formation flying spacecraft. This application differs from terrestrial and airborne relative navigation in various aspects that are of relevance for ambiguity resolution:

- Continuous carrier-phase tracking arcs for a receiver in low Earth orbit last for typically less than 30 min and changes in the set of tracked satellites occur once every few minutes. Overall, some 500 single-difference ambiguities arise in a one-day dataset making it difficult to apply existing best integer estimation schemes for a joint resolution of all ambiguities.
- Due to limited communication bandwidths or restricted onboard processing capabilities that inhibit more frequent filter updates, the effective measurement rate is typically much less than in common real-time kinematic (RTK) applications. Considering, for example, a 30 s sampling interval, a spacecraft in low Earth orbit moves by roughly 200 km between two observations. This induces notable variations in the differential ionosphere for long baseline formations and affects both ambiguity resolution and cycle-slip detection capabilities in an adverse manner.
- As a positive aspect, the orbital motion causes a notable change of line-of-sight directions between the receiver and the tracked GNSS satellites. This results in an improved observability of both the relative position and the float ambiguity parameters. Further constraints are provided by the orbital dynamics, if the employed relative motion model is of adequate accuracy. Both aspects can assist the ambiguity resolution unless counteracted by lacking knowledge of the differential ionospheric path delays.

In accordance with the properties of actual formation flying missions, ambiguity resolution has mainly been studied and applied for two extreme use cases. On the one side, narrow formations with baselines in the subkilometer range have been considered, where differential ionospheric path delays can essentially be neglected and relative navigation can readily be performed with single-frequency GNSS receivers. As shown in [32.98], ambiguity resolution can even be performed with a simplistic integer-rounding of float-valued double-difference ambiguities under these conditions. Large baselines of several hundreds of kilometers, in contrast, require use of dual-frequency observations and are substantially more challenging from an ambiguity resolution point of view. For batch least-squares estimation of the relative motion of the GRACE satellites, a bootstrapping approach has been adopted in [32.100]. Here double-difference wide-lane ambiguities are first determined based on the Melbourne–Wübbena combination of the dual-frequency observations, while the associated narrow-lane ambiguities are fixed from float ambiguity parameters estimated in the course of the relative orbit determination. As an alternative, the least-squares ambiguity decorrelation adjustment method (LAMBDA [32.103]) is employed in the relative navigation filter of [32.99], which implements a purely sequential processing scheme. Here, double differences are formed at each epoch from the single-difference float ambiguities estimated in the Kalman filter. A subset-fixing is then performed for reliably determined integer ambiguities. Both approaches have successfully been applied with actual flight data but depend on low-noise pseudorange observations to properly constrain the carrier-phase ambiguities in the absence of a suitable model for constraining the relative ionospheric path delays.

### 32.3.4 Flight Demonstrations

The use of GPS for relative navigation in space was first demonstrated in the mid-1990s as part of various rendezvous missions involving close approaches of the US space shuttle to free-flying payloads and the Russian Mir station [32.89, 104] and references therein). Most of these test campaigns were conducted in preparation for the European automated transfer vehicle (ATV), which makes use of GPS navigation during the far- and mid-range approach to the International Space Station (ISS) and conducted its maiden flight in 2008. Relative position accuracies of about 10 m and velocity accuracies of a few cm/s were achieved for ATV

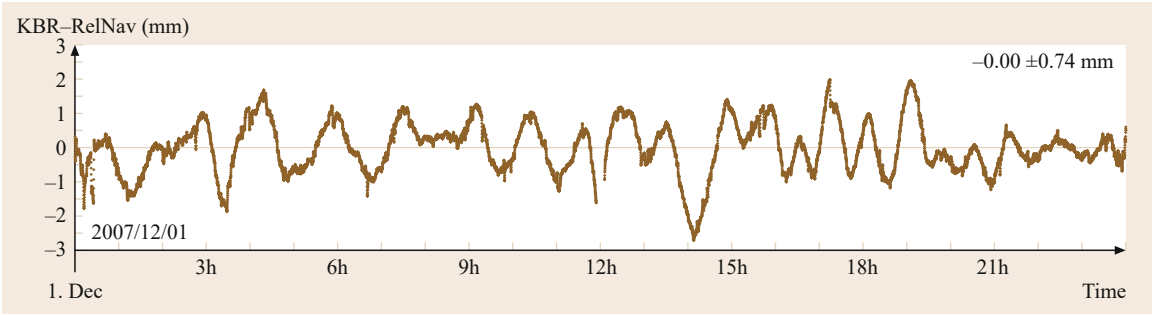

**Fig. 32.16** Comparison of GPS-derived distances of the GRACE satellites with K-band ranging measurements (after [32.89])

and its precursor missions through filtering of differential pseudorange and range-rate observations along with simple models of the orbital dynamics. A similar performance has also been obtained in 1998 as part of the Japanese ETS-VII mission [32.105], which served as a platform for space robotics demonstration and conducted various GPS-controlled approaches of a chaser and target satellite.

However, none of the above mission were able to exploit the potential differential carrier-phase observations and the feasibility of mm-level relative navigation could only be verified many years later with flight data collected in the GRACE formation flying mission. GRACE comprises two identical spacecraft orbiting the Earth at a separation of about 200 km. Distance variations are continuously measured by a K-band intersatellite link with a precision of about 10 μm. The formation thus acts as a large gradiometer and enables a detailed study of the Earth's gravity field and its temporal variations [32.106]. Due to the availability of geodetic-grade dual-frequency GPS receivers and the K-band ranging system, the GRACE formation represents a unique testbed for high-performance relative navigation and has triggered extensive research in the field [32.92, 99, 100]. Making use of high-fidelity a priori force models, empirical (relative) accelerations, integer ambiguity resolution, and in-flight phase pattern calibrations, a precision of 0.5–1.0 mm (1-D RMS) has consistently been demonstrated in comparison to K-band ranging measurements by various research groups (Fig. 32.16).

Building upon these pioneering results, relative GPS was later adopted for precision baseline reconstruction in the TanDEM-X SAR formation flying mission ([32.107], Fig. 32.15). The mission aims at the construction of a global digital elevation model (DEM) of unrivaled resolution and accuracy from interferometric SAR images. In order to avoid a tilt and shift of individual DEM tiles prior to the mosaicking, the relative position of the two spacecraft (or, more specifically,

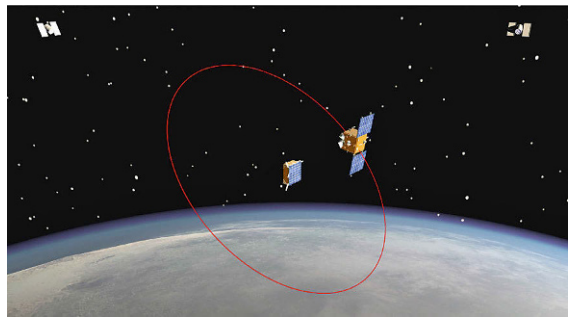

**Fig. 32.17** GPS-enabled autonomous formation flying of the PRISMA satellites (courtesy of OHB Sweden)

the X-band SAR antennas) must be known with an accuracy of about 1 mm in both the radial and cross-track direction. Both satellites of the formation are therefore equipped with dual-frequency IGOR GPS receivers and choke ring antennas (Fig. 32.4) similar to those of the GRACE mission.

Other than GRACE, TanDEM-X offers no independent sensor system enabling a direct validation of the relative navigation accuracy. Various forms of consistency tests such as overlap tests, comparisons of single- and dual-frequency solutions, and, finally, comparisons of baseline products generated by different institutions using independent processing tools are therefore used to assess the resulting navigation performance. As demonstrated in [32.108], a consistency of 1 mm (1-D standard deviation) is typically achieved for baseline products generated by DLR, Deutsches GeoForschungsZentrum Potsdam (GFZ), and AIUB, but systematic biases of similar order may be noted. While slightly outside the mission specification this performance is still appropriate for DEM generation as demonstrated through dedicated tests with SAR calibration sites [32.109].

The use of carrier-phase differential GPS for accurate real-time navigation was first demonstrated in the Swedish PRISMA technology demonstration mis-

sion (Fig. 32.17), which was launched in 2010. The mission comprises two small satellites with a total mass of about 200 kg and serves as a testbed for autonomous formation flying and rendezvous operations. Both spacecraft are equipped with single-frequency Phoenix GPS receivers (Table 32.1). GPS pseudorange and carrier-phase observations collected on board the smaller target satellite are transmitted to the main spacecraft via a radio link and processed jointly with the local GPS observations in a real-time navigation system [32.102]. The GPS navigation system of PRISMA serves as the primary reference for monitoring the relative motion of the two spacecraft and enabled the first demonstration of autonomous formation control.

For maximum flexibility, the PRISMA navigation system processes both GRAPHIC observations of the individual satellites as well differential carrier-phase measurements of commonly observed GPS satellites. In this way it can operate in all mission phases irrespective of the orientation of the two spacecraft and their GPS antennas. In view of frequent orbit and attitude maneuvers, priority is given to maximum robustness rather than utmost accuracy in the filter tuning. Also, the handling of carrier-phase ambiguities is limited to float ambiguity estimation and no effort is made to resolve integer ambiguities in the real-time onboard processing. Compared to a ground-based reference solution, the relative motion of the PRISMA could be determined on board with representative accuracies of better than 10 cm and 1 mm/s for position and velocity respectively [32.89, 102]. While this is still well below the theoretical performance limit for carrier-phase differential GPS, it is fully compatible with the PRISMA mission specification and represents a hundred times improvement over early relative navigation trials in the rendezvous missions discussed above.

## 32.4 Other Applications

The presentation given so far has focused on the use of GNSS for navigation and orbit determination of Earth orbiting satellites, which clearly represent the majority of applications for spaceborne GNSS receivers. The discussion would be incomplete, though, without addressing the use of GNSS for other types of space vehicles as well as nonnavigation-related applications. These topics are briefly introduced within this section.

### 32.4.1 Attitude Determination

The attractive performance of spaceborne GNSS receivers for positioning and navigation has also triggered an early interest in employing them for determining a satellite's attitude in space. Leaving aside single-antenna systems that exploit the directivity of the receiving antenna to obtain orientation-related information from measurements of the carrier-to-noise density ratio (see [32.110] and references therein), GNSS-based attitude determination relies on differential carrier-phase observations from typically three antennas forming two orthogonal baselines (Fig. 32.18). The respective principles and fundamental algorithms are presented in Chap. 27 in full detail. The present section is therefore confined to a short summary of relevant flight experiments and the experience gained in actual space missions.

Early demonstrations of GPS attitude determination were conducted on the RADCAL satellite [32.111, 112], the CRISTA-SPAS pallet satellite deployed by the US Space Shuttle [32.113] and the REX-II satellite [32.114] in the 1993–1996 time frame. The experiments made use of Trimble TANS Vector or TANS Quadrex receivers that had been adapted for use in space and provided attitude information based on multiplexed carrier-phase measurements of four antennas. Since independent attitude sensors of adequate quality were not available on the above missions, the achieved performance has mainly been assessed through self-consistency tests or comparisons with low-grade references such as magnetometers. Typical accuracies of 0.5–1.0° have been reported, which is in rough accord

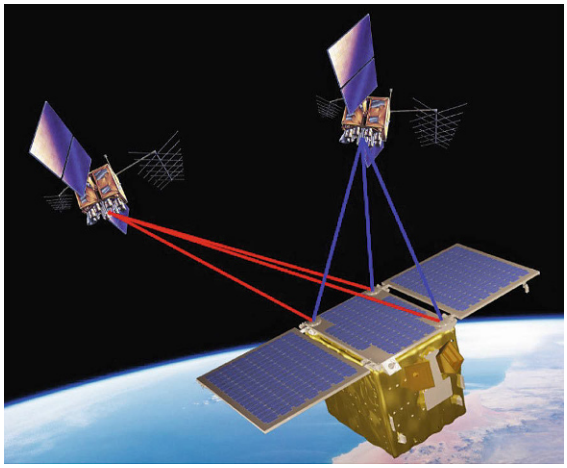

**Fig. 32.18** GPS-based attitude determination of the *Flying Laptop* satellite (artist's drawing based on images of IFR, Univ. Stuttgart/NASA/US Gov)

with the performance expected for baselines of about 0.5 m and carrier-phase accuracies at the level of few millimeters.

Within Europe several demonstrations of GPS-based attitude determination have been conducted on various SSTL microsatellites equipped with SGR-20 four-antenna GPS receivers. Typical accuracies of about 1–2° have, for example, been obtained for UoSat-12 and TopSat [32.115, 116] in comparison with horizon sensors providing a reference attitude at the 0.2°-level.

Finally, GPS measurements from the Space Integrated GPS/Inertial navigation system (SIGI) are routinely used for attitude determination system on board the International Space Station (ISS). The SIGI unit comprises a Trimble Force 19 GPS receiver connected to an array of four antennas on the S0 truss of the ISS [32.117]. Despite the use of multipath limiting choke ring antennas and an antenna baseline of several meters, the achieved standalone GPS attitude performance does not meet the 0.5° specification. GPS-based attitude solutions are therefore merged with other sensor data in the onboard attitude determination filter to obtain a robust and accurate blended solution.

Overall, multipath and phase pattern distortions remain a limiting factor for the achievable accuracy for GNSS-based attitude determination on space vehicles. Surface space is naturally limited on common satellites, which inhibits the accommodation of large and widely separated antennas. Despite initial hopes, GNSS attitude sensors have not been found to be competitive with Earth horizon sensors or star cameras and their use has mainly been confined to selected experiments and demonstration campaigns.

### 32.4.2 Ballistic Missions

Aside from Earth orbiting satellites, GNSS is also an attractive tracking system for ballistic space vehicles that stay in space for only a limited time before returning to ground. Among others, GNSS receivers are now widely used on sounding rockets, which provide low-cost platforms for atmospheric and astronomical research as well as biological and physical experiments in microgravity. Sounding rockets fly at suborbital velocities ($v < 7$ km) but may reach altitudes of 100–1000 km during their parabolic flight phase.

As an example, Fig. 32.19 illustrates the flight parameters of a Maxus rocket, which represents the most powerful sounding rocket employed in the European microgravity research program. Within the 60 s boost phase the vehicle achieves a total speed of 3200 m/s and is accelerated with about 100 m/s (10 G) near burnout of the second stage. Even higher accelerations of 50 G and more are experienced near the end of the 900 s flight when the payload enters the atmosphere.

GNSS tracking of sounding rockets is primarily employed for flight safety purposes and complements or substitutes ground-based radars for the instantaneous impact point (IIP) prediction during the propelled flight. The IIP describes the touchdown point reached by the vehicle as computed from the current position and velocity [32.118]. It is used to validate a nominal flight performance during the boost phase and, if necessary, to destroy the booster in case of anomalies. Other uses of GNSS navigation data may include onboard timing, relative positioning of ejected payloads [32.119], payload recovery, and finally overall flight performance assessment.

The extreme dynamics of a sounding rocket flight poses specific requirements on the environmental robustness and the signal processing within a GNSS receiver. The employed hardware must be robust enough to withstand high levels of vibration and to operate in vacuum (but need to be radiation-hardened due to the very short mission duration). To cope with high accelerations and acceleration changes (jerk), the code- and carrier-tracking loops (Chap. 14) must be of adequate order and width. In addition high navigation update rates (5–20 Hz) are typically desired to resolve individual flight phases with adequate resolution. Antenna accommodation represents a further challenge for the use of GNSS on sounding rockets. Wraparound antennas are commonly favored to enable continuous tracking irrespective of vehicle spin and attitude but need to be tailor-made for the specific body diameter and are unsuitable for large vehicles. Alternative concepts offering different levels of complexity and reliability include helical tip antennas as well as body-mounted blade and tip antennas.

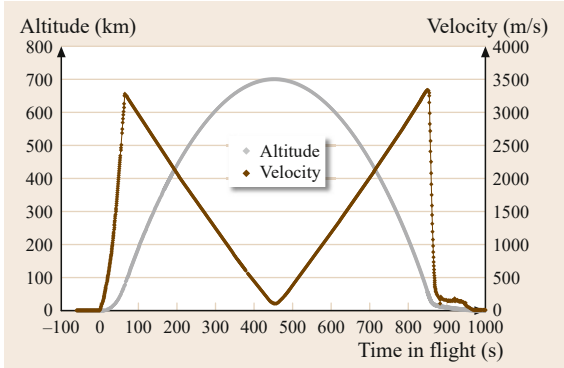

**Fig. 32.19** Altitude and total velocity as measured by an Orion GPS receiver during the Maxus-5 sounding rocket flight in April 2003

In terms of performance, the better than 10 m and 0.1 m/s navigation accuracy offered by public GNSS signals and services is generally deemed fully adequate for sounding rockets and other (nonmilitary) ballistic vehicles. In accord with this, single-frequency GNSS systems are almost exclusively employed in view of the reduced antenna and receiver complexity. While external reference standards are rarely available, a comparison of multiple GPS L1 C/A-code receivers and antenna assemblies flown jointly on an Orion sounding rocket in 2001 [32.120] has indeed confirmed the desired precision for most of the employed systems.

Despite an adequate navigation performance GNSS cannot normally ensure a fully continuous availability as a standalone sensor but is subject to a potential loss-of-track in phases of extreme acceleration changes, antenna switches, unfavorable attitude, rapid spin or blackouts due to ionization. Also, strong scintillation is considered a potential risk for use at launch sites in tropical regions. A coupling of GNSS sensors with inertial navigation systems (INSs) is therefore considered mandatory for use on guided vehicles, large launchers, human space flight and re-entry capsules [32.121, 122].

An example of an advanced GPS/INS navigation system for sounding rocket missions is shown in Fig. 32.20. The hybrid navigation system [32.123] was first flown as part of the Shefex-II sounding rocket mission and employs a tightly coupled system architecture (Chap. 28). It computes a strapdown navigation solution from high-rate (400 Hz) acceleration and angular rate observations of an Inertial Measurement Unit (IMU) with three servo accelerometers and fiber optic gyros. This is updated once per second in a common navigation filter with raw pseudorange observations of a GPS L1 C/A-code receiver.

### 32.4.3 GNSS Radio Science

Beyond their primary purpose, GNSS navigation signals may also serve as signals of opportunity for different types of remote sensing applications from spaceborne platforms. This includes their use in radio occultation measurements for sounding the state of the troposphere and ionosphere [32.75] but also scatterometry and reflectometry for surveying the ocean surface [32.124]. While the first application is already supported by numerous space missions (such as CHAMP, Metop, TerraSAR-X and COSMIC) and has in fact evolved into an indispensable data source for near-real-time weather forecasts [32.125], the use of reflected or scattered GNSS signals from space is still in an experimental state [32.126] and waiting for dedicated missions and payloads to be developed.

GNSS receivers for radio occultation (RO) observations are offered by various manufacturers building upon existing concepts of spaceborne dual-frequency receivers for precise orbit determination. Typical differences include the need for multiple antennas (forward/backward looking for RO, zenith looking for POD), open-loop tracking with model-based predictions of the expected code delay and high-data rate phase observations (or raw in-phase/quadrature (I/Q) samples). Furthermore, dedicated antenna arrays with beam patterns focused on the limb of the Earth are commonly used to compensate the attenuation of signals passing deep through the lower atmosphere.

For a more detailed discussion of GNSS radio occulation as well reflectometry and scatterometry the reader is referred to Chapters 38 and 40 respectively.

# 33. The International GNSS Service

Gary Johnston, Anna Riddell, Grant Hausler

The International global navigation satellite system (GNSS ) Service (IGS) is an organization devoted to the generation of high-precision GNSS data and products; a service that benefits science and society. It is a voluntary federation of over 200 self-funding agencies, universities, and research institutions in more than 100 countries. Established in 1992 and formally launched on 1st January 1994, the IGS has delivered an uninterrupted time series of products that are utilized by a broad spectrum of users. IGS products have evolved over time, including the provision of GNSS data for constellations other than GPS, and the addition of real-time GNSS data and products.

This chapter provides an overview of the IGS, including a brief history and details of the current organization and its key components. The various products offered by the IGS are described and an outlook of future activities is given.

## 33.1 Mission and Organization

### 33.1.1 Mission

The stated mission of the IGS is as follows [33.1]:

> *The International GNSS Service provides, on an openly available basis, the highest-quality GNSS data, products, and services in support of the terrestrial reference frame; Earth observation and research; Positioning, Navigation and Timing (PNT); and other applications that benefit the scientific community and society.*

The IGS promotes a culture of shared expertise to encourage global best practice for developing and delivering GNSS data and products worldwide. This collaborative approach encourages input from a diverse user community to strengthen uptake and promote innovation. The IGS has a strong interface with providers of GNSS equipment and services, and the owners of GNSS themselves. Drawing on a global research community, the IGS ensures that new technologies and systems can be integrated into its routine products. To support best practice among the global user community, the IGS also develops and publicly releases standards, guidelines, and conventions relating to the collection and use of GNSS data and products.

The IGS is a key element of the Global Geodetic Observing System (GGOS [33.2]) and fulfils three essential roles. The first is to provide the global linkage between the other elements of the global geodetic observing network, namely Satellite Laser Ranging (SLR) systems, Very Long Baseline Interferometry (VLBI)

**Table 33.1** Key dates and milestones for the IGS

| Date | Event |
|---|---|
| Aug 1989 | First ideas for an International GPS Service were presented at the IAG General Meeting in Edinburgh |
| Jun 1992 | Start of 1992 IGS Test Campaign (ended 23 Sep 1992) |
| Aug 1993 | IAG Approval for IGS at IAG Scientific Meeting in Beijing. |
| Jan 1994 | Start of official IGS |
| May 2000 | Selective Availability removed from GPS |
| Mar 2001 | GLONASS Service Pilot Project commenced |
| Mar 2001 | TIGA (GPS Tide Gauge Benchmark Monitoring) project established |
| Apr 2003 | Ionosphere maps (IONEX) etc. became official IGS product |
| May 2003 | First operational combined GPS/GLONASS analysis products released |
| Mar 2005 | IGS renamed as International GNSS Service |
| Dec 2005 | International Committee on GNSS created by the UN office of Outer Space Affairs |
| Aug 2011 | Multi-GNSS Experiment (MGEX) Call for Participation |
| Jul 2013 | Real-Time Pilot Project commenced |

telescopes, and Doppler Orbitography and Radio positioning Integrated by Satellite (DORIS) ground beacons. These links are fundamental to generating the International Terrestrial Reference Frame (ITRF) [33.3]. Given the high cost of establishing and maintaining SLR and VLBI facilities, and the fact that direct colocation of SLR, VLBI, and DORIS is not always viable, IGS products provide a cost-effective means of geometrically linking these other observing techniques. The second role is to densify and improve the geometric distribution of the global geodetic network, allowing accurate modeling of satellite orbits and clocks, atmospheric behavior, and Earth processes like neo-tectonics. The final role is to provide the user segment with access to the ITRF, which is increasingly important as both the accuracy of publicly accessible GNSS positioning improves and the consequent need to better understand the relationship between the ITRF and national datums emerges.

There are numerous benefits for an organization or station operator to support the IGS, including increased accuracy of the reference frame in the organization's region of interest; simpler and more accurate connections to the reference frame; increased accuracy of global positioning products, such as satellite orbit and clock products; and more accurate determination of transformations between realizations of the reference frame in that region and the respective national datum. The adoption of a United Nations General Assembly Resolution in 2015 supporting the Global Geodetic Reference Frame is in many ways recognition of the role the IGS plays in supporting society and more specifically the UN Sustainable Development Goals [33.4].

The IGS strives to maintain an international federation with committed contributions from its members. It does this by providing effective leadership, management, and governance. While the value proposition for participation in the IGS varies for different contributors, its data and products are largely driven by user needs. IGS governance encourages an inclusive culture, and particular attention is given to outreach across regions and countries with lower than expected participation levels. The IGS also provides support and leadership to a multitude of other science programs. Considerable attention is paid to providing advocacy for the IGS into the Group on Earth Observations (GEO); the Global Earth Observation System of Systems (GEOSS); the Committee on Earth Observation Satellites (CEOS); and a variety of United Nations committees.

A comprehensive history of the IGS can be found in [33.5] and Table 33.1 lists key dates and milestones since the IGS was first conceived.

### 33.1.2 Structure

An overview of the IGS organization as of 2015 is provided in Fig. 33.1. Key elements include:

- The *Governing Board (GB)* that oversees the IGS activities establishes its policies and decides on the establishment of new activities and products.
- The *Central Bureau (CB)* that performs the overall coordination and day-to-day management of IGS activities.
- The *IGS Network* of globally distributed monitoring stations that provide continuous observations of all GNSS constellations.
- The *Analysis Centers (ACs)* that generate quality controlled products such as precise orbit and clock solutions, tropospheric and ionosphere maps, and station position estimates from GNSS observations.
- The *Data Centers (DCs)* that make all data and products available to the community.
- Various *Working Groups (WGs)* that provide technical guidance and expertise in specific fields to advance the product generation and to establish new data and processing standards.

The tasks of each organizational element are further described in Sect. 33.2.

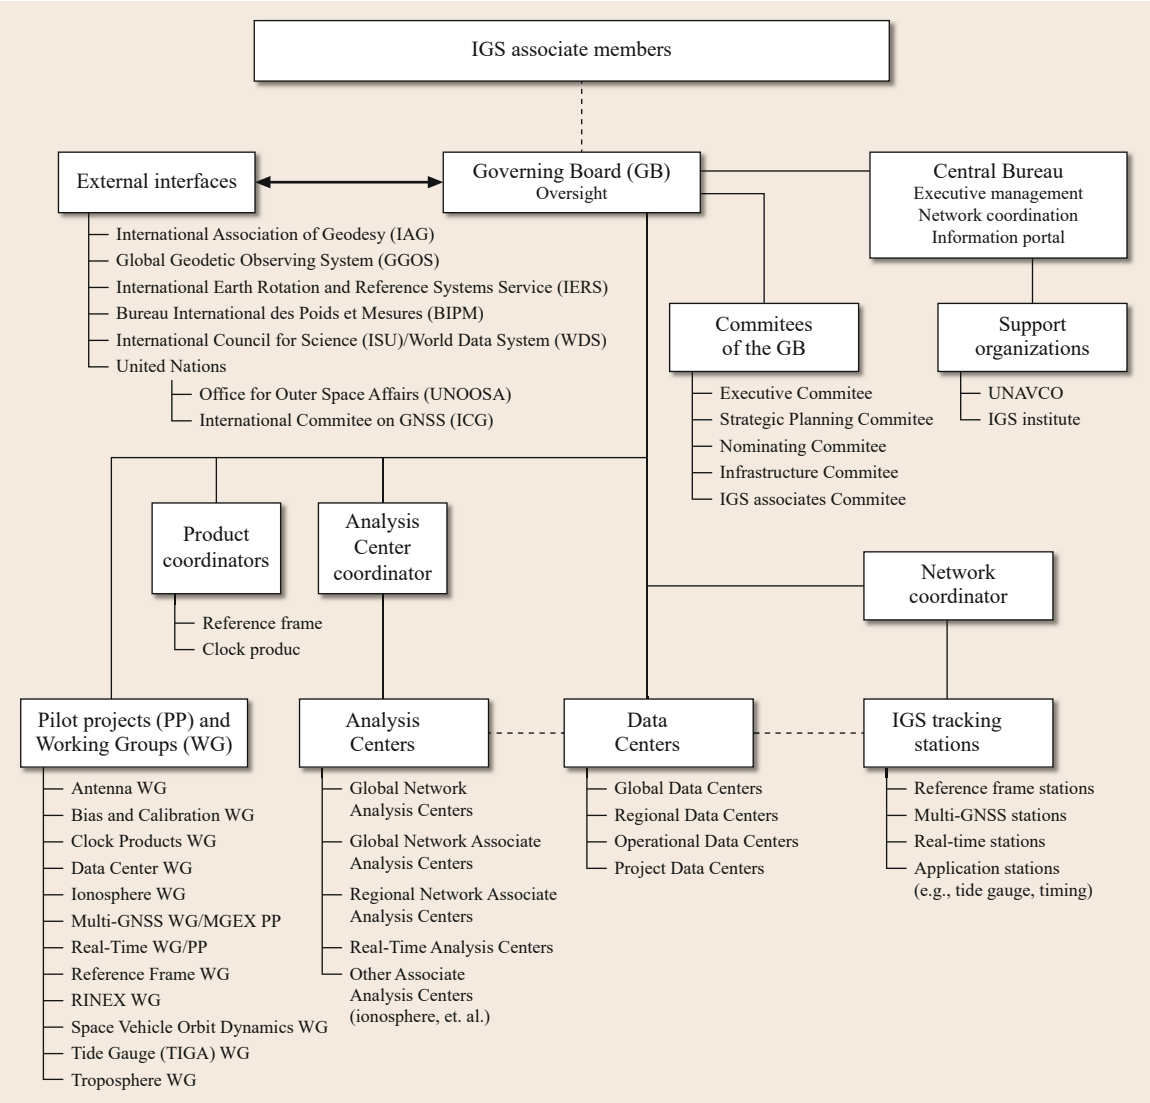

**Fig. 33.1** Organizational structure of the IGS

## 33.2 Components

Key components of the IGS were identified in Fig. 33.1. This section provides a brief summary of the roles and responsibilities associated with each of these components. Further details are provided in the IGS Terms of Reference [33.1].

### 33.2.1 IGS Governing Board and Executive Committee

The Governing Board (GB) is the international body that sets policy for the IGS and exercises broad oversight of all IGS functions and components. It controls the general activities of the IGS and implements restructuring if needed to increase the organization's efficiency and reliability for integrating and making full use of all available GNSS technologies.

The GB has an Executive Committee (EC) with specific responsibilities that allow it to act on behalf of the GB outside formal GB meetings.

### 33.2.2 IGS Central Bureau

The Central Bureau (CB) coordinates the day-to-day operations of the IGS. It is the executive arm of the

IGS GB with responsibilities for coordinating general aspects of IGS network operations; promoting compliance to IGS standards; monitoring network operations and providing quality assurance of data; maintaining documentation; organizing meetings and workshops; and coordinating development and publishing of IGS reports. The performance of the CB is formally reviewed by the GB at least every 5 years to ensure it is capable of fulfilling its long-term coordination role.

### 33.2.3 IGS Network

The foundation of the IGS is a global network of over 450 permanent and continuously operating stations of geodetic quality, which track signals from GPS. Increasingly signals from GLONASS, Galileo, BeiDou, QZSS, and several Space-Based Augmentation Systems (SBAS) are also tracked. To ensure continuous tracking of high-accuracy GNSS data, stations in the IGS network are developed to a minimum set of physical and operational standards defined by the *IGS Site Guidelines* [33.6]. For example, IGS infrastructure must be physically stable to support long-term operation of the IGS network, and any changes to a station's configuration should be carefully planned and documented to minimize discontinuities in the station's position time-series. Minimum scheduling requirements are also implemented to ensure that data from each station is transmitted as rapidly as possible to global and regional DCs for archiving and analysis.

Station locations in the global IGS tracking network are illustrated in Fig. 33.2.

### 33.2.4 Analysis Centers

ACs receive and process tracking data from one or more DCs for the purpose of producing IGS products. ACs are recognized by the GB as those groups which commit to deliver some or all of the core IGS products (Sect. 33.3), within a specified time period, using designated IGS standards and conventions. Core products typically include satellite ephemerides, Earth rotation parameters, station coordinates, and clock information. The products are produced in Ultra-rapid, Rapid, Final, and Reprocessed versions for each AC.

Associate ACs (AACs) are a second category of AC that produce specialized products, including ionospheric information, tropospheric parameters, or station coordinates and velocities for global or regional subnetworks. Regional Network Associate Analysis Centers (RNAACs) and Global Network Associate Analysis Centers (GNAACs) are currently recognized by the GB. The functions of AACs continue to evolve as new capabilities and products emerge within the IGS.

Finally, the Analysis Center Coordinator (ACC) is responsible for combining products from each AC into a single set of orbit and clock products, which are the official IGS products made available to users through the Global DCs. The ACC monitors and assists the activities of ACs to ensure IGS objectives and standards for quality control, performance evaluation, and analysis are carried out. The ACC is a voting member of the IGS GB and interacts regularly with the CB and International Earth Rotation and Reference Systems Service (IERS). The responsibilities for the ACC typically rotate around the ACs with appointments and terms specified by the GB.

### 33.2.5 Data Centers (DCs)

The *Charter for IGS DCs* [33.7] defines three categories – Operational, Regional, and Global DCs – each of which builds redundancy into the IGS network. DCs are approved by the GB based on recommendations of the DCWG, and a demonstrated commitment to IGS principles and standards.

Operational DCs are in direct contact with IGS tracking sites. Their tasks include station monitoring,

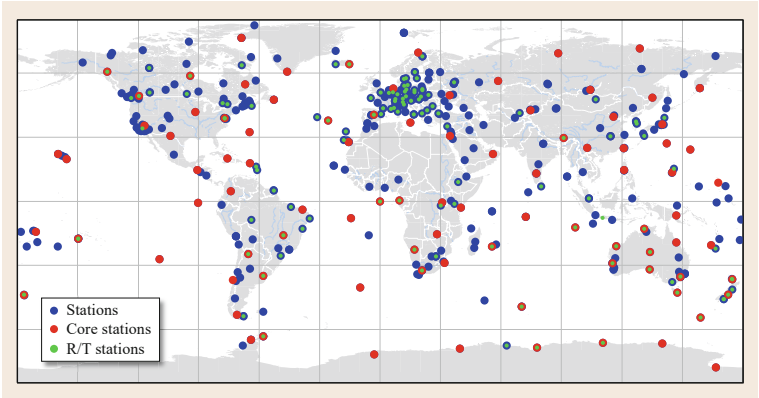

**Fig. 33.2** Sites in the global IGS tracking network. Out of an overall set of about 470 stations available in Oct. 2015, the 90 core stations marked in *red* are used to establish the IGb08 reference frame. *Green dots* indicate stations with real-time data transmission capability

data validation, data formatting and exchange (e.g., RINEX), data compression, local archiving of GNSS data, and the electronic transmission of data to Regional and Global DCs [33.8]. Download schedules and data continuity requirements are specified in the IGS Site Guidelines for Operational DCs.

Regional DCs collect tracking data in the required exchange format from several Operational Centers and/or stations. They maintain a local archive of this data, provide on-line access to the data, and transmit the data from a subset of their sites (minimally, the IGS reference frame stations) to Global DCs. The stations managed by Regional DCs can be those of an individual agency or those located across a specific geographic region (Europe, Australia, etc.).

Global DCs are the main interfaces to the ACs and general user community. They receive, retrieve, archive, and provide online access to tracking data from Operational and Regional DCs. They are responsible for archiving and backing up IGS data and products, and exchanging data between other DCs to balance data holdings across the IGS network. At a minimum, Global DCs must archive GNSS data that has been sampled at 30 s intervals from IGS reference frame sites. As of 2015, the IGS comprises four global DCs hosted by institutions in the United States, France, and Korea:

- Crustal Dynamics Data Information System (CDDIS [33.9])
- Institut National de l'Information Géographique et Forestière (IGN)
- Scripps Institution of Oceanography (SIO)
- Korean Astronomy and Space Science Institute (KASI).

Routine quality control is encouraged by all DCs to validate data prior to transmission.

### 33.2.6 Working Groups

The IGS has a number of working groups that focus on different aspects of product generation. These WGs also support IGS pilot projects (Sect. 33.4) to investigate future GNSS developments that could lead to the generation of new IGS products.

The current WGs are briefly summarized below along with their goals and objectives:

- *Antenna Working Group (AWG)* – To increase the accuracy and consistency of IGS products the AWG coordinates research on GNSS receiver and satellite antenna phase center determination, and manages official IGS antenna files and their formats.
- *Bias and Calibration Working Group (BCWG)* – Different GNSS observables are subject to different satellite biases that can degrade the IGS products. The BCWG coordinates research for retrieving and monitoring GNSS biases, and develops rules for handling these biases.
- *Clock Products Working Group (CPWG)* – The CPWG is responsible for aligning the combined IGS products to a highly precise timescale traceable to the world standard; Coordinated Universal Time (UTC).
- *Data Center Working Group (DCWG)* – The DCWG works to improve the provision of data and products from the Operational, Regional, and Global DCs, and recommends new DCs to the GB.
- *Ionosphere Working Group (IWG)* – The IWG produces global ionosphere maps of Ionosphere Vertical Total Electron Content (TEC). A major task of IWG is to make available global ionosphere maps from the TEC maps produced independently by Ionosphere Associate Analysis Centers (IAACs) within the IGS.
- *Multi-GNSS Working Group (MGWG)* – The MGWG supports the MGEX Project by facilitating estimation of intersystem biases and comparing the performance of multi-GNSS equipment and processing software. The MGEX Project was established to track, collate, and analyze all available GNSS signals including those from BeiDou, Galileo, and QZSS in addition to GPS and GLONASS satellites.
- *Reference Frame Working Group (RFWG)* – The RFWG combines solutions from the IGS ACs to form the IGS station positions and velocity products, and Earth rotation parameters for inclusion in the IGS realization of ITRF.
- *Real-Time Working Group (RTWG)* – The RTWG supports the development and integration of real-time technologies, standards, and infrastructure to produce high-accuracy IGS products in real time. The RTWG operates the IGS Real-Time Service (RTS) to support Precise Point Positioning (PPP) at global scales, in real time.
- *RINEX Working Group (RINEX-WG)* – The RINEX-WG jointly manages the RINEX format with the Radio Technical Commission for Maritime services-Special Committee 104 (RTCM-SC104). RINEX has been widely adopted as an industry standard for archiving and exchanging GNSS observations, and newer versions support multiple GNSS constellations.
- *Space Vehicle Orbit Dynamics Working Group (SVODWG)* – The SVODWG brings together IGS groups working on orbit dynamics and attitude

modelling of spacecraft. This work includes the development of force and attitude models for new GNSS constellations to fully exploit all new signals with the highest possible accuracy.

- *Tide Gauge (TIGA) Working Group* – TIGA is a pilot study for establishing a service to analyze GPS data from stations at or near tide gauges in the IGS network to support accurate measurement of sea-level change across the globe.
- *Troposphere Working Group (TWG)* – The TWG supports development of the IGS troposphere products by combining troposphere solutions from individual ACs to improve the accuracy of PPP solutions.

Information on the WG charters and membership can be found at [33.10]. WG chairs report to the IGS GB on a regular basis.

## 33.3 IGS Products

The primary objective of the IGS is to provide the reference GNSS products and observations for a wide variety of scientific and engineering users involving GNSS. To fulfil this role, the IGS produces a number of fundamental products such as:

- GNSS orbits and clocks
- Earth orientation parameters and station coordinates
- Ionosphere and troposphere parameters and
- Systematic bias estimates.

These high-quality products are used to support scientific applications such as the realization of the ITRF, monitoring the deformation of the solid Earth due to ocean tides and hydrology, and monitoring of sea-level change and associated climate change events. Increasingly the products are also used for sounding the atmosphere and producing ionospheric and tropospheric maps. Lastly, the IGS products are used extensively to support precise positioning applications for industry and society.

### 33.3.1 Orbits and Clocks

In order for a user to achieve precise positioning (Chap. 25), knowledge of the orbits and clocks of the GNSS satellites is fundamental. The positioning accuracy is directly affected by errors in the satellite orbits and clocks. Relatively low accuracy orbit and clock information are transmitted through the GNSS navigation messages. Other more precise orbits and clock information are provided by the IGS and its individual ACs. An indicative list of the IGS orbit and clock products, together with their latency and availability, is provided in Tables 33.2 and 33.3.

**Table 33.2** Accuracy, latency, continuity, availability, and sampling intervals for IGS orbit and clock products relating to GPS satellite orbits and satellite (sat) and station (stn) clocks as of 2013 (after [33.11, 12]). For definition of latency, continuity, and availability see [33.11]

| GPS satellite ephemerides Satellite and station clocks | | Sample interval | Accuracy | Latency | Continuity | Availability (%) |
|---|---|---|---|---|---|---|
| Broadcast (for comparison) | Orbits<br>Sat. clocks | – | ≈ 100 cm<br>≈ 5 ns RMS,<br>2.5 ns $\sigma$ | Real time | Continuous | 99.99 |
| Ultra-rapid (predicted half) | Orbits<br>Sat. clocks | 15 min | ≈ 5 cm<br>≈ 3 ns RMS,<br>≈ 1.5 ns $\sigma$ | Predicted | 4× daily, at 3 h, 9 h, 15 h, 21 h UTC | 95 |
| Ultra-rapid (observed half) | Orbits<br>Sat. clocks | 15 min | ≈ 3 cm<br>≈ 150 ps RMS,<br>≈ 50 ps $\sigma$ | 3–9 h | 4× daily, at 3 h, 9 h, 15 h, 21 h UTC | |
| Rapid | Orbits,<br>Sat. & stn. clocks | 15 min<br>5 min | ≈ 2.5 cm<br>≈ 75 ps RMS,<br>≈ 25 ps $\sigma$ | 17–41 h | daily,<br>at 17 h UTC | 95 |
| Final | Orbits,<br>Sat. & stn. clocks | 15 min<br>30 s (Sat)<br>5 min (Stn) | ≈ 2 cm<br>75 ps RMS,<br>20 ps $\sigma$ | 12–18 d | weekly,<br>Thursday | 99 |
| Real-time | Orbits<br>Sat. clocks | 5–60 s | ≈ 5 cm<br>300 ps RMS,<br>120 ps $\sigma$ | 25 s<br>5 s | Continuous | 95 |

**Table 33.3** Accuracy, latency, continuity, availability, and sampling intervals for IGS orbit and clock products relating to GLONASS satellite ephemerides as of 2013 (after [33.11, 12])

| GLONASS satellite orbits | Sample interval | Accuracy | Latency | Continuity | Availability (%) |
|---|---|---|---|---|---|
| Final | 15 min | ≈ 3 cm | 12–18 d | Weekly, every Thursday | 99 |

The IGS continuously monitors the performance of its products through its ACC. The ACC is in charge of monitoring the performance of the orbits and clocks by comparing the final products against each individual AC product. An example of this comparison is illustrated in Fig. 33.3 where each individual AC orbit is compared to the IGS final orbits via three-dimensional (3-D) differences.

## 33.3.2 Earth Orientation and Site Coordinates

The Earth Orientation Parameters (EOPs) are another product derived from the complex computations performed by the IGS (Table 33.4). EOPs specify the motion of the Earth's rotation pole and its irregularities through time. These parameters provide the connection or tie of the International Celestial Reference Frame (ICRF) to the ITRF and the IGS Terrestrial Reference Frame, known as the IGb. They consist of:

- The Universal Time (UT), which is the time of the Earth clock
- The length-of-day (LOD), which describes any excess in the revolution time
- The polar motion, which describes the varying position of the Earth's pole through coordinates $x$ and $y$ of the Celestial Ephemeris Pole (CEP) relative to the IERS reference pole
- The polar motion rate, which represents the velocity of the polar coordinates and how they vary through time.

The physical meaning of the individual parameters is further discussed in Chap. 2 of this Handbook and the IERS Conventions [33.14].

### Site Coordinates

Site positions and velocities (Table 33.5) for the IGS stations are generated by the analysis centers on a weekly basis. The individual solutions are provided

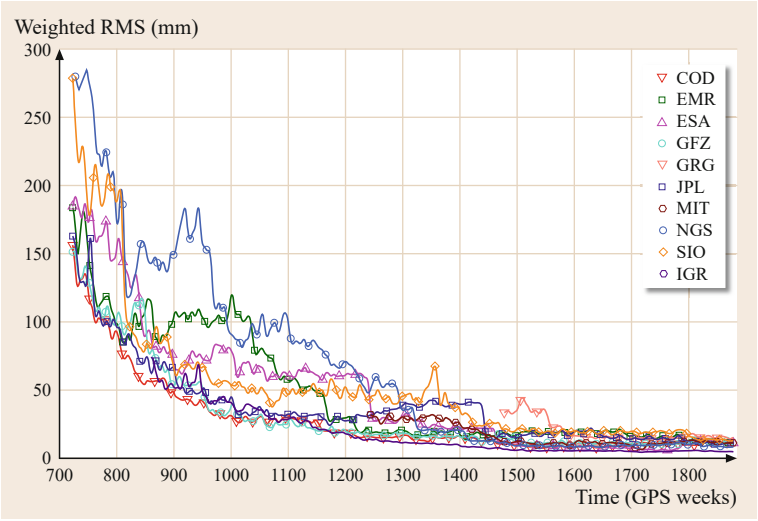

**Fig. 33.3** Weighted RMS (mm) of the individual AC orbit solutions with respect to the IGS Final orbits for the period 1994 to Dec. 2015 (smoothed). Individual Analysis Centers are identified by their three-letter acronyms (COD: Center for Orbit Determination in Europe, Switzerland; EMR: Natural Resources Canada; ESA: European Space Agency; GFZ: GeoForschungsZentrum Potsdam, Germany; GRG: Groupe de Recherche de Géodésie Spatiale – Centre National d'Etudes Spatiales (CNES) and Collecte Localisation Satellites (CLS); JPL: Jet Propulsion Laboratory, USA; MIT: Massachusetts Institute of Technology, USA; NGS: National Geodetic Survey, National Oceanic and Atmospheric Administration (NOAA), USA; SIO: Scripps Institute of Oceanography, USA [33.13]). **Table 33.4** IGS Earth orientation products (after [33.11, 12])

| Earth rotation parameters | | Sample interval | Accuracy | Latency | Continuity | Availability (%) |
|---|---|---|---|---|---|---|
| Ultra-rapid (predicted half) | Polar motion<br>Polar motion rate<br>Length-of-day | Daily integrations at 0 h, 6 h, 12 h, 18 h UTC | ≈ 200 μas<br>≈ 300 μas/d<br>≈ 50 μs | Real time | 4× daily, at 3 h, 9 h, 15 h, 21 h UTC | 99 |
| Ultra-rapid (observed half) | Polar motion<br>Polar motion rate<br>Length-of-day | Daily integrations at 0 h, 6 h, 12 h, 18 h UTC | ≈ 50 μas<br>≈ 250 μas/d<br>≈ 10 μs | 3–9 h | 4× daily, at 3 h, 9 h, 15 h, 21 h UTC | 99 |
| Rapid | Polar motion<br>Polar motion rate<br>Length-of-day | Daily integrations at 12 h UTC | ≈ 40 μas<br>≈ 200 μas/d<br>≈ 10 μs | 17–41 h | Daily, at 17h UTC | 99 |
| Final | Polar motion<br>Polar motion rate<br>Length-of-day | Daily integrations at 12 h UTC | ≈ 30 μas<br>≈ 150 μas/d<br>≈ 10 μs | 11–17 d | Weekly, Wednesday | 99 |

Note 1: 100 μas = 3.1 mm and 10 μs = 4.6 mm of equatorial rotation at the Earth's surface.
Note 2: The IGS uses VLBI from IERS Bulletin A to partially calibrate for LOD biases over a 21-day sliding window, but residual time-correlated LOD errors remain.

**Table 33.5** IGS station coordinate products (after [33.11, 12])

| Geocentric coordinates of IGS tracking stations (> 250 sites) | | Sample interval | Accuracy | Latency | Continuity | Availability (%) |
|---|---|---|---|---|---|---|
| Final positions | Horizontal<br>Vertical | Weekly | 3 mm<br>6 mm | 11–17 d | Weekly, Wednesday | 99 |
| Final velocities | Horizontal<br>Vertical | Weekly | 2 mm/yr<br>3 mm/yr | 11–17 d | Weekly, Wednesday | 99 |

in the Solution Independent Exchange (SINEX) format (Annex A.2.3), which facilitates combinations of different ACs but also of GNSS-derived solutions with other space-geodetic techniques.

Through its GNSS network and processing the IGS contributes to, extends, and densifies the ITRF. The ITRF provides an accurate and consistent frame, or datum, for referencing positions at different times and in different locations around the world. The IGS realization of ITRF, which extends the number of stations significantly, makes the reference frame easily accessible.

The IGS network shown in Fig. 33.2 includes a well-distributed subset (the *reference frame stations* indicated in red) called the IGb08 core network. This subnetwork is recommended for comparison or alignment of global solutions to the IGb08 reference frame, in order to mitigate the aliasing of station nonlinear motions into transformation parameters (network effect). It is used for the alignment of the IGS weekly combined solutions to IGb08.

IGS reference frame stations are the highest-quality GNSS stations in the world. This quality directly impacts the level of accuracy that can be achieved by using the ITRF. Requirements for stations include: a high-quality monument on stable crustal bedrock with excellent sky visibility; a long observing history; high-quality, consistent, continuous, and complete raw data; minimal changes to equipment and its surroundings; and a commitment to keep the station operating for as long as possible. Full requirements are detailed in the IGS Site Guidelines [33.6]. These site requirements are stringent in order to ensure reliable measurements uniformly across the global network in support of projects such as sea-level change, which occurs at the millimeter level. Limitations in a reference frame negatively impact the accuracy of numerous scientific and positioning applications, especially in the region immediately surrounding the station.

### 33.3.3 Atmospheric Parameters

Other IGS products are developed by AACs in relation with WGs and pilot projects. These products include Zenith Troposphere Delay (ZTD; also known as Zenith Path Delay, ZPD) parameters and ionospheric vertical total electron content (VTEC) maps, which have application in climate and atmospheric research (Chaps. 38 and 39). A summary of the IGS atmospheric products is given in Table 33.6.

#### Troposphere

The ZTD products are generated from the IGS ACs through the processing of ground-based GNSS

**Table 33.6** IGS atmospheric products (after [33.11, 12])

| Atmospheric parameters | Sample interval | Accuracy | Latency | Continuity | Availability (%) |
|---|---|---|---|---|---|
| IGS final tropospheric delay (ZTD and gradients) | 5 min | ≈ 4 mm for ZTD | ≈ 3 weeks | Daily | 99 |
| Ionosphere TEC grid | 2 h, 5° × 2.5° (lon./lat.) | 2–8 TECU | ≈ 11 d | Weekly | 99 |
| Rapid ionosphere TEC grid | 2 h, 5° × 2.5° (lon./lat.) | 2–9 TECU | < 24 h | Daily | 95 |

data [33.15, 16]. For the extraction of the ZTD and its horizontal gradients, observations of the surface pressure and temperature at the GNSS sites are needed. In order to produce these ZTD products, the IGS ACs need to use all of the aforementioned products as known parameters, that is orbits, clocks, and EOPs.

#### Ionosphere

The ionosphere products, which comprise a set of VTEC maps [33.17], are also a product of a GNSS processing strategy using orbits, clocks, and EOPs, which are derived from dual frequency observations. Another by-product of this is the estimates of the differential code biases (DCBs) (discussed in the following section). These ionosphere products are available from the rapid solutions with a latency of less than 24 hours, a final solution with a latency of approximately 11 days, and a predicted solution available both 1 and 2 days prior. Ionosphere products are provided in IONEX (Ionosphere Exchange) format (Annex A.2.4).

### 33.3.4 Biases

All GNSS observations are biased and contain unknown quantities characterized as systematic errors. The IGS, through the Bias and Calibration Working Group (BCWG), coordinates the production, research, and monitoring of these biases. The BCWG is responsible for defining the rules and procedures, which dictate the consistent handling and processing of these biases in an inhomogeneous GNSS environment.

The current set of IGS bias estimates comprises DCBs for GPS and GLONASS signals on the L1 and L2 frequencies:

- L1 P(Y)- or P-code minus L1 C/A-code biases (termed *P1-C1* in accord with the heritage two-letter RINEX 2 observation designations) for the GPS and GLONASS constellation for a moving 30-day combination (considering the bias estimates of the latest 30 daily solutions).
- L2 P(Y)- or P-code minus L2C or L2 C/A-code biases (termed *P2-C2*) for the GPS and GLONASS constellations for a moving 30-day combination.
- P1-P2 bias values for GPS and GLONASS as a by-product of the ionospheric analysis as monthly values.

These biases are generated by two methods: the indirect and direct method. In the indirect estimation process the biases are generated as estimable parameters in the clock determination process. In the direct process, the biases are generated directly from the differences of the observations of the different signals.

In the face of GPS and GLONASS modernization programs and upcoming GNSS, like the European Galileo and the Chinese BeiDou, an increasing number of types of biases are expected [33.18]. Some of the future biases products that the IGS will have to produce in the context of multi-GNSS multifrequency signals are:

- Transition to RINEX 3.xx compatible bias types and designations (e.g., C1W-C1C, C2W-C2S, C1W-C2W, etc.)
- Biases for particular linear combinations such as wide-lane biases (WLB), ionosphere-free biases (LCB), narrow-lane biases (NLB)
- GLONASS interfrequency code biases
- GLONASS differential code-phase biases for ambiguity resolution
- Uncalibrated phase delays (UPD) relevant to undifferenced integer fixing for precise point positioning
- GPS quarter-cycle phase offset issues (specifically between L2W and L2C)
- Differentials code biases for new signals and constellations
- Absolute or observable code bias values, being consistent with respect to each DCB set and with respect to the signals currently used for the clock offset determination.

The generation of multi-GNSS DCB products has been initiated in the frame of the IGS multi-GNSS Experiment (MGEX; Sect. 33.4.2), where prototype DCB products covering new signals and constellations are made available by selected analysis centers since 2014 [33.19].

## 33.4 Pilot Projects and Experiments

Throughout its history, the IGS has organized various campaigns, experiments, and pilot projects to actively support emerging GNSS developments and to prepare for the generation of new IGS products. Past examples include the International GLONASS Experiment [33.20] and the subsequent International GLONASS Service (IGLOS) pilot project [33.21], which laid the foundation for today's IGS GLONASS products. Another example is the GPS Tide Gauge Benchmark Monitoring (TIGA) project, which applies precise GPS results to monitor vertical motion of tide gauges. The TIGA pilot project became the TIGA Working Group in 2010. More recent activities include the IGS RTS and the Multi-GNSS Experiment (MGEX), which are discussed in this section.

### 33.4.1 Real-Time

Launched in April 2013, the IGS RTS generates GNSS products in real time to support Precise Point Positioning (PPP; Chap. 25) at global scales. It makes use of raw data which are continuously streamed from a subset of high-quality GNSS receivers in the global IGS network. The RTS products consist of GNSS satellite orbit and clock corrections. Data and products from the RTS provide real-time access to the global reference frame. The RTS is a public service made openly available to users that hold a free subscription.

Prior to launching the RTS, access to the global reference frame using IGS products has been *ex post factor* or *after-the-fact*. The RTS makes these products available with little or no latency to support PPP in real time. This enables scientific, educational, and commercial applications at worldwide scales, including geophysical hazard detection and warnings, conventional and space weather forecasting, time synchronization, and performance monitoring of GNSS constellations [33.22].

The RTS is built on the network of tracking stations, DCs and Real-Time Analysis Centers (RTACs) that underpin the global IGS network. Planning for the RTS has been underway since 2002, with careful attention given to network design and management, algorithm development, product generation, and defining real-time protocols and standards for accessing data and products. Support is provided by over 120 station operators, multiple DCs, and 10 RTACs around the world.

A brief outline of the RTS network and its data and products is provided below. Up-to-date information on the network status, product types, and performances as well as user access is provided through the IGS RTS website [33.23].

#### RTS Network

The RTS is built on the global IGS infrastructure that functions as a world standard for high-precision GNSS data and products. Contributions to the IGS are made on a collaborative and best-efforts basis, meaning the RTS including all data and products is offered without a service guarantee. However, it is these global contributions that build redundancy into the RTS and its products. The global RTS architecture ensures that a reliable flow of data and products is available without interruption.

The RTS comprises over 120 globally distributed GNSS stations maintained by a wide variety of local and region IGS operators. These stations deliver 1 Hz data to real-time DCs within the IGS network, with typical latencies of 3 s or less. The distribution of real-time tracking stations within the overall IGS network is illustrated in Fig. 33.2.

Network redundancy and a global distribution of stations are needed to provide full coverage and a reliable flow of real-time data. Coverage is challenging in some areas, particularly in regions of vast open ocean. Additional contributions to the network are encouraged where possible, however new stations in the RTS network must adhere to a minimum set of infrastructure standards and IGS best practices for real-time operations. Examples of these best practices are provided in [33.24] and illustrated in Fig. 33.4:

- Real-time data should be transmitted to a minimum of two separate real-time DCs.
- Stations that contribute to the realization of the IGS reference frame should be operated in real time to

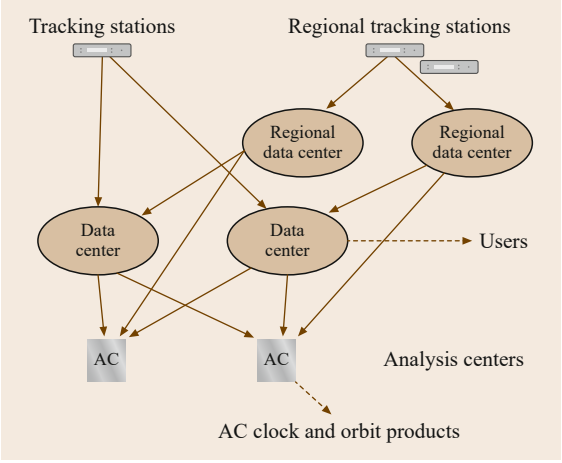

**Fig. 33.4** Real-time data is streamed to multiple DCs and ACs to build redundancy into the RTS (after [33.24])

guarantee reliable alignment of the real-time products to a stable reference frame.
- RTACs are encouraged to ingest data from two or more global data centers.

Individual correction products are produced within each RTAC once the real-time data streams have been received from each DC. The final orbit and clock correction products delivered from the RTS are actually a combination of the individual RTAC correction products, producing a more reliable and stable set of products than any single RTAC product alone.

This highly redundant design is made possible through the contribution of 10 RTACs within the RTS. Operational responsibility for producing the official combination products lies with the IGS RTAC Coordinator (RTACC), which is currently contributed by European Sapce Agency (ESA/ESOC) in Darmstadt, Germany. Figure 33.5 illustrates the RTS architecture for combining and distributing RTAC solutions via multiple DCs worldwide.

To support ongoing development and management of the RTS, the IGS RTWG addresses issues pertaining to infrastructure management and data analysis. The activities of the RTWG consist of planning, designing, and implementing next stages for the RTS, including development of multi-GNSS correction products and associated standards, along with outreach to new IGS participants and users of the RTS. This work is guided by the broader IGS strategy to enhance standards and best practices for GNSS infrastructure management and data availability to benefit the global user community.

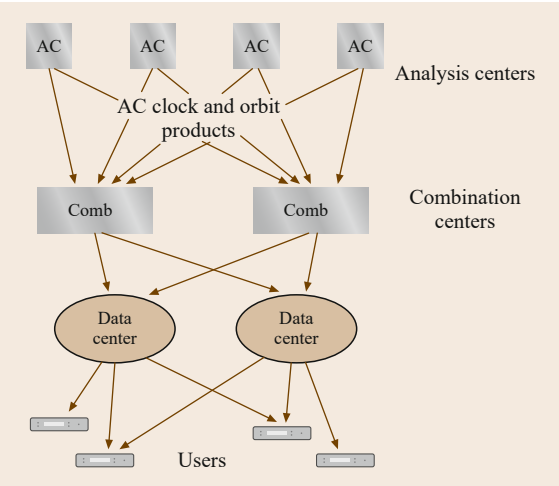

**Fig. 33.5** Orbit and clock corrections produced by each AC in the RTS are combined to deliver a more reliable and stable correction product to users (after [33.24])

### RTS Data and Products

To support global interoperability and integration of GNSS technologies and systems, the IGS develops and maintains standards and formats for disseminating GNSS data and products. IGS joined the Radio Technical Commission for Maritime Services Special Committee 104 (RTCM-SC104) in 2008 and adopted the RTCM-3 format for GPS and GLONASS observation messages shortly after. In Fig. 33.4, for example, the real-time GNSS data streams flowing from IGS tracking stations to the RTACs, via each DC, are formatted in the latest version RTCM-3 (most recently v3.2 [33.25]). Annex A.1.3 of this Handbook also describes the new RTCM3 Multi-Signal Message (MSM) format being developed to handle all GNSS constellations, signals, and observation types as part of the IGS Multi-GNSS Experiment (MGEX). Prototype MSM data streams are already being tested through the MGEX project and receiver manufacturers have started to release firmware supporting MSM [33.26].

The IGS has also adopted the RTCM-State Space Representation (RTCM-SSR [33.27]) format for disseminating real-time orbit and clock correction messages. RTCM-SSR currently supports GPS and GLONASS constellations. These orbit and clock corrections are expressed within the International Terrestrial Reference Frame 2008 (ITRF08) and are designed to enable real-time PPP. The combined resolution of the RTCM-SSR corrections supports millimeter-accuracy corrections, and these corrections are broadcast over the Internet using the Network Transport of RTCM by Internet Protocol (NTRIP, [33.28]). NTRIP is an RTCM standard for disseminating and receiving RTCM-SSR messages.

Official IGS products from the RTS service are described in the IGS Strategic Plan 2013-2016 and briefly summarized in Table 33.7. Aside from orbit and clock corrections, the RTS also provides real-time access to broadcast ephemeris through the two data streams described below:

- RTCM3EPH: Broadcast ephemeris data for GPS, GLONASS, and Galileo satellites. This data stream is derived from receivers in the real-time IGS global network and encoded in RTCM-3 messages. The complete set of messages is repeated every 5 s.
- RTCM3EPH01: A GPS-only broadcast ephemeris stream also derived from the real-time IGS global network and encoded in RTCM Version 3 messages with a 5 s repetition rate.

Along with the state-space correction messages, these broadcast ephemeris can be used to reconstruct

**Table 33.7** Content description of the RTS Product Streams (IGS, 2015b). APC: Antenna Phase Center; CoM: Center-of-Mass (not part of current RTCM-SSR standard). The figures in brackets next to each RTCM message ID denote the message sample interval in seconds

| Stream name | Description | Ref. point | RTCM messages | Provider/Sol. ID | Bandwidth (kbits/s) | Combination center |
|---|---|---|---|---|---|---|
| IGS01 | Orbit/Clock correction, single-epoch combination | APC | 1059 (5), 1060 (5) | 258/1 | 1.8 | ESA/ESOC |
| IGC01 | Orbit/Clock correction, single-epoch combination | CoM | 1059 (5), 1060 (5) | 258/9 | 1.8 | ESA/ESOC |
| IGS02 | Orbit/Clock correction, Kalman filter combination | APC | 1057 (60), 1058 (10), 1059 (10) | 258/2 | 0.6 | BKG |
| IGS03 | Orbit/Clock correction, Kalman filter combination | APC | 1057 (60), 1058(10), 1059(10), 1063(60), 1064(10), 1065(10) | 258/3 | 0.8 | BKG |

RTCM message types:

1057 GPS orbit corrections to Broadcast Ephemeris
1063 GLONASS orbit corrections to Broadcast Ephemeris
1058 GPS clock corrections to Broadcast Ephemeris
1064 GLONASS clock corrections to Broadcast Ephemeris
1059 GPS code biases
1065 GLONASS code biases
1060 Combined orbit and clock corrections to GPS Broadcast Ephemeris.

the precise orbit and clock information for use in real time or near-real-time PPP applications.

Standard IGS data and products are traditionally made available to users after-the-fact once a sufficient period of GNSS observation and processing has been undertaken to accurately model satellite orbits and clocks. The latency of these corrections ranges from hours to days to weeks depending on the final accuracy requirement. For example, *Final* orbit and clock products provide the highest accuracy and are delivered with a latency of 12–18 days. By contrast, the current RTS architecture enables real-time orbit and clocks products for GPS to be produced with an average latency of 25 s. The final accuracy of the RTS products is less than that of the Final IGS products, but sufficient enough to support real-time PPP. The accuracy, latency, continuity, and availability of all IGS orbit and clock products are compared in Table 33.2 above for the year 2013. Up-to-date performance monitoring results of the real-time products are provided at the IGS RTS website [33.23] on a routine basis.

### 33.4.2 Multi-GNSS

Today there are many GNSS signals available from multiple satellite navigation systems in addition to the well-known US Global Positioning System (Table 33.8). Other global systems include the Russian Global'naya Navigatsionnaya Sputnikovaya Sistema (GLONASS), the Chinese BeiDou Navigation Satellite System (BDS), and Europe's Galileo. In addition to the global systems, there also exist regional systems such as the Japanese Quasi-Zenith Satellite System (QZSS) and the Indian Regional Navigation Satellite System (IRNSS/NavIC) as well as various Satellite-Based Augmentation Systems. This multi-GNSS environment offers various advantages to the users:

- Increased signal availability, even in undesirable environments (such as urban canyons)
- Increased number of frequency bands to improve robustness against interference
- Superior continuity of service and reduced dependency on a single system
- Efficiency gains due to faster ambiguity resolution
- Better reliability and redundancy, which enhances outlier detection
- Improvements in accuracy of position estimates.

The IGS Multi-GNSS Working Group (MGWG) was formed by the IGS in recognition of the rapidly evolving GNSS landscape to explore and promote the use of new constellations and navigation signals. The core activity of the MGWG is the Multi-GNSS Experiment (MGEX), which aims to build up a network of sensor stations, characterize the space segment and user equipment, develop theory and data-processing tools, and generate data products for the emerging satellite systems. The MGWG works closely with other IGS entities, such as the Data Center Working Group, the

**Table 33.8** Global and regional satellite system deployment status and transmitted signals as of Oct. 2016. Brackets denote satellites not yet declared operational

| System | Type | Signals | Satellites |
|---|---|---|---|
| GPS | IIR | L1 C/A, L1/L2 P(Y) | 12 |
| | IIR-M | +L2C | 7 |
| | IIF | +L5 | 12 |
| GLONASS | M | L1/L2 C/A + P | 23 |

| | GEO | L5, S | 3 |

Antenna Working Group, and the Infrastructure Committee to achieve these goals.

The Multi-GNSS EXperiment was launched in February 2012. It was initially targeted at the global tracking of new and modernized GNSS signals as well as the build-up of analysis center capabilities to process such data and to generate associated multi-GNSS products. Within a couple of years, most of these goals have been reached and the IGS can offer its user a global network with multi-GNSS tracking capabilities supported by the corresponding data centers, analysis centers, and prototype products [33.26].

### MGEX Network

Starting from a handful of individual stations available in early 2012, the MGEX network has grown to almost 130 sensor stations providing global/regional coverage of GPS, GLONASS, BeiDou, Galileo, and QZSS in late 2015. Figure 33.6 illustrates the location of stations offering tracking of at least one of the new constellations in addition to GPS or GLONASS.

The MGEX network contains a diverse assortment of receiver and antenna equipment with five basic receiver types and eight main antenna types. All of the user equipment in the MGEX network is recognized and characterized by the IGS in the equipment description file. Many of the stations contain multiple receivers connected to the same antenna, known as a *zero-baseline* setup, which provides a basis for cross-validation of equipment performance. Some of the sites also contain multiple stations for short baseline comparison experiments. The variety of equipment used in the tracking network is both an asset as well as a challenge. The diversity of deployed receivers and antennas poses a challenge for consistent data processing, but allows a greater understanding of the types of data received and how the assessment of navigation signals is to proceed. The cross comparison of different receivers can contribute directly to design improvement by receiver manufacturers.

During the initial deployment of the MGEX network, relaxed site requirements were imposed on new station contributions and the network was essentially operated independently and in parallel to the legacy IGS tracking network for GPS and GLONASS to avoid any adverse impact on the standard IGS product generation. With the ongoing modernization of the legacy stations and the improved quality of new MGEX contributions, the vast majority of MGEX stations could ultimately be integrated into the standard IGS network in the course of 2015. Users can now take advantage of a single network of stations meeting the high-quality standards imposed by the IGS site guidelines. While only a subset of all IGS stations is presently multi-GNSS capable, the fraction of such stations is expected to grow continuously over time in the years to come.

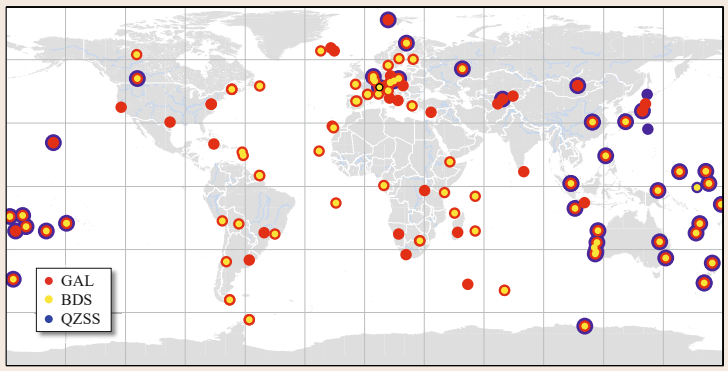

**Fig. 33.6** MGEX network of stations (Oct. 2015)

**Table 33.9** MGEX analysis centers generating precise multi-GNSS orbit and clock products on a routine basis (Oct. 2016)

| Institution | Constellations |
|---|---|
| CNES/CLS, France [33.30] | GPS + GLO + GAL |
| CODE, Switzerland [33.31] | GPS + GLO + BDS + GAL + QZS |
| GFZ, Germany [33.32, 33] | GPS + GLO + BDS + GAL + QZS |
| JAXA, Japan | GPS + QZS |
| TUM, Germany [33.34] | GAL + QZS |
| Wuhan Univ., China [33.35] | GPS + GLO + BDS + GAL + QZS |

All IGS multi-GNSS stations provide offline observation files in RINEX3 format [33.29], which supports all required observation types and constellations. Data archives are hosted by established IGS DCs including NASA's Crustal Dynamics Data Information System (CDDIS) in the United States, the French National Geographic Institute (IGN), and the German Federal Office for Cartography and Geodesy (BKG) Daily RINEX3 files with observation rates of 30 s are made available for all multi-GNSS stations and a subset of stations also delivers high-rate data files with 1 Hz observation data.

Next to the offline data, roughly 60% of all multi-GNSS stations also provide their data as real-time data streams. Where needed, manufacturer-specific data formats are encoded in the RTCM3 Multiple-Signal-Message (MSM) format once received from the individual sites and transferred to a dedicated MGEX NTRIP caster hosted by BKG in Frankfurt. The dedicated caster provides an experimental platform on which the new MSM format can be tested and facilitates user software adaptation.

### MGEX Products

The data collected by the MGEX network provide the basis for the generation of precise orbit and clock products for the new constellations. As of late 2015, six analysis centers contribute such products to the MGEX project on a regular basis (Table 33.9). While early products were often confined to individual GNSSs, a growing number of ACs have lately moved to generating five-constellation products with a common underlying time and reference frame. Except for the Indian Regional Navigation Satellite System, the MGEX products thus cover all legacy and emerging navigation systems. Addition of IRNSS is foreseen, once an adequate number of monitoring stations with dual-frequency IRNSS tracking capability becomes available within the IGS.

Clock products were initially confined to 5 min or 15 min but have later been made available with sampling intervals of down to 30 s. Furthermore, various ACs also provide associated data such as Earth orientation parameters, intersystem biases, or estimated station coordinates along with their orbit and clock products.

Other than for GPS and GLONASS, no combination process has yet been implemented within the IGS for precise orbit and clock products of the new constellations, but cross-comparison of different ACs as well as satellite laser ranging can serve to assess the precision or accuracy of the various products. For Galileo, a performance at the 10–20 cm level (3-D rms orbit consistency and differences w.r.t. SLR observations) has been demonstrated in [33.36] for the 2013–2014 time frame. Further improvements are expected through better characterization of the spacecraft and respective refinements of radiation pressure models or antenna phase center variations. A performance at the few dm-level is also achieved for BeiDou MEO and IGSO satellite, whereas the orbit consistency for geostationary satellites is limited to a few meters [33.37]. The degraded GEO orbit determination accuracy reflects the adverse impact of a near-static viewing geometry, which does not enable a reliable determination of the along-track position from one-way pseudorange and carrier-phase observations.

Even though the accuracy of the multi-GNSS products lags behind the performance of the standard IGS products for GPS and GLONASS, they pave the way for a full exploitation of new signals and constellations in navigation, surveying, geodesy, and remote sensing.

Special products provided in the frame of MGEX include combined multi-GNSS broadcast ephemeris data as well as multi-GNSS DCBs. The combined broadcast ephemeris data have initially served as a substitute for constellations not yet covered by the precise orbit and clock products, but are of continued interest because of their lower latency and the access to GNSS-specific system time scales.

An understanding of DCB is a prerequisite for processing multiconstellation code observations, which are essential in many navigation applications. They are also essential for many nonnavigation applications such as time transfer and ionospheric analysis for correction of pseudorange differences. The need for comprehensive DCB analysis is increasing as the rate of signals offered by new and modernized satellite systems rises. Prototype DCB products generated by the German Aerospace Center (DLR) and the Chinese Academy of Science (CAS) are available through MGEX at the CDDIS and IGN product archives. GPS, GLONASS, Galileo, and BeiDou DCBs are derived from pseudorange differences corrected for ionosphere path delays [33.19] and are provided in a preliminary version of the Bias SINEX format, which is currently under development within the

IGS and will serve as the new standard for the exchange of phase and code bias information.

For real-time users, early services include a combined multi-GNSS broadcast ephemeris stream (including GPS, GLONASS, Galileo, BeiDou, QZSS, and SBAS) prepared by BKG as well as Galileo orbit and clock corrections generated by the CNES/ILS analysis center.

For further information about MGEX, including news, constellation status, network and station information, data holdings, real-time data, and products, users are referred to the IGS MGEX website [33.38]. In the long run, it is planned to integrate all MGEX products into the regular IGS processing to offer a reliable and high-performance multi-GNSS service to the GNSS community.

## 33.5 Outlook

The IGS continues to evolve into a truly multi-GNSS service. It is expected that the new constellations of positioning satellites will be fully operational by 2020. This has driven the IGS to commence a strategic review of its activities, products, and services. While it is clear that the IGS has a role to play in producing products for all constellations (orbits and clocks), it is not so clear which combinations of signals will be utilized for the products that are nonconstellation-specific including the reference frame and atmospheric products. A considerable body of research is currently being undertaken to establish evidence to support such decisions.

As the uptake of GNSS as a public utility continues, an emerging need to understand the accuracy and integrity of all positioning satellites, including their system differences, is becoming evident. The use of GNSS now extends well beyond the military and science applications, including many industrial and Location Based Services (LBS) applications. The IGS has been cooperating with Working Group A of the International Committee on Global Navigation Satellite Systems (ICG) to develop a common understanding of the requirement for system monitoring through the International GNSS Monitoring and Assessment (IGMA) subgroup.

Lastly, through GGOS, it has become clear that SLR observations to GNSS satellites and GNSS observations on non-GNSS satellites like GRACE, have a strong role to play in improving our understanding of observational errors, and therefore improving the accuracy of IGS products. The IGS will continue to collaborate with other elements of the GGOS to integrate these observations into the product generation.

# 34. Orbit and Clock Product Generation

Jan P. Weiss, Peter Steigenberger, Tim Springer

Many sophisticated Global Navigation Satellite System (GNSS) applications require high-precision satellite orbit and clock products. The GNSS orbits and clocks are usually derived from the analysis of tracking data collected by a globally distributed GNSS receiver network. The estimation process adjusts parameters for the satellite orbits, transmitter and receiver clocks, station positions, tropospheric delays, Earth orientation, intersystem and interfrequency biases, and carrier-phase ambiguities. The estimation requires detailed modeling of geophysical processes, atmospheric and relativistic effects, receiver tracking modes, antenna phase centers, spacecraft properties, and attitude control algorithms. This chapter describes precise orbit and clock determination of the GNSS constellations as performed by the analysis centers of the International GNSS Service, including models, estimation strategies, products, and the combination of orbit and clock solutions.

Most applications of GNSS rely on knowledge of the orbital positions and clock offsets of the transmitter satellites. These parameters are obtained from an estimation process that combines tracking data from terrestrial stations, measurement models, and satellite force models to adjust a set of parameters representing station positions, atmospheric delays, satellite orbits, clock offsets, and the Earth's orientation.

There are broadly three communities performing routine orbit and clock determination of the GNSS constellations: the control segments, the analysis centers (ACs) of the International GNSS Service (IGS; Chap. 33), and commercial services. The GNSS operational control segments perform orbit and clock determination in real time or near real time using tracking data from a limited set of highly secure ground stations. The orbit and clock solutions are then predicted forward and transmitted to users via the navigation message for real-time use. While the Global Positioning System (GPS) and Global'naya Navigatsionnaya Sput-

nikova Sistema (GLONASS) broadcast orbit and clock have been very good in recent years, they are nevertheless significantly less accurate than solutions produced by the IGS or comparable precise services [34.1]. The main reason for this is that the broadcast orbit and clock is predicted based on a *zero age of data* solution derived from a small tracking network. The prediction time-span can be significant: currently for GPS and GLONASS the update interval can be as long as 24 h. For Galileo, the update rate is reduced to about 100 min, which makes more accurate broadcast ephemerides possible. However, the accuracy of broadcast ephemerides is not likely to become sufficient for applications requiring decimeter or better positioning and time transfer, which in turn drives the need for more accurate and precise orbit determination (POD) and clock products.

The main goals of the IGS are to collect and archive GNSS data from a global network, and to generate precise products for the GNSS constellations. The products of the IGS, in particular the orbits, clocks, and station positions give users direct access to the International Terrestrial Reference Frame (ITRF) with accuracies not previously available with such ease. By taking at least one of the stations of the IGS tracking network, the IGS orbits, and the IGS station position solution, a user can position a network of stations with millimeter precision in the global reference frame. The high quality and public availability of the IGS products have led to the use of GNSS for many new applications, for example, meteorology and time transfer, and most certainly paved the way for commercial high-accuracy GNSS services operating in the market today. Details of the roles and products of the IGS are given in Chap. 33.

Commercial services typically aim to bridge the gap between the control segment solutions, which are very robust but have lower accuracy, and products available from the IGS, which are very accurate but provided on a *best effort* basis. These services generally cater to precise real-time navigation needs of, for example, the maritime and agricultural industries.

This chapter describes what is required for the generation of highly accurate GNSS orbit and clock products for the most demanding applications. We discuss the tracking network, describe relevant models, key GNSS system parameters, estimation strategies, and software implementations. We summarize post-processed GNSS products available from analysis and combination centers, and look at POD for multiple GNSS constellations.

## 34.1 Global Tracking Network

GNSS POD requires geodetic GNSS tracking stations providing at least dual-frequency measurements to account for ionospheric path delays. A globally distributed tracking station network is needed to ensure adequate observation strength for all satellites at every epoch in the processing arc. This particularly benefits clock offset determination since these parameters are normally not constrained in the estimation. Due to the unknown satellite and receiver clock offsets, and the ambiguous carrier-phase observations, GNSS phase observations contain only limited information regarding the station-satellite geometry. Basically, the carrier-phase observations only provide information about the change in the station-satellite geometry between observation epochs. This lack of information may be overcome – to a certain extent – by ensuring that the satellites are always observed by multiple ground stations. Complete loss of tracking of a satellite, even for only a few epochs, would mean that all the carrier-phase observations will be reset, and thus new ambiguity parameters will have to be estimated. This not only weakens the solutions with regard to orbital parameters, but also makes it impossible to solve for the transmitter clock offset during the outage.

An interesting question is how many stations are needed to obtain an acceptable high-accuracy solution. The response is driven by the following considerations:

- *Accuracy*: while additional stations in principle improve the accuracy and robustness of the solution, there is a point of marginal return given the precision of the measurements and redundancies in the tracking geometry (we expect accuracy to improve as a function of $\sqrt{n}$, where $n$ is the number of observations).
- *Computational expense*: more stations lead to longer computation times, typically increasing by a factor of $p^2$, where $p$ is the number of estimated parameters. This is a key consideration for services with stringent latency requirements, as fewer stations allow for faster processing.
- *Station costs*: more stations mean more costs for equipment installation and data transmission. This is an important factor for services relying on pro-

prietary networks (GNSS operators and commercial providers).

To investigate the impacts of the size of the network, we computed GPS POD solutions for eight consecutive days using real data from a network of 20 to 100 stations in steps of five. The obtained orbit quality was determined by comparing the resulting orbit to the IGS final orbit for the days in question. Figure 34.1 plots the median of the (absolute) residuals of the orbit differences as a function of the number of stations that were used in the solution. When increasing the number of stations, we kept the previous network and added new stations.

The results in Fig. 34.1 indicate that 60 stations should be sufficient to reach IGS orbit quality. A further increase in the number of stations does not significantly improve the orbit quality, at least not as reflected in the median of the squared residuals. So we may conclude that 60 stations are sufficient to achieve the accuracy of the IGS Rapid or Final products, as long as the tracking network is sufficiently well distributed to track all satellites from at least a handful of stations at any given epoch.

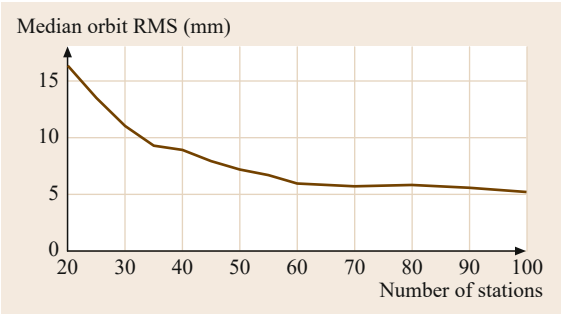

**Fig. 34.1** Relation between the number of stations and the satellite orbit quality compared to the final orbits of the IGS

## 34.2 Models

GNSS software developers are well aware of meter level corrections that must be applied to range observations to eliminate effects such as special and general relativity, clock offsets, and atmospheric delays. All these effects are quite large, exceeding several meters, and must be considered even for pseudorange-only applications. When combining satellite positions and clocks precise to a few centimeters with ionospheric-free carrier-phase observations (few millimeter resolution), it becomes important to apply additional corrections that may not need to be considered in pseudorange or even differential phase processing.

This section describes relevant models given in the IERS conventions [34.2], followed by discussions of antenna phase center calibrations and key parameters related to the GNSS spacecraft. An overview of the important models is given in Table 34.1. References to sections of this handbook with more detailed information are given in the right column.

### 34.2.1 Reference Frame Transformation

The orbit dynamics of GNSS satellites is usually modeled in an Earth-centered inertial (ECI) frame (Sect. 3.2). However, station and satellite positions are conventionally expressed in an Earth-centered Earth-fixed (ECEF) reference frame, so a transformation between the ECI and the ECEF frame is necessary. This transformation is traditionally composed of three components (Sect. 2.5):

- Precession and nutation
- Polar motion
- UT1 and length of day (LOD).

In global GNSS solutions, precession and nutation are modeled with the IAU2000A R06 model, whereas polar motion and LOD are usually estimated (Sect. 34.4.6). UT1 cannot be determined by GNSS due to correlations with cross-track components of estimated orbital elements [34.3]. As a consequence, UT1 is fixed to values determined by very long baseline interferometry (VLBI) published in the *Bulletin A* [34.4] or the IERS C04 series [34.5]. As polar motion and LOD parameters are usually estimated with a temporal resolutions of 1 day, subdaily variations in these parameters mainly caused by ocean tides have to be considered with a specific model (Table 34.1).

### 34.2.2 Site Displacement Effects

Terrestrial stations undergo periodic movements (real or apparent) reaching a few decimeters that are not included in linear terrestrial reference frame (TRF) position models. Details are given in Chap. 2. Since most of the periodic station movements are nearly the same over broad areas of the Earth, they nearly cancel in relative positioning over short ($< 100$ km) baselines. However, to obtain precise station coordinates consistent with ITRF conventions with longer baselines or undifferenced processing, such station movements must

be considered. This is accomplished by adding the site displacement correction terms to the linear nominal coordinates. The most significant corrections are summarized next.

### Solid Earth Tides

The *solid* Earth is deformed due to the gravitational forces of the Sun and Moon. These solar and lunar tides cause periodic vertical and horizontal site displacements, which can reach about 30 cm and 5 cm in the radial and horizontal directions, respectively (Sect. 2.3.5). There is a latitude-dependent permanent displacement and a periodic displacement with predominantly semidiurnal and diurnal periods of changing amplitudes (Fig. 34.2). The periodic part is largely averaged out for static positioning over 24 h. The permanent part, however, remains. Even when averaging over long periods, neglecting this effect in point positioning would result in systematic position errors of up to 12 cm and 5 cm in the radial and horizontal directions, respectively.

The solid Earth tides may be represented by spherical harmonics of degree and order $(n, m)$ characterized by the Love number $h_m$ and the Shida number $l_n$. The effective values of these numbers weakly depend on station latitude and tidal frequency, which need to be taken into account when a millimeter-level position solution is desired. Note that the estimated ITRF station positions are corrected for the (conventional) permanent part of the solid Earth tides, resulting in a so-called *conventional* coordinate system.

### Tidal Ocean Loading

Ocean loading results mainly from the load of ocean tides on the Earth's crust and is dominated by diurnal and semidiurnal periods (Fig 34.3). Displacements due to tidal ocean loading are almost an order of magnitude smaller than those due to solid Earth tides. Tidal ocean loading is also more localized, and by convention does not have a permanent component. Tidal ocean loading effects can be modeled for any station using the software package provided with the IERS conventions [34.2]. Computation of the station-specific loading effects using HARDISP requires the amplitudes and phases for the radial, south (positive), and west (positive), directions. The amplitudes and phases for any site may be obtained from the on-line ocean loading service of Chalmers University [34.32].

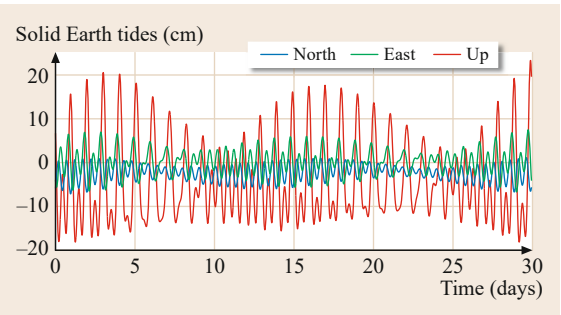

**Fig. 34.2** Deformations due to solid Earth tides at Wettzell, Germany

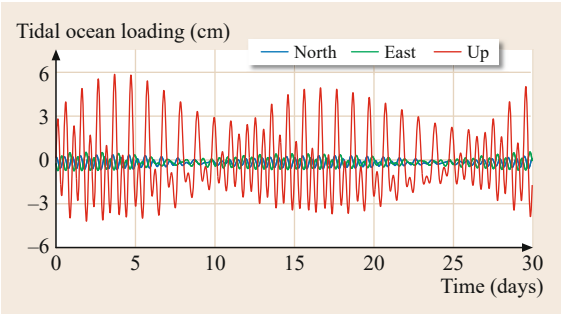

**Fig. 34.3** Deformations due to tidal ocean loading at O'Higgins, Antarctica

Typically, the M2 amplitudes are the largest and do not exceed 5 cm in the radial and 2 cm in the horizontal directions for coastal stations. For centimeter precision, one should use a recent global ocean tide model, such as FES2004, EOT11a, FES2012, or newer. It may even be necessary to augment the global tidal model with local ocean tides digitized, for example, from local tidal charts. The station-specific amplitudes and phases may also include subdaily center-of-mass (CoM) tidal variations. In that case, ocean loading corrections have to be included for all stations regardless of proximity to an ocean. To be consistent with the subdaily Earth orientation parameter (EOP) convention, the IGS includes subdaily tidal CoM in ocean loading corrections when generating IGS POD solutions.

### Pole Tides

Changes in the Earth's spin axis with respect to its crust, that is, the polar motion, cause periodical deformations due to minute changes in the Earth centrifugal potential. The variation of station coordinates caused by the pole tide can amount to around 2 cm and therefore needs to be taken into account. Unlike solid Earth tide and ocean loading effects, the pole tides do not average to nearly zero over 24 h. They are slowly changing according to the polar motion, and predominately vary at seasonal and Chandler (430 days) periods. Polar motion can reach up to 0.8 as and the maximum polar tide displacements can be up to 25 mm in height and 7 mm in the horizontal directions [34.2].

### Ocean Pole Tides

The ocean pole tide is generated by the centrifugal effect of polar motion on the oceans. Polar motion is dominated by the 14-month Chandler wobble and annual variations. At these long periods, the ocean pole tide is expected to have an equilibrium response, where the displaced ocean surface is in equilibrium with the forcing equipotential surface. A self-consistent equilibrium model of the ocean pole tide is presented in [34.11]. This model accounts for continental boundaries, mass conservation over the oceans, self-gravitation, and loading of the ocean floor. The load deformation vector is expressed in terms of radial, north, and east components and is a function of the wobble parameters. Given that the amplitude of the wobble parameters is typically of order 0.3 as, the load deformation is typically no larger than about (1.8, 0.5, 0.5) mm in the (radial, north, east) components.

### Tidal Atmospheric Loading

The diurnal heating of the atmosphere causes surface pressure oscillations at diurnal S1, semidiurnal S2, and higher harmonics. These atmospheric tides induce periodic motions on the Earth's surface [34.33]. The maximum amplitude of the vertical deformation is 1.5 mm for both the S1 and the S2 component. Being close to the orbital period of the GPS satellites, modeling of the S2 effect is especially important in order to minimize aliasing into dynamic parameters [34.34]. The IERS2010 conventions recommend calculating the station displacement using the S1 and S2 tidal model given by [34.12] (Fig. 34.4). As of 2015, not all IGS analysis centers apply tidal atmospheric loading models but this will likely be harmonized in time for the next IGS reprocessing campaign.

## 34.2.3 Tropospheric Delay

The nondispersive delay imparted by the atmosphere on a radio signal up to 30 GHz in frequency reaches a magnitude of about 2.3 m in the zenith direction at sea level [34.35]. It is conveniently divided into hydrostatic and wet components. The hydrostatic delay is caused by the refractivity of the dry gases (mainly $N_2$ and $O_2$) in the troposphere and by most of the nondipole component of the water vapor refractivity. The rest of the water vapor refractivity is responsible for most of the wet delay. The hydrostatic delay component accounts for roughly 90% of the total delay at any given site globally, but can vary between 80 and 100% depending on location and time of year. The relation between the delay at zenith direction and the actual observation direction is given by a mapping function (Chap. 6). Common mapping functions are the empirical Global Mapping Function (GMF, [34.14]) and the Vienna Mapping Function 1 (VMF1, [34.36]).

The hydrostatic delay can be accurately computed a priori based on reliable surface pressure data using the formula of [34.37] as given by [34.38]. One source for pressure data are the Global Pressure and Temperature (GPT) model and its successor GPT2 [34.13, 15]. Another possibility is the use of troposphere zenith delays derived from numerical weather models. Global grids with a spatial resolution of 2.0°×2.5° and a temporal resolution of 6 h obtained from European Centre for Medium-Range Weather Forecasts (ECMWF) data are provided together with the VMF1 coefficients.

There is currently no simple method to derive an accurate a priori value for the wet tropospheric delay, although research continues into the use of external monitoring devices (such as water vapor radiometers) for this purpose. Thus, in precise applications the residual zenith delay is usually estimated. Likewise, horizontal troposphere gradient parameters, needed to account for a systematic component in the North/South direction, are estimated rather than modeled (Sect. 34.4.3).

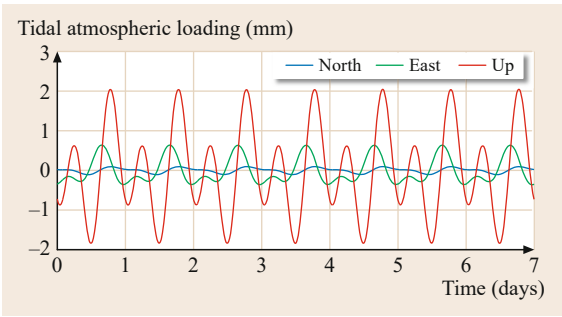

**Fig. 34.4** Deformations due to tidal atmospheric loading at Fortaleza, Brazil

## 34.2.4 Ionospheric Delay

GNSS signals are refracted by free electrons and ions in the ionosphere, causing the signals to bend and change speed as they traverse this region. The ionization is caused by rays from the Sun and depends strongly on local time and solar activity. The signal delay due to the ionosphere can vary from meters to tens of meters depending on the ray path and ionospheric activity [34.35]. The delay is dispersive and may be eliminated to first order by linearly combining observations on two or more frequencies (with the side effect of increasing measurement noise, Sect. 20.2.3).

The second-order ionospheric effect can be removed using total electron content (TEC) estimates based on tracking data, an estimated global ionosphere model (GIM), or a climatological model such as the

International Reference Ionosphere [34.39]. The effect can be as large as a few centimeters and should be considered in precise GNSS analyses. An important impact of modeling second-order ionospheric delays is on the recovered terrestrial reference frame, which experiences an apparent southward shift of station coordinates of up to a few millimeters [34.40, 41]. For TRF comparisons spanning several years, this can equate to just over 1 cm in the Helmert transformation $z$-translation component at the fit epoch [34.42]. Other TRF transformation parameters are negligibly affected. There is also a small impact to satellite orbit positions (a few millimeter shift that is latitude dependent) and up to a 1 cm difference in the transmitter clock estimates [34.43]. Third-order ionospheric delay effects accumulate due to small path differences between signals at different frequencies. These can reach 1 mm in magnitude and are typically ignored in contemporary GNSS processing [34.17, 44]. Another ionospheric effect that is neglected by most IGS ACs is related to ray bending (excess path length) although it can reach a few millimeters at low elevations [34.2].

### 34.2.5 Relativistic Effects

Relativistic effects relevant for GNSS can be separated into three categories:

- Orbit effects (Sect. 3.2.2)
- Clock effects (Sect. 5.4)
- Propagation effects (Sect. 19.2).

The largest effect is a periodic transmitter clock variation caused by the noncircular orbits of the GNSS satellites. As a result, the satellites' speed and gravitational potential vary with orbital position, introducing a once-per-revolution variation of the transmitter clock with an amplitude of about 23 ns for a GPS satellite with an eccentricity of 0.01 [34.45]. In GNSS POD processing (including IGS products) this effect is modeled by convention, so the published transmitter clocks do not include this term. Smaller effects due to the oblateness of the Earth [34.46] and higher order terms of the Earth's gravity field are usually not considered for the product generation.

### 34.2.6 Antenna Phase Center Calibrations

Antenna calibrations are critical to high-accuracy GNSS processing. The calibrations define the points in space at which the electromagnetic ranging signal emanates from the transmitter antenna and induces voltage in the receiver antenna. In other words, the measurement geometry refers to the electrical phase centers. These are a function of local azimuth and elevation, frequency, and pseudorange or carrier phase (i. e., group or phase delay). Phase center calibrations are typically separated into a phase center offset (PCO, mean of the total calibration) and a phase center variation (PCV), which varies as a function of azimuth and elevation. In the IGS, absolute calibration standards have been adopted since 2006 [34.47]. The reader is referred to Chap. 17 and Sect. 19.5 for more details.

The transmitter calibrations are needed to refer range measurements to the spacecraft CoM. This is an important link because in POD the modeled spacecraft dynamics and estimated orbits refer to the CoM. The corresponding clock estimates, however, refer to the transmitter antenna phase center. Hence a user of precise products must apply antenna calibrations consistent with those used in the POD solution in order to realize the best accuracy.

Antenna calibration models are closely related to TRF implementation in POD. This is because antenna PCOs in the radial direction for both transmitters and receivers are not separable from TRF scale. IGS standard transmitter antenna calibrations are estimated while keeping scale fixed to a particular ITRF realization. The calibrations are estimated in global POD solutions, with receiver antenna positions fixed to the ITRF and ground calibrations fixed to absolute test range measurements [34.47]. In this manner, the TRF scale is handed off to the transmitter calibrations. It is therefore necessary to apply antenna calibrations consistent with the desired ITRF realization in POD solutions. Furthermore, a consistent set of calibrations must be derived for each version of the ITRF.

### 34.2.7 Phase Wind-Up

GNSS satellites transmit circularly polarized radio waves, so the observed carrier-phase depends on the mutual orientation of the satellite and receiver antennas. A full rotation of either the receiver or transmitter antenna around its boresight axis will change the carrier-phase measurement by one cycle. This effect is called *phase wind-up* [34.20]. A static receiver antenna remains oriented toward a fixed reference direction (usually north), but the motion of the transmitter relative to its boresight induces wind-up. Furthermore, the transmitter antennas rotate as the satellites yaw about their Earth-pointing axis (coincident with the antenna boresight, see Sect. 34.2.8).

During a satellite eclipse, the rotation can reach up to one revolution within half an hour. Consequently the phase data should be corrected for the wind-up effect. If wind-up is neglected in POD processing, the unmodeled change in carrier phase is absorbed as much as possible in unrelated parameters (Sect. 34.2.8).

### 34.2.8 GNSS Transmitter Models and Information

High-accuracy POD requires knowledge of and models for many satellite system parameters. These include satellite attitude, physical spacecraft geometry and material properties, operational information regarding the pseudo-random noise (PRN) codes transmitted by each space vehicle, maneuvers, and satellite health.

#### Spacecraft Attitude

POD requires knowledge of the satellite's attitude to relate range measurements from the antenna phase center to the spacecraft CoM using known antenna calibrations in the spacecraft body system. Nominal GNSS attitude control is guided by two constraints: pointing the transmit antenna toward the Earth's center, and pointing the solar panels, which rotate about their longitudinal axis, toward the Sun in order to obtain maximum energy transfer (Sect. 3.4). As discussed in [34.21], the IGS commonly adopts a right-handed spacecraft coordinate system where the body-fixed $z$-axis is aligned with the antenna boresight direction, where the $y$-axis points along the solar panel longitudinal axis, and $x$ completes the right-handed set. Typically, the $z$-axis is controlled to point to the center of the Earth and the $y$-axis is kept perpendicular to the Sun direction. Within this so-called yaw-steering mode [34.48], the yaw angle $\Psi$ is the angle between the $x$-axis of the spacecraft and the along-track direction (or, approximately, the velocity vector $\boldsymbol{v}$). This geometry is illustrated in Fig. 34.5.

To maintain nominal attitude, the spacecraft yaws about its $z$-axis and rotates the solar panels about $y$ as it traverses the orbit. Because the solar panels can only rotate by 180°, the satellite performs a yaw maneuver at orbit noon and midnight (represented by $\mu$ equal to 180° and 0° when the spacecraft is closest and furthest from the Sun, respectively) so the solar panels can track the Sun for the next semi-orbit. The rate of the noon and midnight yaw maneuvers depend on the elevation of the Sun above the orbital plane of the GNSS satellite, commonly referred to as $\beta$ (Fig. 34.5). The smaller $\beta$, the faster the satellite has to maneuver to maintain nominal attitude.

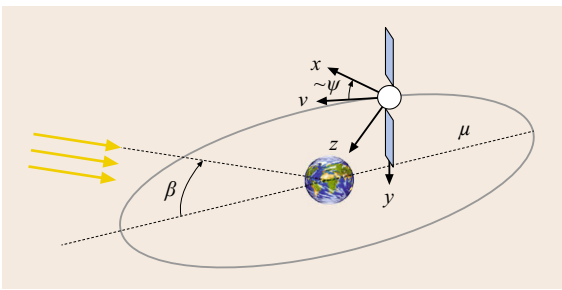

**Fig. 34.5** Illustration of spacecraft body-fixed coordinate system and yaw attitude

Due to hardware limitations, GNSS satellites cannot maintain nominal attitude for small $\beta$ angles. Spacecraft attitude control during these periods differs for each GNSS and even for satellite types within a GNSS. Correct attitude modeling is important because mismodeled yaw attitude in principle introduces errors in all estimated parameters. Mismodeled attitude in particular affects transmitter clock estimates because yaw maneuvers induce phase wind-up that is essentially common to all stations observing a satellite and therefore induces a clock-like effect. Detailed descriptions of the GPS, GLONASS, Galileo, BeiDou, and Quasi-Zenith Satellite System (QZSS) attitude models are found in Sect. 19.4.2.

#### Spacecraft Structure

Space vehicle geometry and material properties relate to dynamic force models. After gravity from the Earth, Moon, and Sun, solar radiation pressure (SRP) is the third largest force acting on a satellite orbiting the Earth at GNSS altitudes (Chap. 3). The magnitude and direction of the SRP depends on the satellite attitude and the spacecraft's structural geometry and material properties. Several approaches for dealing with SRP have been devised.

One approach is to solve for empirical accelerations representing SRP and other unmodeled forces in each orbit solution. This strategy originated at the Center for Orbit Determination in Europe (CODE), one of the IGS ACs, and is discussed further in Sect. 34.4.4 below.

A second approach is to generate an empirical SRP model from dynamic fits to precise orbits. The result becomes a background model in POD solution which then estimate only tightly constrained correction factors. The Jet Propulsion Laboratory (JPL) GNSS solar pressure model follows this approach to formulate Fourier expansions representing acceleration due to SRP as a function of the spacecraft type, orbit plane $\beta$ angle, and satellite orbit angle $\mu$ [34.49, 50].

A third approach is to apply ray-tracing techniques to the spacecraft structure and optical material properties. Published models include early work by [34.51], resulting in a set of *ROCK* models for GPS Block I/II, as well as work by [34.52] for the GPS IIR spacecraft. Ray-tracing approaches are attractive because they promise to isolate the effects of SRP from other nonconservative forces, but are burdened by heavy computational loads for their generation and typically limited access to precise physical property information for the GNSS spacecraft.

In addition to SRP, POD nowadays requires modeling of forces on the GNSS spacecraft from optical and infrared Earth radiation, or Earth albedo [34.53]. Albedo radiation explains about half of the few-centimeter height biases seen between radiometric orbits and satellite laser ranging (SLR) measurements [34.54]. Currently all IGS ACs implement albedo visible and infrared models. Most use a model developed by [34.55] that computes albedo forces as a function of spacecraft type, position, time, and Sun position based on measurements of Earth radiation made by the Clouds and the Earth's Radiant Energy System (CERES, [34.56]). The forces due to albedo are largest in the radial orbit component.

#### Antenna Thrust

GNSS transmitters emit electromagnetic signals with total transmit powers upward of 70 W [34.29]. This results in a *recoil* acceleration in the orbit radial direction, which is now modeled by most IGS ACs, at least for GPS and GLONASS [34.52]. While the impact can be absorbed by an empirical acceleration parameter, modeling this physical effect in principle improves the recovery of transmitter phase centers and clock offsets since these parameters are correlated with antenna thrust.

#### Operational Information

Operational GNSS information is also needed for POD of GNSS satellites. Receivers typically identify the observations of tracked satellites by the number of their PRN code or the orbital slot number (for GLONASS). However, they do not know the relation between a given PRN/slot and the physical spacecraft, which may vary over time. Complementary knowledge of the unique space vehicle number (SVN) is required for POD because it defines characteristics including attitude control mechanisms, solar pressure and Earth radiation response, clock properties, antenna calibration, signal types, and emitted power. PRN/SVN assignments are tracked by the IGS ACs based on information provided by the GNSS system operators where available (see, e.g., the constellation status websites summarized in Table 34.2).

Knowledge of satellite health status over time, as extracted from the navigation message, is needed because unhealthy periods may indicate payload maintenance, orbit maneuvers, or nonstandard signal transmission. One typically excludes unhealthy satellites from low-latency, automated processing (e.g., ultra-rapid and rapid) to ensure reliable product delivery, but several IGS ACs include unhealthy satellites in their final products as long as all quality metrics are satisfied. This approach is possible because sometimes satellites are marked unhealthy for reasons unrelated to the navigation signal performance. Such unhealthy periods are usually announced in advance by the GNSS system operators via a so-called Notice Advisory (Table 34.2).

**Table 34.2** Constellation status and notice advisories for GPS, GLONASS, Galileo, and QZSS. For BeiDou no such official information is available as of early 2016

| GNSS | Item | Reference |
|---|---|---|
| GPS | Status | [34.57] |
| | NANU[a] | [34.58] |
| GLONASS | Status | [34.59] |
| | NAGU[b] | [34.60] |
| Galileo | Status | [34.61] |
| | NAGU[c] | [34.62] |
| QZSS | Status | [34.63] |
| | NAQU[d] | [34.64] |

### 34.2.9 Models in Downstream Applications

It is important to apply consistent models in POD processing and downstream applications utilizing POD products (e.g., precise point positioning (PPP), Chap. 25). In particular, inconsistent antenna calibration and satellite attitude models can result in measurement model errors, which will be absorbed by estimated parameters to the extent possible. The remaining misfit will be evident in postfit residuals. The risk of contaminating physical parameters of interest is, therefore, significant. For this reason, GNSS software providers recommend using POD products generated with the same software as this reduces the likelihood of inconsistent models.

## 34.3 POD Process

The POD process consists of several discrete steps leading from raw observations through data editing and measurement modeling to parameter estimation and product generation. A high-level diagram showing the connected steps is shown in Fig. 34.6. The top row depicts needed inputs, including raw observation data (typically in Receiver INdependent EXchange (RINEX) format, Annex A.1.2), nominal GNSS orbits/clocks, and EOPs. Satellite and station metadata (PRN/SVN conversions, spacecraft models, nominal station coordinates, antenna information, etc.) are needed at various steps and are not explicitly depicted.

Item 1 in the figure represents the data editing procedure, which evaluates the raw observations and linear data type combinations (e.g., range minus phase, widelane phase, see Chap. 20) to identify poor quality observations (such as very short arcs, inconsistent range/phase) and carrier-phase cycle slips. If the nominal orbits and clocks are of good quality, then data for each station may be edited using a PPP procedure that includes editing based on raw observations as well as iterative editing based on postfit residuals. The latter approach is generally possible if an ultra-rapid or better nominal orbit and clock product is used as input, and has the advantage of identifying data to remove for each station independently. When postfit residual editing is performed in a global solution, there is some risk that poor quality or nonsensical observations from one station impact postfit residuals across many stations since the global estimation process adjusts parameters to minimize postfit residuals (in a least-squares sense) over all network participants.

Item 2 employs an orbit integrator to generate a dynamic fit to a set of nominal orbits. The nominal orbits could come from the broadcast ephemerides, prior precise solutions, or predictions of past precise orbits to span the processing arc. The dynamic fit is performed iteratively to minimize the difference between the es-

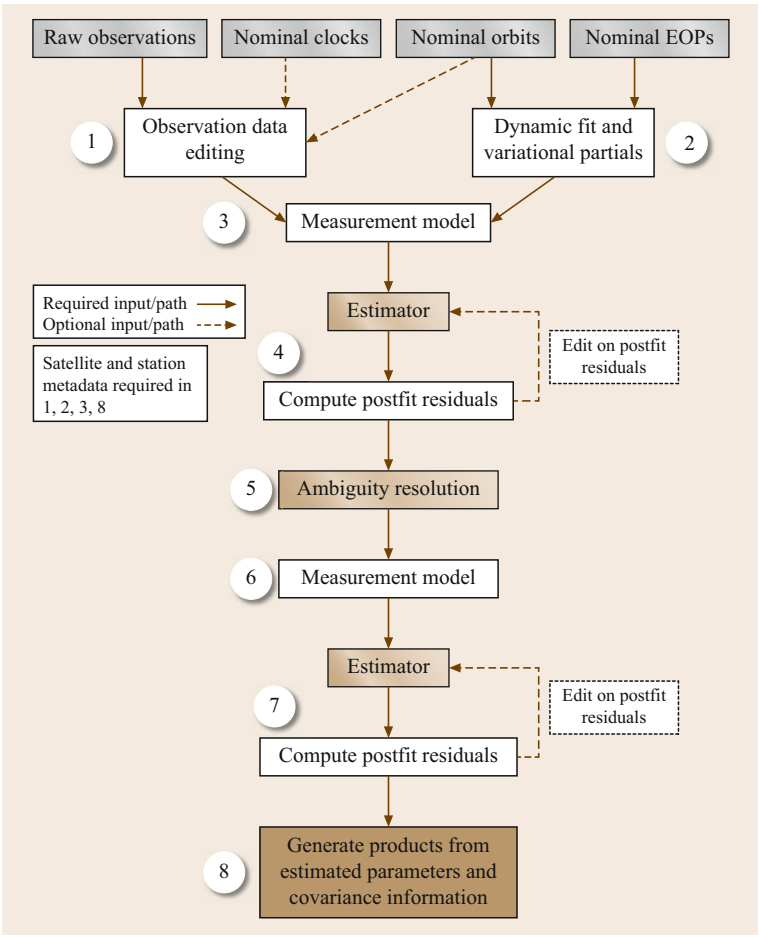

**Fig. 34.6** High-level overview of the POD process (representative example)

timated and the nominal orbits using a small set of parameters (at least the epoch state vector or orbital elements as well as a limited number of SRP parameters). The difference between the nominal and generated dynamic orbits reflects both the accuracy of the nominal orbits and the number of fitted parameters. Significant misfits can be used to screen for model errors and satellites not following a sufficiently dynamic trajectory due to, for example, orbit maneuvers or unusual attitude configurations. This step also computes the partial derivatives of the position and velocity vectors with respect to the orbit parameters (variational partials).

The measurement model, labeled as item 3, computes the expected measurements corresponding to the input set of observations (item 1). These are based on instantaneous nominal receiver and transmitter antenna phase centers determined from nominal values and the models described in Sect. 34.2. Since the GNSS measurements (observations) have nonlinear relationships to the estimated parameters (state variables), the observation-state equations are linearized about the nominal state. The computed measurements are subtracted from the observations at this step, and the partial derivatives of the linearized measurement model with respect to the estimated parameters are determined.

The variational partials and outputs of the measurement model are then passed to an estimator that adjusts parameters to minimize a cost function such as the sum of the square of the postfit residuals (item 4). The estimator solves for an adjustment to the nominal state that best fits the observations, typically iterating the solution until the adjustment is smaller than some threshold (i. e., convergence). This works as long as the nominal state and the estimated state fall within the linear regime of the observation–state relationships. The estimator solution is the sum of the nominal and adjusted parameter values.

The set of estimated parameters usually includes the following: station coordinates, station troposphere delays, transmitter satellite orbits (epoch state, empirical accelerations and/or solar pressure model scales), EOPs, receiver and transmitter clocks, floating point, and integer fixed carrier-phase ambiguities. When more than one GNSS is used, receiver intersystem biases and/or interfrequency biases (IFBs) are additionally estimated. The outputs of the estimator include the parameter adjustments, estimated covariance, and postfit residuals. The residuals may be examined for outliers, and the solution iterated using successively smaller residual outlier thresholds.

The results of this step also provide the input for the subsequent carrier-phase integer ambiguity resolution (item 5, see Sect. 34.4.7 and Chap. 23). After ambiguity resolution, the measurement model is run again to account for resolved integers in the observations (item 6), after which the ambiguity resolved estimator solution is generated (item 7). Here, too, one can iteratively edit observations based on postfit residuals, although almost all outliers should have been removed in prior iterations. The estimated parameters and covariance information is then used to create product files (item 8) for distribution to the users.

## 34.4 Estimation Strategies

Various estimation strategies are used within the IGS POD community. Some analysis centers process undifferenced pseudorange and carrier-phase observations and estimate all parameters in one integrated solution. Others process double-difference carrier-phase observations, which remove clock parameters from the measurements, and solve for orbits, EOPs, station positions, tropospheric delays, and carrier-phase integer ambiguities. The estimates can then be held fixed in a follow-on solution that uses undifferenced observations to solve for clock parameters consistent with the double-difference solution. The processing arcs found within the IGS range from 24 h to 3 days. Longer arcs are preferred for orbit parameters since additional revolutions improve knowledge of the dynamics. A 1-day arc is preferred for EOP and station position parameters if a daily terrestrial reference frame is of interest. Carrier-phase observations are usually weighted at least 100 times higher than pseudorange due to their significantly higher precision (e.g., 1 cm and 1 m, respectively). Sometimes data from individual stations are also weighted according to the overall root mean square (RMS) level of their postfit residuals in an initial solution, since relatively high postfit residuals may indicate issues with model fidelity or data editing at particular locations. In the following subsections, we describe common estimators, parameterizations, and strategies for additional aspects of POD in further detail.

### 34.4.1 Estimators

In the IGS community, two primary types of estimators are utilized for GNSS orbit and clock determination. The first is the batch least-squares estimator, which takes all observations, partial derivatives, and a priori covariance for the processing arc to form

a normal equation system that is inverted to compute state variable adjustments and covariance information (state variable uncertainties and correlations). The second category comprises sequential estimators (such as the Kalman or square root information filter [34.65]), which ingest observations one epoch at a time to produce the best state adjustment based on measurements processed so far. Both types of estimators are discussed in detail in Chap. 22. We also refer the reader to [34.66, 67] for thorough reviews of filtering techniques in the context of range measurement processing.

A significant difference between the batch least-squares estimation and Kalman filtering lies in the treatment of stochastic, time-variable parameters [34.67]. In the case of the batch estimator, distinct estimation parameters need to be set up for each new epoch or time interval (e.g., a clock offset at each epoch, a zenith troposphere delay every hour, and daily station coordinates). This creates large normal equation matrices (Sect. 34.4.10), so parameter elimination and back-substitution techniques are used to reduce the computational burden [34.68]. For the Kalman filter, the number of parameters remains constant, but process noise is applied between epochs. The process noise can be configured to apply white noise (no correlation from estimate to estimate), colored noise (correlation over a period of time), or random walk (infinite correlation) updates to a parameter.

### 34.4.2 Parameterization

All state-of-the-art precise GNSS software packages make available a variety of parameterizations. The most common are as follows:

- *Offset*: adjusts a single, constant value over the processing arc. Commonly used for station coordinates since geodetic stations are considered static over processing arcs of up to several days. Also used for differential code biases (DCBs) (spanning up to monthly intervals) and antenna PCOs.
- *Piecewise-constant*: offset parameters with discrete steps. Typically used for carrier-phase ambiguities.
- *Piecewise-linear*: described by an offset and a slope. Typically used for EOPs.
- *Continuous piecewise-linear*: a piecewise-linear parameterization with imposed continuity at the interval boundaries. It is typically achieved by estimating the parameter values at discrete nodal points located at these boundaries. Compared to the piecewise-linear representation, the number of estimation parameters is reduced by $n-1$ with $n$ being the number of time intervals. Equivalent to a piecewise-linear representation with a tight continuity constraint. No discontinuities occur inside the processing interval allowing for a more physical parameter representation. The piecewise-linear representation can be transformed to a continuous piecewise-linear representation but not vice versa. Used for station troposphere delays, EOPs in high-rate or multiday solutions, and nadir-dependent satellite antenna PCVs.
- *Epoch independent*: an independent parameter values is estimated at each epoch, for example, used for receiver and transmitter clocks. Equivalent to a constant parameter with a stochastic white noise reset applied at every epoch.

An illustration of these five types of parameterizations is shown in Fig. 34.7.

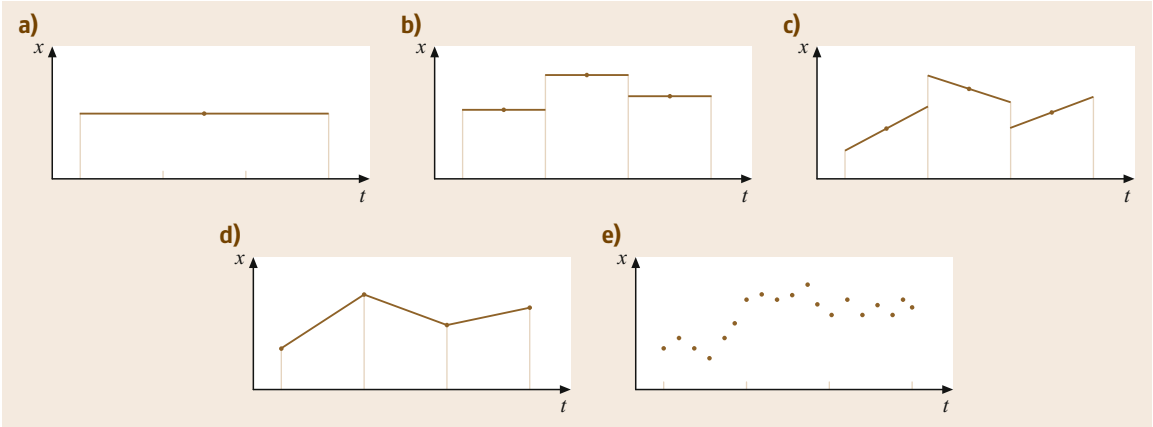

**Fig. 34.7a–e** Parameterizations used in GNSS data processing: **(a)** offset, **(b)** piecewise-constant, **(c)** piecewise-linear, **(d)** continuous piecewise-linear, **(e)** epoch independent

### 34.4.3 Ground Stations

For ground stations one must estimate coordinates, tropospheric delay, and receiver clock parameters. For geodetic stations, it is usually sufficient to estimate a constant position over the processing arc with loose a priori constraints in the range of meters to kilometers.

The troposphere is modeled using a zenith path delay, a mapping function which may vary by time and the station location (e.g., Global Mapping Function, [34.14]), and horizontal gradient parameters. Although the analysis of observations at low elevations is degraded by increased noise, multipath, and model deficiencies, these observations are important for a decorrelation of troposphere zenith delays, receiver clock, and station height ([34.69] and Fig. 6.3). Therefore, low-elevation data are included but downweighted. Common weighting functions are $1/\sin e$ and $1/\sin^2 e$ with the satellite elevation $e$, additional weighting functions are discussed in [34.70] and [34.71]. Nevertheless, data at very low elevations are excluded by applying an elevation mask. Typical elevation cut-off angles range from 3° to 10°.

Horizontal tropospheric gradient parameters are needed to account for a systematic component in the north/south direction toward the equator due to the atmospheric bulge [34.72] with magnitudes of about −0.5 and +0.5 mm at mid-latitudes in the Northern and Southern hemispheres, respectively. The gradients are generally parameterized for each station as components of a sinusoid varying in azimuth. The gradients also capture the effects of random components in both directions due to weather systems. Failing to model gradients in radiometric analyses can lead to systematic errors in the scale of the estimated terrestrial reference frame at the level of about 1 ppb, and cause latitude and declination offsets in station and transmitter positions [34.73].

The zenith path delay parameter may be estimated as a piecewise constant (random walk) process with an a priori sigma of tens of centimeters and process noise $< 1$ mm over 5 min ($1\sigma$). Likewise gradient parameters, usually the in-phase and quadrature components of an empirical sinusoid fit, may be modeled as random walk processes with similar a priori sigmas and process noise an order of magnitude smaller than the zenith delay. The estimation of receiver clock parameters is discussed in Sect. 34.4.5.

### 34.4.4 GNSS Orbits

The satellite orbits are estimated using a *reduced dynamic* approach [34.74]. The basic outline is to solve for an epoch state vector (position and velocity or set of osculating elements at a reference epoch), empirical accelerations and/or model scale factors to absorb force model errors (mainly solar radiation, Earth radiation, spacecraft thermal radiation, and transmitter antenna thrust), and, optionally, yaw attitude parameters. For SRP modeling, the strategies currently represented in the IGS analysis community may be broadly divided into two categories.

The first is the *CODE approach* described in [34.75, 76]. Here, one estimates an epoch state plus constant and per-revolution accelerations in the DYB-frame (where D refers to the spacecraft-Sun direction, Y to the body-fixed solar panel axis, and B completes the right-handed set). The classic ECOM (Empirical CODE Orbit Model) approach solves for 6 epoch state parameters and 5 empirical accelerations as constant terms in D, Y, and B and 1/rev terms in B (Sect. 3.2.4). In 2015, the CODE AC updated this strategy to also include two- and four-times per revolution accelerations in the spacecraft-Sun direction (ECOM-2), as this was empirically found to reduce signals related to the GNSS draconitic period seen in terrestrial reference frame transformation parameters [34.77].

The second category, developed at JPL, emphasizes high-fidelity a priori SRP models and estimates tightly constrained SRP model scale and empirical accelerations for each arc [34.49, 50]. A typical set of parameters is the epoch state, an overall constant solar pressure model scale factor, tightly constrained stochastic solar scale in the spacecraft body-fixed $x$- and $z$-components, plus constant and constrained stochastic accelerations in $y$ (accounting for unmodeled thermal radiation and SRP forces).

Contemporary orbit solutions submitted to the IGS are derived using both approaches and variations thereof. They show agreement within the expected precision of the estimates. In other words, the approaches independently validate one another and produce high-quality solutions. There are, of course, some advantages and disadvantages for each. The CODE approach has the advantage that it requires no a priori model for SRP forces as they are simply absorbed by the empirical accelerations. It is therefore well suited to dealing with new spacecraft types as soon as tracking data are available. The disadvantage of the approach is that significant empirical forces must be estimated, and there is the risk of mixing dynamical parameters with other physical parameters such as EOPs and geocenter [34.77, 78].

The advantage of the second category is that the forces acting on the satellite are defined by a high-fidelity a priori model such that empirical accelerations can be tightly constrained to account for hopefully small deficiencies in the background models. This, in principle, allows for less mixing of spacecraft dynamics into other geodetic parameters. The disadvantage of

this approach is that it relies on a prior set of precise orbits (from which the SRP model is generated) so it cannot be readily applied to new satellites. Further, any systematic errors in the prior orbit set can affect the resulting SRP model.

The estimation of yaw rates for orbit shadow and noon maneuvers for the GPS Block II/IIA/IIF satellites is also beneficial. In the case of the Block II/IIA spacecraft, this is needed because the maneuver is controlled by analog sensors resulting in yaw rates that can differ from nominal values by as much as 25% [34.48]. While the Block IIF attitude is deterministic, nonetheless discrepancies between nominal and actual attitude for some $\beta$ angle regimes have been found [34.24]. A new yaw parameter should be setup (or stochastic update performed) for each yaw maneuver since they are independent events. Analyses have shown that GPS Block IIR and GLONASS-M attitude may be accurately modeled without the need for empirical parameters [34.22, 24].

### 34.4.5 Clock Offsets

The next class of parameters are receiver and transmitter clock offsets. The clocks are generally modeled as unconstrained epoch-independent parameters (no correlation from one epoch to the next). This parameterization makes the solution independent of the quality of the individual station clocks, most of which are not tied to an atomic reference.

Transmitter clocks are driven by atomic frequency standards, but may exhibit discontinuities that make modeling them as, for example, a quadratic function unreliable. The solution is singular if all clocks are left unconstrained, so a reference must be selected. In practice this implies that one holds a particular clock offset or an ensemble of clocks fixed, meaning all other clock offsets are estimated relative to the reference. Generally one can use a station stably tied to a reference time scale such as the coordinated universal time (UTC) realizations of national timing labs.

An alternate approach less sensitive to data gaps is to apply an overall zero mean constraint to an ensemble of clock offsets. Some ACs, for instance, apply a zero-mean constraint to the transmitter clocks. The resulting orbit and clock solution is internally consistent and yields valid formal error estimates for all parameters. The timescale of the solution may be adjusted after the fact by removing a single reference clock offset at each epoch from all clock estimates based on a prioritized list of receiver clocks aligned to GPS time.

The GPS clock parameters provided by the IGS refer (by convention) to the ionosphere-free linear combination of the L1 P(Y) and L2 P(Y) signals. However, several geodetic GPS receivers only track the C/A code on L1. Therefore, DCBs between the different types of signals have to be considered (Sect. 19.6.1). One can either estimate the DCB parameters, as done by the CODE AC, or one can correct for the DCBs, for example, with the cc2noncc tool utilizing the CODE DCB estimates [34.79]. Users of IGS clock products must ensure consistency between the clock parameters on the one hand and the observation types on the other hand by applying the corresponding DCBs. Further sources for DCBs are the Time Group Delay (TGD) parameters of the GPS navigation message (Sect. 7.4.3), the Inter Signal Corrections (ISCs) of the GPS Civil Navigation Message CNAV [34.80], and the IGS MGEX DCB product [34.81].

### 34.4.6 Earth Orientation

Earth orientation parameters relate the terrestrial reference frame to the celestial reference frame. UT1–UTC measures the rotation rate of the Earth relative to an atomic time scale. The period of one Earth revolution is not constant in time, and rotation time in excess of 24 h is referred to as the length of day (LOD). Global GNSS solutions are sensitive to changes in the Earth rotation rate over a processing arc but not the absolute rotational alignment at the start of the arc. From the change in rotation one can compute LOD as described in [34.2]. The $x$- and $y$-coordinates of the Earth rotation axis, as well as their rates, can also be determined from GNSS. By convention the estimated pole coordinates are with respect to the IERS Reference Pole [34.2].

### 34.4.7 Phase Ambiguity Resolution

To achieve the best precision and accuracy, one should resolve phase measurement integer cycle ambiguities. Details on ambiguity resolution algorithms are provided in Chap. 23, here we focus on the steps taken in a global POD solution.

The process usually starts with a solution that estimates the float-valued ambiguities of the ionosphere-free combination of dual-frequency carrier-phase observations along with the station, troposphere, satellite orbit, clock, Earth orientation, and DCB parameters. For a daily solution with 60 or more well-distributed ground stations one can expect orbit accuracies around 10 cm (3D RMS) and clock accuracies of about 10 cm.

This accuracy is generally sufficient to facilitate ambiguity resolution in a second step, where the above parameters are introduced as known parameters (with given accuracy) to setup systems of equations for resolving double-difference ambiguities for individual pairs of stations. The specific techniques employed in

this step differ widely between analysis centers and software packages [34.82–84], although many of them are based on a widelane/narrowlane approach utilizing the Melbourne–Wübbena linear combination.

Given the wealth of observations available, it is usually best to apply conservative thresholds for accepting ambiguities. It is far better to resolve fewer ambiguities correctly than resolving more ambiguities and resolving an integer incorrectly. This is critical since the integers are introduced as fixed values in a follow-up estimation that effectively treats carrier-phase measurements as highly precise, unbiased ranges. Typically one can expect to resolve upward of 90% of ambiguities in a 60+ station global solution.

### 34.4.8 Multi-GNSS Processing

Although the orbital configurations of GLONASS, Galileo, and BeiDou satellites in medium Earth orbit (MEO) are similar to GPS, the existing estimation strategies partly fail for these satellites.

Systematic errors have been revealed at the 20 cm level in the Galileo orbit and clock products of four different ACs [34.85]. The stretched shape of the Galileo satellites have been identified as the root cause of these errors and an a priori box model has been developed, significantly reducing the systematic errors [34.86]. A similar orbit quality can also be achieved with the newly developed ECOM-2 model [34.77]. While spacecraft attitude and antenna phase centers differ for these satellites they can in principle be derived using procedures developed for GPS. POD of geostationary satellites as employed by BeiDou is still challenging due to the small changes in observation geometry and frequent maneuvers [34.87], although some progress has been made with alternative orbit parameterizations [34.88].

The estimation of clocks for these systems is also similar to GPS in that the offsets can be treated as unconstrained epoch-independent parameters. In a solution involving GLONASS several additional parameters are, however, needed. First, one must estimate a GLONASS intersystem bias at each receiver. GNSS receiver data typically refer the measurements to the respective system time, while the POD solution refers all estimates to GPS time (by convention). So an overall clock bias captures the difference between the GPS and GLONASS timescales at each receiver. It affects all GLONASS range and phase measurements equally. The estimated values should, in general, be in the vicinity of the GPS–GLONASS system time offset, which today is better than 1 μs after accounting for the constant 3 h UTC(USNO)–UTC(SU) bias [34.89].

A second set of additional parameters needed for GLONASS are IFBs along each receiver–transmitter pseudorange link. These link biases are necessitated by the frequency division multiple access (FDMA) architecture of the GLONASS system (Sect. 8.2.2), as the hardware delays experienced by GLONASS signals traveling through the receiving equipment are dispersive. The delays vary due to both the physical equipment as well as environmental factors such as temperature. A reasonable strategy is to estimate each IFB as a constant parameter over each day. Due to the estimation of IFB parameters, the choice of the reference signals for GLONASS clock estimation (e.g., P- or C/A-code) is arbitrary.

The magnitude of the IFB parameters is in the range of decimeters to 3 m depending on the receiver type [34.90]. One must choose a reference for both the system time offsets and IFBs or the solution is singular. One can fix to calibrated values or artificially set these biases to zero for a particular receiver. Either way the solution yields a consistent set of GPS and GLONASS clock offsets suitable for use in combined GPS/GLONASS point positioning; however one must take care to also estimate a GLONASS time offset and IFBs in that solution.

It is clear that the GLONASS clock estimates depend strongly on the choice of the system time offset and IFB reference, as well as the choice of receiver network in general since the IFBs essentially bias the pseudorange on each link (unlike GPS where IFBs are not needed since all signals are on common frequencies). For these reasons, it is quite complicated to compare GLONASS clock estimates from different solutions if a different reference and receiver networks were used. This is the main reason the IGS does not currently produce a GLONASS clock combination [34.91].

Galileo and BeiDou are code division multiple access (CDMA) systems like GPS. Thus, in a combined solution one only needs to estimate GPS to Galileo and/or BeiDou time offsets at each station, parameterized as an overall constellation bias (intersystem bias) over the processing arc. A key choice related to the bias magnitudes is the ionosphere-free observable type. For Galileo an E1/E5a convention is emerging [34.85], while for the BeiDou B1/B2 signals are used [34.92].

An important consideration in multi-GNSS solutions is the weighting of observations from each GNSS. Weighting observations in the same manner regardless of GNSS is of course one possibility. Two other commonly used approaches are to downweight observations from non-GPS constellations, or to derive station clock and troposphere parameters with GPS alone and hold the results fixed in a follow-on solution that estimates intersystem biases, transmitter clocks, IFBs, and satellite orbits for one or more additional constellations. This is beneficial since the satellite constellations and

ground networks for the other GNSSs are (currently) not as large or well distributed as for GPS. Also, detailed models for the newer constellations are still being developed and refined. This situation will change rapidly in the next few years and it is likely that new weighting strategies will emerge.

### 34.4.9 Terrestrial Reference Frame

A stable, accurate, and well-maintained global TRF is a prerequisite for precise orbit and clock determination and its applications. The TRF underpins POD by defining the origin from which receiver and transmitter locations are defined. It furthermore establishes the framework upon which geophysical processes, such as solid Earth tides or vertical motion due to ocean loading, are modeled and analyzed. Details on the definition and realization of terrestrial reference systems are given in Sect. 2.3.

The most recent version of the International Terrestrial Reference Frame is ITRF2008. However, ITRF2008 is usually not directly used in GNSS applications as the predecessor of the current antenna model was applied for the IGS contribution to ITRF2008. Therefore, a GNSS-only TRF called IGS08 was computed [34.6]. It is aligned to ITRF2008 but includes station-specific corrections to account for the antenna calibration differences. In 2012, an updated version of IGS08 called IGb08 [34.93] was released as the coordinates of more than 30 reference frame stations were degraded due to station displacements induced by earthquakes or equipment changes.

The TRF is realized in global POD solutions in one of three ways:

1. Fixing or tightly constraining a set of station positions to the values defined by the TRF. In principle, three fixed stations are sufficient, although in practice IGS ACs hold at least two dozen globally distributed stations fixed. The positions of the remaining stations in the solution, as well as the GNSS orbits, will therefore be estimated relative to the realization of the TRF defined by the subset of fixed stations. However, fixing or constraining more stations than necessary might result in distortions of the network geometry. This approach is typically used only for low-latency solutions (i. e., ultra-rapid) where realizing a TRF a posteriori is time consuming or not valuable for user applications.
2. Applying *minimum constraints* for a selected set of (core) stations w.r.t. the a priori TRF. For global GNSS solutions, a no-net-rotation condition is mandatory. If the origin of the tracking network (geocenter) is estimated, an additional no-net-translation condition has to be applied. The advantage of this approach is that the inner geometry of the network is not distorted.
3. Estimation of all station positions in the global solutions with loose a priori constraints. Other than relating to the TRF through antenna calibrations (discussed below), this type of *fiducial free* POD solution does not provide orbits and clocks in a particular TRF but instead realizes a unique frame for that solution. This solution's frame is likely to exhibit notable rotations with respect to ITRF because the GNSS technique is insensitive to rotating the entire observation geometry. One can compute a best fit Helmert transformation (Chap. 2) for the estimated ground network relative to ITRF using the set of overlapping stations (XYZ translations, XYZ rotations, and scale) and apply this transformation to the orbit solution to place it in the ITRF frame.

The products resulting from one of these approaches are provided in the underlying TRF and therefore directly transfer the TRF to users.

Due to orbit dynamics, the GNSS satellites orbits refer to the CoM of the total Earth system including the oceans and the atmosphere. Tides cause periodic variations in the CoM of the oceans and the atmosphere. This so-called geocenter motion can reach up to 1 cm for diurnal and semidiurnal ocean tides [34.94]. If a corresponding CoM correction (CMC) is applied, the orbits refer to a crust-based Center-of-Network (CoN) frame, otherwise to a CoM frame. Within the IGS, the CoN frame is used for the orbits as well as the clocks [34.95].

### 34.4.10 Sample Parameterizations

Table 34.3 gives an overview of the estimated parameters and their sampling for a global GPS solution with

**Table 34.3** Number of observations and estimation parameters in a global GPS solution with 32 satellites and 160 stations. It is assumed that 10 satellites are visible per station and observation epoch

| | Sampling | No. of obs./par. |
|---|---|---|
| Observations | 5 min | 460 800 |
| Station coordinates | 24 h | 480 |
| Troposphere zenith delays | 2 h | 2080 |
| Troposphere gradients | 24 h | 640 |
| Orbit parameters | 24 h | 576 |
| Earth orientation parameters | 24 h | 5 |
| Ambiguities | Dep. on data | ≈ 10 000 |
| Satellite clocks | 5 min | 9216 |
| Receiver clocks | 5 min | 46 080 |
| Total number of parameters | | ≈ 69 000 |

**Table 34.4** Sample receiver station parameterization (JPL approach) (after [34.50])

| Parameter | Configuration | $\sigma_{apr}$ | $\sigma$ process noise |
|---|---|---|---|
| Station coordinates (all or a subset of stations) | Offset | 1 km | – |
| Station zenith wet troposphere | Random walk, 10 min updates | 0.5 m | 0.03 mm $s^{-1/2}$ |
| Station gradient wet troposphere | Random walk, 10 min updates | 0.5 m | 0.003 mm $s^{-1/2}$ |
| Station clock offset | White noise, update each epoch | 1 s | 1 s |

**Table 34.5** Sample satellite parameterization (CODE approach) (after [34.76, 96])

| Parameter | Configuration | $\sigma_{apr}$ |
|---|---|---|
| Keplerian elements at epoch | Offset | No constraint |
| Acceleration in the Sun-direction (D) | Offset | No constraint |
| Acceleration in the Y-direction | Offset | No constraint |
| Acceleration in the B-direction | Offset | No constraint |
| Acceleration in the B-direction (once per revolution) | Offset | No constraint |
| Constant radial velocity change | Every 12 h | $1 \cdot 10^{-6}$ m $s^{-1}$ |
| Constant along-track velocity change | Every 12 h | $1 \cdot 10^{-5}$ m $s^{-1}$ |
| Constant cross-track velocity change | Every 12 h | $1 \cdot 10^{-8}$ m $s^{-1}$ |

**Table 34.6** Sample satellite parameterization (JPL approach) (after [34.50])

| Parameter | Configuration | $\sigma_{apr}$ | $\sigma$ process noise |
|---|---|---|---|
| Position at epoch | Offset | 1 km | – |
| Velocity at epoch | Offset | 1 cm $s^{-1}$ | – |
| Y acceleration | Offset | 1 nm $s^{-2}$ | – |
| Y acceleration | Colored noise, 4 h correlation, updated every 1 h | 0.01 nm $s^{-2}$ | 0.0002 nm $s^{-2} s^{-1/2}$ |
| SRP model scale | Offset | 1.0 | – |
| SRP model scale in X and Z | Colored noise, 4 h correlation, updated every 1 h | 0.01 | 0.0002 $s^{-1/2}$ |
| GPS Block II/IIA yaw rates | Offset per eclipsing midnight/noon turn | 0.01 deg $s^{-1}$ | – |
| Transmitter clock offset | White noise, update each epoch | 1 s | 1 s |

a full constellation of 32 satellites and a network of 160 terrestrial stations at a 5 min sampling rate. Clock offsets make up the vast majority of parameters. These parameters are removed if double-difference measurements are processed. The next largest parameter group is for ambiguities whose number strongly depends on the data quality. Efficient methods to deal with the huge number of almost 70 000 estimation parameters are discussed in Sect. 34.4.11.

More specific sets of estimated parameters are discussed in the following. We list sample a priori standard deviations ($\sigma$) and stochastic properties, which provide reasonable solutions based on POD strategies described in [34.50, 75, 76]. We note that some software packages apply stochastic updates directly in a Kalman filter [34.67], while those using a batch filter typically configure a new (optionally constrained) parameter for each update and apply elimination techniques to the normal equations to reduce the computational burden. For the purposes of this discussion we consider both approaches to yield equivalent parameterizations. Table 34.4 shows a sample receiver station parameter configuration, Tables 34.5 and 34.6 show possible satellite parameterizations, and Table 34.7 refers to EOPs. Range and phase data are often given a priori measurement sigmas of 1 m and 1 cm, respectively, or a factor of 1:100, to give credit to the high precision of the carrier-phase measurements. This in effect produces a phase-based solution that aligns the clock estimates to the pseudoranges.

**Table 34.7** Sample Earth orientation parameterization (JPL approach) (after [34.50])

| Parameter | Configuration | $\sigma_{apr}$ |
|---|---|---|
| X and Y pole | Offset | 5 m (relative to a priori) |
| UT1-UTC rate per arc | Offset | $3.5 \cdot 10^{-8}$ s/s |

### 34.4.11 Reducing Computation Cost

A given arc and dataset can of course be processed as one solution from start to finish. This approach is often taken to produce few-hour latency (ultra-rapid) or next-day (rapid) solutions. There are, however, trade-

offs between accuracy, processing time, and the number of stations and orbiters processed, as discussed in Sect. 34.1. A few strategies are commonly used to maximize the number of receivers and transmitters while minimizing processing time:

- Real-time clock estimation (few second latency) based on ultra-rapid orbits: GNSS orbits can be predicted from a precise solution with sufficient accuracy (over many hours and even days) that they may be input and held fixed in a real-time GNSS clock filter. This reduces the computational burden and complexity of the real-time process, which estimates only clock and troposphere parameters. This approach is widely used to produce real-time GNSS solutions [34.97].
- Reuse of normal equation systems from prior POD solutions: many software packages include tools to manipulate and stack normal equation systems, and take advantage of these capabilities to minimize new computations for low-latency processing. For instance, utilizing prior rapid or ultra-rapid normal equation systems and appending a few hours of new data to generate an ultra-rapid solution. This avoids recomputing the measurement model and partial derivatives for a significant portion of the dataset. Normal equation stacking is also an efficient tool to generate multiday orbital arcs.
- Stacking normal equation systems for a set of non-overlapping networks: this approach is sometimes used where it is desired to process as many stations as possible (e.g., to contribute to the TRF). This is a parallelization technique as the subnetwork normal equations are generated on separate systems prior to stacking and inversion.
- Double-difference processing: some software packages process double-difference observable combinations to eliminate transmitter and receiver clock offsets from the observations. This reduces the number of parameters at each epoch significantly but still provides access to orbit, EOP, atmospheric delay, and station position parameters. Many science applications of GNSS have no interest in clock offsets and benefit from a reduced computational burden when processing double difference observables.
- Clock densification: high-rate satellite clock parameters required for highly dynamic applications (e.g., kinematic ground stations or kinematic orbit determination of low Earth orbiters, Chap. 32) dramatically increase the number of unknown parameters. For the example network of Table 34.3, more than 500 000 clock parameters would have to be estimated for 30 s sampling. In order to save computation time [34.98] developed a method utilizing epoch-differenced phase observations. This *efficient high-rate clock interpolation (EHRI)* algorithm densifies the 5 min satellite clock parameters obtained from the global clock estimation to 30 s or even 5 s sampling and reduces computation time by a factor of about 10.

## 34.5 Software

A variety of software packages for GNSS POD have been developed at academic, research, and commercial institutions. We give brief descriptions of some of these below and summarize the products currently produced by each:

- Bernese GNSS Software, developed at the Astronomical Institute of the University of Bern (AIUB). An extensive software package, Bernese is used for GNSS and low Earth orbit (LEO) POD, precise point positioning, estimation of DCBs, antenna calibrations, ionosphere and troposphere estimation, and more. AIUB along with other institutions make up the Center for Orbit Determination in Europe (CODE), which contribute GPS and GLONASS products (orbits, clocks, DCBs, antenna calibrations, troposphere and ionosphere solutions) to the IGS, as well as multi-GNSS products including Galileo, BeiDou, and QZSS to the IGS MGEX [34.68].
- NAPEOS (NAvigation Package for Earth Orbiting Satellites), developed at the European Space Agency (ESA). NAPEOS is used for GNSS and LEO POD, precise point positioning, estimation of DCBs, antenna calibrations, ionosphere and troposphere parameters, etc. NAPEOS is used to generate products at the ESA IGS AC, which contributes GPS and GLONASS POD as well as troposphere and ionosphere products to the IGS [34.99].
- GIPSY (GNSS-Inferred Positioning System and Orbit Analysis Simulation Software) is developed at the National Aeronautics and Space Administration (NASA) Jet Propulsion Laboratory (JPL). GIPSY is used to generate GPS, GLONASS, and LEO orbit and clock products, PPP solutions, ionosphere and troposphere parameters, and produces the JPL AC contributions to the IGS. GIPSY processing supports NASA flight missions (LEOs and aircraft positioning) as well as atmospheric calibrations for the Deep Space Network [34.100], among others.

- EPOS-8 (Earth Parameter and Orbit System), developed at Deutsches GeoForschungsZentrum (GFZ), is another package with broad capabilities for GNSS POD, troposphere/ionosphere estimation, transmitter antenna calibrations, etc. GFZ is an IGS AC providing GPS and GLONASS products, as well as multi-GNSS solutions for Galileo, BeiDou and QZSS to the IGS MGEX [34.101, 102].
- Centre National d'Etudes Spatiales (CNES, French space agency) develops the GINS/DYNAMO software for GNSS POD. It is used by the CNES IGS AC to produce GPS, GLONASS, and Galileo POD solutions on a routine basis. The software is also used for LEO POD processing [34.103].
- The Position and Navigation Data Analysis (PANDA) software developed at Wuhan University, China, is another software package for GNSS and LEO POD. Wuhan University contributes multi-GNSS products to the IGS MGEX project as well as GPS products to the IGS Rapid combination (currently in evaluation mode) [34.104].
- GAMIT-GLOBK is a GPS processing software developed at the Department of Earth Atmospheric and Planetary Sciences at the Massachusetts Institute of Technology(MIT) [34.105], and is used by the MIT IGS AC to contribute weekly final as well as reprocessed products to the IGS.
- PAGES (Program for the Adjustment of GPS EphemerideS) is developed by the U.S. National Geodetic Survey (NGS) [34.106] and is used to produce GPS orbits, station parameters, and EOPs using a double-difference approach. The NGS is an IGS AC contributing ultra-rapid, rapid, final, and reprocessed products.
- A number of commercial services produce precise GNSS POD solutions using both in-house and externally developed software packages. These providers focus primarily on real-time or low-latency postprocessed products of interest to customers operating in areas such as precise marine and land navigation, cellular device positioning, GNSS integrity monitoring, and meteorological analysis. Providers active in this space include John Deere (Navcom) [34.107], JPL Global Differential GNSS System [34.108], Fugro [34.109], RX Networks [34.110], Trimble [34.111], and Veripos [34.112]. These providers in some cases manage their own ground station networks, operate processing centers, provide real-time GNSS orbits and clocks (typically transmitted as corrections to the broadcast ephemeris) and integrity data via geostationary satellite links, and even sell proprietary receiver hardware. GPS and GLONASS products are standard, with BeiDou and Galileo solutions quickly coming online.

## 34.6 Products

Precise GNSS orbit and clock products must include several items. There are of course the transmitter orbits: these conventionally refer to the CoM and are given as time series of ECEF coordinates and optionally velocities. Given the satellites' altitude, the orbits are sufficiently dynamic to allow accurate interpolation of coordinates given at 15 min intervals (or less) using an 8–11th order interpolator ([34.113] and Annex A.2.1). If desired, the resulting satellite positions can be expressed in an ECI using the EOPs provided along with the orbit and clock products.

Transmitter clock offsets may be provided at various intervals. Solutions submitted to the IGS generally employ intervals of 5 min or 30 s, while intervals as small as 1 s are common in real-time systems. In general, the smaller the interval the better, since a user must interpolate clocks to epochs falling between estimates. Interpolation introduces some error depending on how well the interpolation (typically piecewise-linear) fits the true clock offsets.

It is important to note that clock offsets as provided in the IGS products refer to the transmitter antenna phase center while the orbits refer to the CoM. Since GNSS range data represent the geometric distance between the electrical phase center of the transmitter and receiver antennas, a user must adjust the CoM location given in the orbit product to the phase center. The products should therefore provide information about the phase center model (PCOs and PCVs) used so that a user can apply a consistent model. Metadata, for instance the version of IERS conventions, and the terrestrial reference frame realized in a set of products, is also useful so users can apply consistent models in their processing. This information is provided in the analysis strategy summary files [34.114].

IGS products are commonly named according to latency, including real-time (seconds), ultra-rapid (hours), rapid (next day), final (1–2 weeks), and reprocessed (every few years). Accuracy improves as latency increases for several reasons. Waiting longer tends to increase the available tracking data, especially for outlying stations, improving the distribution of the tracking network. Waiting allows one to use

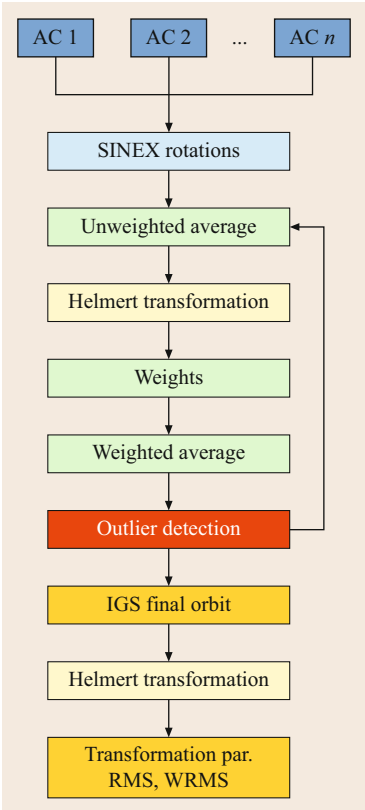

**Fig. 34.8** Flow chart of the IGS orbit combination

more accurate nominal orbits and clocks, or provides time to iterate upon solutions to create improved nominals. This particularly benefits the editing of tracking data in preprocessing. One can use raw measurements or linear combinations thereof to detect unreasonable data and carrier-phase cycle slips, but the use of accurate orbit and clocks for data editing greatly enhances ones ability to screen for outlier tracking data. Other nominal models such as EOPs, zenith troposphere and associated mapping functions, and second-order ionosphere also improve as they progress from predicted quantities to estimates based on observations. The chief benefits of reprocessing campaigns are to have all tracking data available and to apply consistent models and estimation strategies over a long time span.

### 34.6.1 IGS Orbit and Clock Combination

The official IGS orbit and clock products are the result of a combination of the contributions of the individual ACs. Three product lines with different latency and accuracy are provided (Sect. 33.3):

- Ultra-rapid (observed half: 3–9 h, 3 cm, 50 ps)
- Rapid (17–41 h, 2.5 cm, 25 ps)
- Final (12–18 d, 2 cm, 20 ps).

The IGS Analysis Center Coordinator (ACC) is responsible for the generation of the combined products. A combined orbit product provides higher reliability and precision compared to the individual AC orbits. In the following, only the generation of the final orbit and clock products is discussed. The general combination methodology is described in [34.115].

#### Orbit Combination

Input for the orbit combination are satellite positions provided by the IGS ACs in an ECEF reference frame in SP3 format (Annex A.2.1) at 15 min sampling. The combination is based on an iterative weighted averaging (Fig. 34.8). To guarantee consistency of the station coordinates, EOPs, and orbits, AC-specific rotations are applied to the orbits prior to the actual combination [34.116]. These rotations have previously been derived by the IGS reference frame coordinator based on an analysis and combination of the station coordinates and EOPs that have been delivered by the ACs in the so-called SINEX (Solution Independent Exchange) format

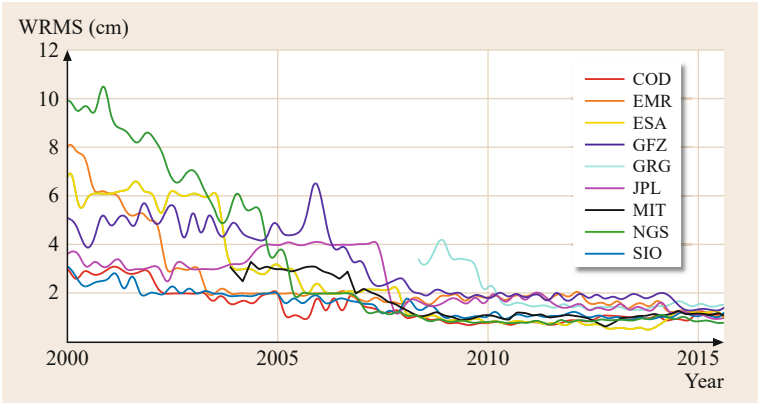

**Fig. 34.9** Smoothed WRMS of individual AC GPS orbit solutions w.r.t. combined IGS final orbit

(Annex A.2.3). Detailed statistics as well as information on the combination are given in the weekly IGS combination summary files `igswwww7.sum` (wwww stands for the GPS week), which are available at ftp://ftp.cddis.eosdis.nasa.gov/pub/ in the corresponding wwww subdirectory.

The historical weighted root-mean square (WRMS) of the GPS orbits of the individual ACs w.r.t. the combined IGS final orbit is shown in Fig. 34.9. The comparison of the orbits improves with time due to the application of more sophisticated and consistent models and processing techniques. For example, in August 2007 JPL adopted the igs05.atx antenna model [34.117] already used at the time by the other ACs, resulting in a WRMS decrease by a factor of about 3. Starting with 2008, two groups of ACs can be distinguished: one group agreeing at the 2 cm level (EMR, GRG, JPL, SIO) and another group agreeing at the 1 cm level (COD, ESA, GFZ, MIT, NGS). In April 2014, ESA started to use an a priori box-wing model [34.118]. Although this model improves the orbit quality, it introduces larger differences w.r.t. the other AC solutions [34.119], resulting in a higher WRMS and a lower weight in the combination. As a consequence, the general WRMS of the individual IGS ACs approaches the 1.5 cm level. Further details on the precision of IGS final orbits are given in [34.120]. The combined IGS final GLONASS orbits are generated with the same procedure but in a separate process.

The WRMS of the orbit combination is, however, only a measure of the internal consistency of the orbits, which may suffer from common systematic errors. Harmonics of the draconitic GPS year (time period between the same orientation of the orbital planes w.r.t. the Sun, $\approx$ 351 d for GPS) have been reported for almost all IGS products [34.121]. It was shown that more sophisticated orbit modeling with an adjustable box-wing SRP model can reduce these draconitic errors [34.122]. However, deficiencies in the subdaily EOP model are also identified in [34.121] as causing artificial periodicities around 7, 9, 14, and 29 d due to aliasing.

The optical SLR technique allows for independent validation of the GNSS satellite orbits determined from microwave observations. An SLR analysis of 20 years of GPS and 12 years of GLONASS orbits computed by the CODE AC was performed by [34.123]. They found a 1 cm bias and 2 cm RMS for the two GPS satellites equipped with laser retro-reflectors. Whereas the SLR bias of the GLONASS satellites is in general on the few millimeters level, the RMS is around 3–4 cm. These numbers illustrate the discrepancies between internal precision as represented by the orbit combination WRMS and the accuracy as evaluated by SLR, which are caused by the systematic errors mentioned above.

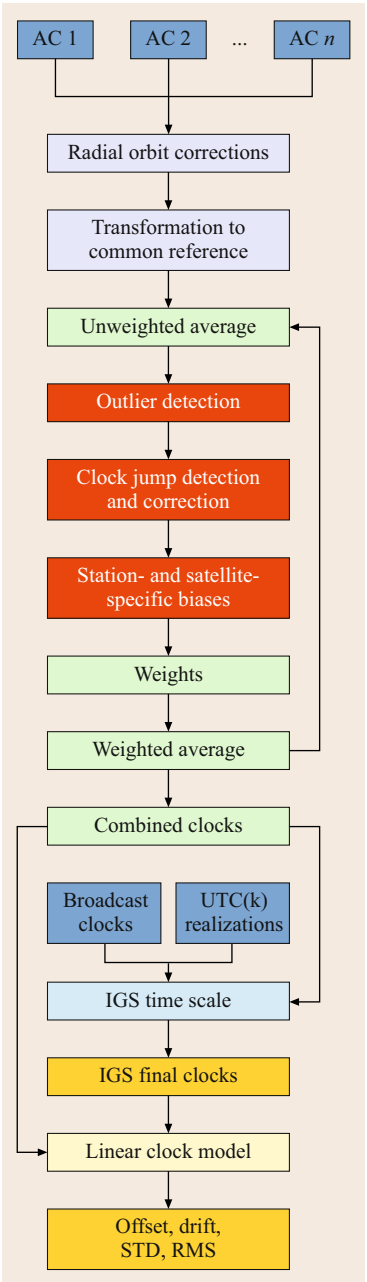

**Fig. 34.10** Flow chart of the IGS clock combination. UTC(k) refers to UTC realizations at dedicated timing laboratories with calibrated GPS receivers included in the combined clocks

### Clock Combination

Input for the clock combination are satellite and receiver clock estimates in RINEX clock format (Annex A.2.2). The general combination procedure is illustrated in Fig. 34.10 and discussed in more detail in [34.124, 125]. As a first step, radial orbit differences between the combined and individual AC orbits are computed and applied to the clocks in order to remove orbit-related systematic errors (radial or-

bit differences and satellite clock offsets are one-to-one correlated). Then, the individual AC clocks are aligned w.r.t. a common reference. Clock offset and drift w.r.t. a selected reference are removed for all ACs. The reference is taken from either the broadcast clock corrections or the clock estimates of a selected AC aligned to the broadcast clock corrections in a previous step.

During the iterative combination process, outliers are detected and clock jumps are corrected. A weighted average is formed based on weights determined from the deviation of the AC clocks w.r.t. an unweighted mean. The combined clocks are used to realize the IGS timescale (IGST, [34.126]). IGST is aligned to UTC via calibrated GPS receivers at time laboratories (labeled UTC(k) in Fig. 34.10) and GPS time from the navigation message. As a final step, the clock summary files are generated providing offset/drift of a linear clock model and RMS/STD w.r.t. the combined clocks as well as information about the time scale generation.

The historical RMS of the AC-specific GPS clock solutions w.r.t. the combined IGS final clocks is illustrated in Fig. 34.11. SIO does not provide clock corrections and NGS is excluded from the combination as only broadcast clocks are provided (due to double-difference observable processing). The RMS of the most consistent ACs is on the 100 ps level. For GLONASS, no combined clock product is available as mentioned in Sect. 34.4.8.

A critical issue for the clock combination is the consistency of the applied transmitter antenna and attitude models. As an example, all IGS ACs except for JPL switched the antenna model from igs05.atx to igs08.atx in April 2011 [34.127]. For JPL, this switch took place in July 2011 [34.117]. The 3 months of inconsistent antenna modeling can be clearly seen in Fig. 34.11 as JPL's clock RMS increases by a factor of more than 3. Discrepancies among ACs in attitude modeling are evident for the eclipse periods of the GPS Block II/IIA satellites. These cause large clock differences responsible for the rejection of individual ACs during the combination process [34.128]. Figure 34.12 illustrates this problem for GPS Block IIA SVN-33. The MIT clock estimates show a significantly different behavior after the satellite leaves the shadow, resulting in an exclusion of this AC for this particular satellite.

## 34.6.2 Formats and Transmission

A variety of GNSS product formats and transmission mechanisms are used today (Annex A). Postprocessed products are usually provided as compressed files. Open standards for data exchange include SP3 (standard product 3) for GNSS orbits and clocks [34.129], clock RINEX for receiver and transmitter clocks [34.130], Earth rotation parameter (ERP) [34.131], and antenna exchange (ANTEX) antenna calibration [34.132] formats. Within the IGS, the fourth comment line in the SP3 orbit files is used to document important modeling options including the phase center model, name of the ocean tidal loading and atmospheric tidal loading models, and whether CoM corrections are applied. The full format description of this SP3 comment line is given in [34.133]. Each POD software generally also uses proprietary formats representing the same information, for example, the GIPSY *pos* or Bernese *standard orbit* [34.68] formats.

Real-time systems distribute products via low-latency files (e.g., each minute) as well as few second latency streams. The real-time streams usually represent the precise orbit and clock solution as corrections to the current broadcast navigation message (with respect to a specific issue of data encoded in the corrections message). This implies that the generator of the corrections must account for any differences in the transmitter antenna phase center offsets used to compute the broadcast ephemerides and precise solutions. The user applies the corrections to the broadcast or-

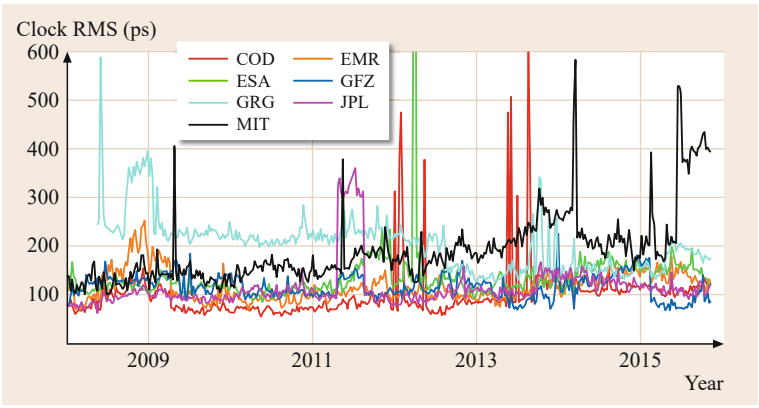

**Fig. 34.11** RMS of individual AC clock solutions w.r.t. combined IGS final clocks

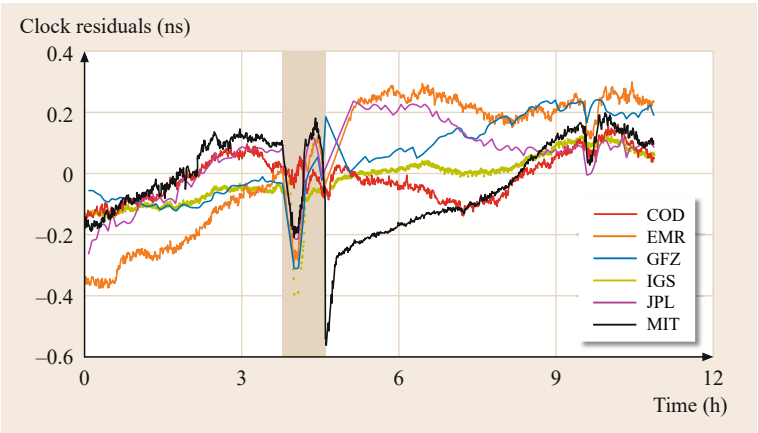

**Fig. 34.12** Individual AC and combined IGS clock residuals of the GPS Block IIA satellite SVN-33 for 6 February 2011. The *light brown shaded* area indicates the eclipse period. The ESA clock estimates are used as reference clock and offset/drift of each AC are removed. EMR and MIT clock estimates of this satellite were excluded from the clock combination on that day

bits and clocks directly. The corrections approach has the benefit that some latency (up to tens of seconds) does not significantly degrade the user solution since the navigation message accounts for the majority of the bias and drift in the satellite position and clock, whereas the corrections terms are relatively steady over short time intervals (at least for nominally performing transmitter clocks). Corrections are usually transmitted at 1 s intervals, and losing some corrections over the communication link, or updating at longer intervals, is possible with this approach. Real-time correction streams from commercial providers are encoded in proprietary binary formats sent as TCP or UDP packets over the Internet or transmitted to user equipment via geostationary satellite links [34.134]. The IGS real-time service transmits corrections over the Internet in the open State–Space Representation (SSR) format [34.135].

### 34.6.3 Using Products

Whether products are acquired as postprocessed files or real-time streams, the user applies a set of precise orbit, clock, and ancillary information in their processing. Maintaining consistency with GNSS products is critical to realizing the best possible accuracy. As discussed, orbits need to be adjusted from the CoM to the antenna phase center, which requires knowledge of both the antenna calibrations and the spacecraft attitude model used to generate the GNSS products. Attitude models in the POD software packages have varying levels of complexity, particularly for non-nominal attitude regimes (e.g., eclipse). The best consistency is therefore achieved by using the same software that generated the products.

The data type to which the clocks products refer should also be consistent. By convention, GPS (broadcast ephemeris and precise) products provide clocks estimated using the L1 P(Y)/L2 P(Y) ionosphere-free linear combination, while GLONASS processing may use either the coarse or precise ranging code to form the ionosphere-free linear combination (it does not matter since the user needs to estimate range biases on each receiver–transmitter link again). For the Galileo and BeiDou CDMA systems conventions are currently developing (Sect. 34.4.8). In any case, the user should process the same data type used to generate the GNSS products. If the data type is not available, the user must apply the appropriate DCBs (e.g., GPS L1 C/A vs. L1 P(Y)) in preprocessing.

## 34.7 Outlook

For many years the POD community mainly focused on GPS since this was the only stable constellation. Over the course of nearly three decades, the knowledge of physical properties underlying the measurement system have been continually refined. The high accuracies achieved today are enabled by several key factors: taking advantage of tracking data provided by a large, global set of geodetic stations, careful treatment of measurement biases, robust data editing schemes, sophisticated modeling of station motion, atmospheric effects, clock offsets, electrical phase centers, spacecraft dynamics and attitude.

In recent years, the renewal of the GLONASS constellation and the building of Galileo and BeiDou has

resulted in a total of four usable GNSSs. The level of knowledge about the newer systems, and accuracy of POD products, is in many ways comparable to the first decade of precision GPS. The challenges that lie ahead are multifaceted: areas such as the handling of measurement biases between the GNSSs, treatment of more complex signal structures, multi-GNSS ambiguity resolution, and the generation of consistent time scales provide rich grounds for research and development. Details regarding spacecraft attitude control, physical satellite properties and force models, antenna-phase centers, and constellation operations are still in limited distribution. It is, therefore, paramount for the precision GNSS community to engage system operators to make available detailed system information enabling precise POD. For the foreseeable future, GPS will remain the cornerstone of multi-GNSS processing, but the accuracies achieved with the other systems should rapidly improve.

For all GNSSs, model improvements and the determination of clock offsets remain important research topics. Orbit parameters are constrained by well-understood dynamics, but clocks are treated as unconstrained epoch parameters to mitigate for steering, reset events, and other difficult-to-model behaviors. Epoch-independent parameterization, coupled with least-squares estimation, allows clock estimates to absorb model errors to minimize postfit residuals.

Since clock estimates refer to antenna phase centers, accurate models for phase and group delay (receiver and transmitter) and spacecraft attitude are particularly critical. Correlations between receiver clock, geodetic station height, and zenith tropospheric delay are concerns for some science applications. Highly stable satellite clocks may alleviate some of these issues. For instance, the Galileo passive hydrogen masers allow for modeling the clock instead of epoch-wise estimation. It was demonstrated that this approach promises to also improve the orbit quality [34.136].

A challenge for the IGS is the development and implementation of a new software for a fully consistent combination of orbits and clocks of multiple GNSSs, also known as *ACC 2.0*. Currently, combined GPS and GLONASS products are generated by completely separate processing chains. Furthermore, no combined Galileo and BeiDou products are generated although several ACs provide solutions for these systems. The need for such a software upgrade has long been recognized but little progress has been made so far. Related to this, the determination and communication of GNSS timescales in a multi-GNSS world requires an expanded set of signal conventions.

Increasing demands from scientific users drive many of these challenges. GNSS provides important baseline and orientation information to the determination of the global terrestrial reference frame, but does not contribute to geocenter and scale due to the lack of independent, absolute antenna calibrations. Many precise geodetic and atmospheric science applications are taking advantage of the improved spatial and temporal observation coverage offered by multiple GNSS constellations, but continue to observe signals in physical parameters at frequencies related to GNSS spacecraft dynamic forces. The societal benefits provided by emerging low-latency, high-accuracy GNSS applications in areas such as tsunami and earthquake early warning place significant demands on GNSS measurement and processing infrastructure. These are only some examples illustrating the continued promise of precise GNSS POD and its applications, with technical and scientific rewards that will progress well beyond this generation.

*Acknowledgments.* We would like to thank the Editors for their helpful reviews during the development of this chapter and Mathias Fritsche, Deutsches GeoForschungsZentrum Potsdam (GFZ) for providing information on orbit and clock combination.

# 35. Surveying

Chris Rizos

The Global Positioning System (GPS) became available as a civilian geodetic survey technology in the early 1980s. It has since revolutionized not only geodesy, but surveying operations as well. Global Navigation Systems (GNSSs) are today a fundamental tool for the land, engineering, and hydrographic surveyor. The majority of GNSS survey tasks relate to the determination of high-accuracy coordinates in a well-defined reference frame, typically using differential GNSS positioning techniques based on the analysis of carrier-phase measurements. Carrier-phase-based positioning is capable of distinct *levels* of accuracy – submeter, few decimeters, centimeter, and even subcentimeter – through a combination of special instrumentation, sophisticated software, and unique field operations. The evolution of GNSS from a geodetic surveying technology to a versatile surveying tool has seen precise positioning implemented in real-time, using ever shorter spans of measurements, and even when the user receiver is in motion. Furthermore, new techniques based on precise single-point positioning, as well as wide-area reference receiver networks, are starting to find wider use.

Among the first civilian GPS user communities in the early 1980s were geodetic surveyors, who used the technology to determine the coordinates of ground marks in control networks. Today, around the world, GNSS is unchallenged as the primary technology for geodetic surveying.

Geodetic surveying requires the determination of geodetic coordinate information that is of high accuracy. This implies a level of coordinate accuracy significantly higher than that possible using standard GNSS open services, such as GPS's Standard Positioning Service (Chap. 7) or Galileo's Open Service (Chap. 9), which deliver meter-to-dekameter level single-point positioning accuracy (Chap. 21). In this chapter, the accuracy requirements for surveying and mapping applications will be assumed to be in the range from subcentimeter to the submeter. Such high positioning accuracy requirements have spurred the development of unique observation procedures, measurement technologies, and data analysis methods – all of which are hallmarks of *GNSS surveying*.

High-accuracy GNSS positioning is synonymous with the differential positioning mode [35.1]. The differential GNSS techniques (Sects. 21.5 and 26.1) range from those based on pseudorange measurements to carrier-phase-based positioning which – depending upon the algorithm and operational mode that is used – can deliver accuracies from a few millimeters to several decimeters. New developments in precise point positioning (PPP; Chap. 25) offer an alternate mode of survey receiver operation that does not require a nearby simultaneously operating GNSS reference receiver.

One of the key features of differential GNSS techniques compared to terrestrial geodetic surveying techniques is that intervisibility between pairs of observing GNSS receivers is not necessary. In fact, the distance between GNSS receivers may range from a few kilometers for land or engineering survey applications, to hundreds and even thousands of kilometers in the case of global geodesy applications. Furthermore, the ground marks whose coordinates are to be determined are *static*. In the case of GNSS geodetic surveying great care is taken to build stable monuments upon which the GNSS antennas are mounted – concrete pillars, steel pins, metal tripods, or poles fixed to bedrock or attached to structures. The assumption is that the three-dimensional coordinates are determined once, and then these coordinated ground marks serve as the datum control marks to which all other (lower accuracy) surveys are *connected*. In this way, the datum or reference coordinate system is propagated to all geospatial data observed using any of the standard terrestrial or GNSS-based surveying and mapping techniques.

For many tasks, the geodetic, land, engineering, or hydrographic surveyor does not require coordinate information in *real-time* (RT). GNSS surveys typically have as their raison d'etre the production of a digital map, the computation of the precise coordinates of the GNSS receiver antenna trajectory, or the establishment of a network of coordinated ground control marks. Nevertheless there are GNSS surveying applications where real-time coordinates are required, as in the case of machine automation applications, or for construction set-out tasks, or trajectory determination, or to navigate from one point to another (Chaps. 21 and 30).

It must be emphasized that *GNSS surveying* is actually an extension of *GPS surveying* – a set of precise satellite-based positioning techniques that have evolved over a period of about three decades [35.1–4]. In fact all mathematical concepts, measurement principles, operational procedures, and applications were first developed using GPS technology. With a heritage of geodetic survey applications, the first decade of GPS surveying was characterized by static positioning in which two GPS receivers recorded measurements during an *observation session*, and subsequent data processing generated the baseline vector connecting a ground point of known geodetic coordinate to a point whose coordinate was to be determined [35.2]. Back in the office, the recorded measurements from the pair of simultaneously operating receivers would be processed, one observation session at a time, to compute the single-session baseline vectors. A network of coordinated points observed in this way would be an effective realization of the geodetic datum, which could be used for subsequent survey and mapping tasks.

During the 1990s, a series of developments led to an extraordinary increase in the productivity of GPS:

- GPS surveying was enhanced by developments that offered an increased flexibility due to the short baseline survey mode.
- Rapid GPS positioning techniques, including real-time operations.
- Use of permanent GPS receivers (obviating the need for the surveyor to operate their own reference station receiver).
- High-accuracy (geocentric) geodetic national and regional datums.
- The availability of GPS data products such as those of the *International GNSS Service* (IGS; Chap. 33).

The drive for improvements in the performance of GNSS surveying techniques continues to this day. Key achievements include faster carrier-phase ambiguity resolution (AR; hence shorter observation sessions), more robust positioning (hence fewer erroneous baseline solutions), and lower operational constraints (hence lower field survey costs). These improvements result from several independent developments, such as multi-constellation GNSS (more satellites), more frequencies (more reliable AR, longer baselines), better designed signals (lower multipath), higher quality satellite clock and orbit data products, standardization of data file and transmission formats, permanent reference receiver networks, real-time carrier-phase-based techniques, geoid models (for height determination), and improved GNSS receiver technology.

Such improvements are not only of benefit to the geodetic and surveying community, but also they are facilitating the adoption of carrier-phase-based GNSS techniques into application areas such as machine guidance and automation (including robotics), rapid mapping (using terrestrial, marine and airborne sensors), construction and mining engineering operations, and precise navigation, to name but a few.

In summary, different GNSS positioning modes and data-processing strategies are all designed to account for systematic errors in the GNSS measurements, or contribute supplementary information for observation models, so as to assure a certain level of coordinate accuracy, at the minimum cost and complexity. The following have fundamental influences on the methods of GNSS positioning (Chaps. 21 and 26 and [35.1, 3, 4]):

1. The type of GNSS measurements – *carrier-phase* measurements are used because of their low noise.
2. Whether positioning is determined in an *absolute* sense using only *single-receiver* measurements, or

defining the position of one receiver *relative* to one or more reference receiver – the former implying the coordinate datum is fixed by satellite orbit information (as in the case of single point positioning or PPP); and the latter by the fixed/known coordinates of the reference receiver(s).
3. Whether the coordinated point is *stationary*, or is in *motion* – the former allows for a *stacking* of measurements that increase the solution redundancy (Chap. 22), and hence improve the precision (and, in general, the accuracy) of the estimated parameters; whereas the quality of kinematic positioning is strongly influenced by instantaneous satellite geometry and the magnitude of residual measurement biases or disturbances.
4. Whether the coordinate solution must be generated in *real-time*, or is derived *post-survey* – the former requires more complex instrumentation and additional infrastructure (variety of communication links, generation of real-time augmentation information, data formats, and protocols); whereas coordinate solutions generated in post-survey mode are typically more accurate than those derived in real-time.

This chapter focuses on the precise positioning applications for geodetic, land, engineering, and hydrographic surveying, and is organized as follows. Section 35.1 introduces the fundamental classes of precise positioning techniques used for the various surveying applications, and discusses the characteristics of static and kinematic type positioning, as implemented in real-time or post-processing methods, based on either the relative or point positioning modes. Section 35.2 discusses the first of the GPS applications that used carrier-phase-based relative positioning techniques – geodetic surveying. All other forms of GNSS surveying have been derived from the basic geodetic surveying principles. Land surveying is introduced in Sect. 35.2. Sections 35.3 and 35.4 deal with engineering surveying and hydrographic surveying applications, respectively.

## 35.1 Precise Positioning Techniques

Civilian users have from the earliest days of GPS availability demanded ever increasing levels of performance, in particular higher accuracy, improved reliability, lower costs, and faster results. This is particularly true of geodesists, surveyors, and engineers, who seek accuracy that is several orders of magnitude higher than that required by other GNSS users. Although it is possible to categorize positioning applications according to a range of criteria, the following considerations are useful: accuracy, time sensitivity of positioning, time-to-coordinate-solution, receiver kinematics, infrastructure requirements, and nature of supplementary model information. Each of these is discussed below.

*Accuracy* traditionally has been expressed in relative terms, for example, as a ratio of coordinate error (typically expressed as a 95% uncertainty) to distance (between ground marks, or between GNSS receivers when operated in differential mode). The coordinate error then can be expressed in metric or distance units by scaling the ratio by receiver or ground mark separation. Hence *one part-per-million* (or 1 ppm) is a relative accuracy measure of one centimeter between two points separated by 10 km, or 0.5 cm over 5 km, or 10 cm over 100 km, etc. Furthermore, it can refer to a single coordinate component (e.g., $x$, $y$, or $z$ Cartesian coordinates, or the *height component*) or a transformed coordinate quantity such as the *horizontal component*.

Surveys (and hence coordinates derived from them) were (and still are to a major extent) categorized in a *hierarchical* sense, from the highest *geodetic* categories through to lower accuracy control, engineering, and mapping surveys. Nowadays, the range of accuracies for high-accuracy GNSS surveys would be from subcentimeter to perhaps the decimeter-level. There is a complex relationship between, on the one hand, accuracy sought, and on the other hand the GNSS hardware, field procedures, and data-processing strategies that should be used. Some are formulated as recommended standards and guidelines; however many are not. Interestingly, the GNSS hardware varies the least, as invariably multi-frequency GNSS equipment is used no matter what type of survey is conducted (although there are different receiver/antenna form factors). In contrast, the measurement modeling used within the data-processing software varies considerably from commercial systems designed to satisfy the needs of land and engineering surveyors, optimized for rapid and easy use in constrained conditions (primarily with regards to length of observation time and inter-receiver distance), and geodetic software capable of ultra-high-accuracy intended for crustal motion and geoscientific applications (Chaps. 36 and 37).

*Timeliness* is a critical concern for some engineering and machine guidance applications, where the coordinate results are required without delay. This

gives rise to one of the most important distinguishing characteristics of high-accuracy GNSS: real-time operations or post-survey processing. The former has a considerable impact on operations and supporting infrastructure, whereas the latter is sufficient for geodetic applications, land and surveying, and most mapping needs. *Time-to-solution* is closely related to timeliness. Static geodetic survey operations typically require lengthy *observation sessions*; whereas high productivity and RT surveys must have very short *initialization* periods that subsequently enable precise single-epoch positioning. Long observation sessions are necessary for high-accuracy surveys over extended inter-receiver distances (hundreds to thousands of kilometers) typical of geodetic surveying applications. Hence time-to-solution is also closely related to the competitiveness of GNSS with conventional terrestrial surveying technology operating over typical survey project distances of the order of a few tens of kilometers or less.

*Kinematics* refers to the movement of the GNSS receiver while conducting the positioning task. A GNSS receiver may be in continuous motion, mounted on a variety of land, marine, air, and spaceborne platforms; or attached to a monumented ground mark; or perhaps in hybrid static–kinematic mode. The kinematic survey mode implies single-epoch, single-receiver positioning for each space point on a trajectory. On the other hand, static positioning (especially in post-processed mode) benefits from a massive increase in redundancy in positioning models [35.2] because many measurements can be used to determine the coordinates of a single stationary ground point. However, high-accuracy kinematic positioning capability is critical for many engineering surveying applications (Sect. 35.3).

High-productivity techniques for rapid surveying and real-time operations (e.g., in support of machine guidance, engineering, and construction) are very demanding of *reference receiver infrastructure*, including information technology and wireless communications. Relative positioning requires the operation of one or more *nearby* simultaneously operating reference receivers; whereas techniques such as PPP do not, in general, have this requirement. Furthermore, the density of *reference receiver networks* may vary from very low in the case of the most sophisticated geodetic static techniques or PPP to very high density (typically less than a few tens of kilometers spacing) for high productivity surveys and real-time operations.

*Augmentation information* is required by all precise positioning techniques, ranging from GNSS measurements at reference receivers in the case of relative positioning techniques to precise orbits, clocks, and perhaps atmospheric/bias information for PPP techniques. With respect to supplementary model information, the critical distinction is between the transmission of augmentation information to users (with all the demands that places on infrastructure operations and service providers) and the provision of such information post-survey impacting upon the timeliness of precise positioning.

In the following sections, the major precise positioning techniques and their distinguishing characteristics are discussed in further detail. It must be emphasized that the development of multi-constellation GNSS receivers, and associated data-processing software, to take advantage of the massive increase in the number of available GNSS signals over the coming years (Chaps. 7–11), will lead to significant improvements in performance – from a reduction in observation session lengths for rapid-static surveys, to single-epoch AR, to relaxed (i. e., longer) user-reference receiver distance specifications (and hence lower infrastructure requirements), to increased reliability and quality of positioning. Furthermore, the increase in variety, access, accuracy, and applicability, and the decrease in latency of GNSS services will also lower the constraints for precise GNSS positioning. However, whether the cost of top-of-the-line geodetic-grade GNSS receivers will fall substantially is uncertain.

### 35.1.1 Static Positioning

With a heritage of geodetic survey applications, the first decade of GPS surveying was characterized by *static positioning*. The employed techniques can nowadays be generalized to static GNSS positioning and are summarized in Table 35.1. A survey with a minimum configuration of a pair of GNSS receivers progresses as follows [35.1]:

1. One (or more) receiver antenna would be set up on a monumented control point with known datum coordinates (the so-called *reference station* or *base station*), the other(s) over ground mark(s) whose coordinates are to be determined.
2. During an observation session, sufficient measurements of carrier-phase observations to the visible GNSS satellites would be recorded simultaneously by all receivers for a period ranging from an hour (or so) to several days.
3. One (or more) receiver would then be moved to another point and the antenna set up over a new ground mark. The other (or several) reference receiver(s) would occupy the same (or a new) datum control mark(s), and another observation session would ensure that measurements were recorded by the simultaneously operating receivers.

**Table 35.1** Summary of precise GNSS positioning techniques – static positioning

- Typical scenario: two or more receivers used simultaneously in campaign, multisession mode, to record measurement files at many points
- Reference receiver separations are project-specific, ranging from tens to hundreds, and even thousands kilometers
- Observation session lengths from about an hour to several days; or continuous observations in case of permanent control or deformation monitoring points
- Monumentation: from highly stable to temporary ground marks
- Top-of-the-line GNSS receivers (carrier-phase measurements on at least two frequencies to form ionosphere-free observables), choke-ring (or equivalent) antennas
- Application typically for the establishment of geodetic control points, or densification of existing control marks
- Commercial software processing is in single-baseline mode, with simplified functional model of estimable parameters consisting of baseline (vector) components and double-differenced ambiguities (unresolved); requiring subsequent single-network adjustment of multiple baseline vectors
- Scientific (geodetic) software has rigorous multi-receiver, multi-session analysis capability; with options to estimate a wide variety of additional orbit, clock, bias, atmospheric, and reference frame parameters
- Resolution of ambiguities is not generally necessary
- Post-processed baselines or multi-receiver scenarios; with datum constrained by reference receiver coordinates; quality is a complex function of many environmental and observation factors, and the degree of sophistication of observation and reference frame modeling

**Table 35.2** Comparison of static GNSS positioning techniques

| | Single-baseline static GNSS surveying | Multi-station GNSS geodetic surveying |
|---|---|---|
| Datum | • Base station per baseline processing<br>• Datum station(s) in network adjustment of baselines | • Small number of reference stations<br>• Typically IGS stations; International Terrestrial Reference Frame (ITRF) |
| Inter-receiver distances | • Tens of kilometers | • 100–1000s km |
| Observation session | • One to several hours | • Several hours to several days |
| Accuracy | • Relative accuracy of 0.5–1 ppm horizontal, 1–2 ppm vertical; implying centimeter-level coordinate accuracy over typical baseline lengths | • 1–10 ppb; implying centimeter-level coordinate accuracy within GNSS networks over 100–1000s km extents |
| GNSS hardware | • Single-frequency GPS; or multi-GNSS, multi-frequency receiver<br>• Light-weight antenna, mounted on tripod | • Multi-GNSS, multifrequency receiver<br>• Choke-ring (or equivalent) antenna, mounted on stable monumentation |
| Processing | • Commercial off-the-shelf baseline processing software; automatic processing<br>• Receiver INdependent EXchange (format) (RINEX) or proprietary data files<br>• Simplified functional model | • Multi-receiver, multi-station scientific software; considerable analyst skill<br>• Web processing (automatic)<br>• RINEX data and auxiliary model or information files<br>• Sophisticated functional model |
| Estimated parameters | • Baseline vector<br>• Double-differenced, unresolved (real-valued) ambiguities<br>• Following network adjustment: individual receiver coordinates | • Receiver coordinates<br>• Ambiguities, tropospheric parameters<br>• Optionally satellite orbits, biases, Earth orientation parameters, etc. |
| Applications | • Project control surveys; and other postprocessed surveys<br>• Alternative to terrestrial control survey technologies | • Reference frame observations<br>• Geodynamics and other geodetic applications |

4. This procedure of moving receivers to predefined points, and recording measurements made at all GNSS receivers, would be repeated until all ground marks in the survey area were visited at least once – always ensuring that there was a *link*, or baseline connection, back to one or more datum control points.

There are two classes of static GNSS relative positioning techniques, which are compared in Table 35.2.

On the one hand there are the ultra-accurate, long baseline GNSS techniques – capable of relative positioning accuracies of tenths of ppm up to several parts-per-billion (ppb) over baseline lengths of hundreds to thousands of kilometers. The measurements are made by top-of-the-line, multi-frequency, multi-constellation GNSS receivers and the observation sessions last for many hours or even days. The measurement processing is undertaken using sophisticated scientific software executed in post-survey mode to support a series of global or national geodesy applications (Chaps. 36–39). As an alternative to processing the measurement data themselves – a task that requires considerable analyst skill – surveyors can submit observation data files in the Receiver Independent Exchange (RINEX) format (Annex A.1.2; [35.5]) to one of several web processing engines such as NGS's OPUS [35.6], NRCAN's CRCS-PPP [35.7], GA's AUSPOS [35.8], and others.

At the other end of the spectrum are the medium-to-short baseline GNSS survey techniques. They are capable of accuracies of a few ppm for baselines perhaps up to several tens of kilometers in length and are typically employed to support control network applications. Although low-cost single-frequency hardware could, in principle, be used, today's GNSS surveying hardware is essentially the same *geodetic-grade* receivers as would be used for any of the multi-frequency precise positioning techniques [35.2]. However, the measurement processing is carried out using commercial software packages provided by GNSS receiver manufacturers, distinguished from the scientific software referred to earlier by the use of significantly simplified GNSS observation modeling. In such scenarios the recorded measurements from a pair of simultaneously operating receivers would be processed, one observation session at a time, to compute single-session *baseline* vectors. Following baseline processing, carried out for baselines during each independent observation session, the multiple computed baselines would undergo a *secondary network adjustment* [35.3, 4]. The three-dimensional (3-D) baseline vectors are in effect treated as the observations to be adjusted – with the output being the optimal coordinates of the entire ground control network constrained by datum control points. Such a network of coordinated points can be used for subsequent survey and mapping tasks (Fig. 35.1).

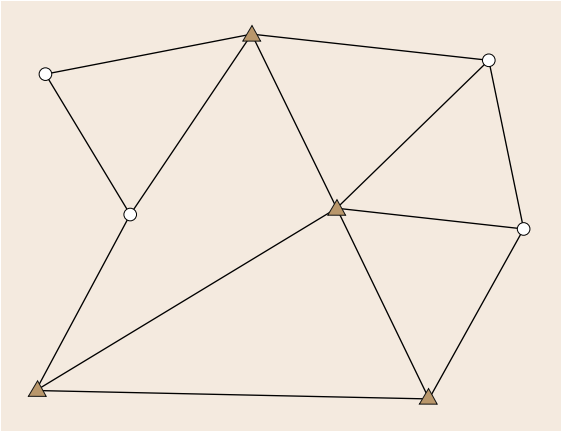

**Fig. 35.1** From independent GNSS baselines to survey network: a network of coordinated points is constructed by linking together separate baselines (i. e., pairs of simultaneously operating GNSS receivers) that connect and propagate the known coordinates of ground control marks (*triangles*) to other points whose coordinates are to be determined (*circles*). Each baseline links a GNSS receiver at a point of known coordinates (available a priori or estimated from a GNSS baseline solution) and a receiver whose coordinates are to be determined. Extra baselines can provide redundant pathways of generating coordinate information for quality control purposes

Conventional static GNSS positioning techniques are characterized by long observation sessions. Although an effective means of mitigating residual systematic biases, multipath, and model errors, this imposes significant constraints for routine surveying applications. Over the last two decades several precise GNSS surveying techniques and methodologies have been developed with the following *liberating* characteristics: (a) static antenna setups not required, (b) long observation sessions not essential, and (c) coordinates could be determined in the field. Each is a technological solution to the challenge of ensuring high productivity (coordinating as many points in as short a field survey time as possible) and/or versatility (e.g., the ability to obtain results even while the receiver is in motion and/or in real-time) without sacrificing coordinate accuracy and solution reliability.

### 35.1.2 Rapid-Static Positioning

For *rapid-static* positioning (Table 35.3) observation session lengths are significantly shorter than for conventional static GNSS surveying discussed above. Ob-

**Table 35.3** Summary of precise GNSS positioning techniques – rapid-static positioning

- Typical scenario: one user receiver in single-baseline configuration
- Reference receiver may be operated by user or by third party, on a single project basis or as continually operated reference receiver; datum defined by reference receiver coordinates
- User-reference receiver separations typically tens of kilometers, often < 10 km for very fast surveys
- Observation session lengths from a few minutes to over 30 mins, but must be sufficient for ambiguities to be resolved
- Monumentation standards are project specific
- Multi-frequency GNSS receivers (carrier-phase and pseudorange measurements), light-weight (portable) antennas
- Applications are typically the coordination of many ground marks, minor control, detail, or as-built surveys
- Data processing via commercial software; may also be undertaken in real-time mode
- Relatively fast high-accuracy GNSS surveying tool
- Assuming use of multi-frequency receiver, quality of solution is a function of baseline length (degree of cancellation of spatially correlated biases), observation session length, quality of measurements, number of tracked satellites, sophistication of data-processing algorithm

servation session length is a complex function of user-reference receiver baseline length, number of multi-frequency measurements, number of satellites tracked, satellite geometry, and presence of multipath disturbances. Accordingly, hard and fast rules are impossible to formulate. Typically, however, receivers need only to occupy a station for a period of perhaps a few minutes for baselines of less than 10 km in length and good satellite coverage. Here, *good* refers to the overall number of tracked satellites (a minimum of six is generally sufficient) and their distribution across the sky (i. e., satellites should be observed in at least three of the four NE-SE-SW-NW quadrants). Extended observation sessions of perhaps up to 15 min or more may be required for longer baselines, less tracked satellites, and/or poor sky distribution of satellites. Several references to GNSS survey guidelines with recommendations regarding observation session length are provided in Sect. 35.2.2. When utilizing measurements from the full complement of GNSS constellations, on two or more signal frequencies, it is expected that the length of the observation session will reduce dramatically, perhaps even down to a single-epoch.

The basis of the rapid-static positioning technique is the ability of the measurement-processing software to resolve the ambiguities using a *very short observation session* – the data analysis software must therefore have a *rapid* AR capability (Chap. 23). The rapid-static field procedures are similar to those for conventional static GNSS surveying, except that: (a) observation session lengths are *shorter*, (b) the baselines are comparatively *short*, (c) the satellite geometry needs to be *favorable*, and (d) signal disturbances such as multipath should be *minimal*. While the observation of independent baselines is the same survey scenario as in the case of conventional static GNSS positioning using commercial software, another more common scenario is the determination of *radiations* of vectors from a single (or two or three) reference stations as indicated in Fig. 35.2.

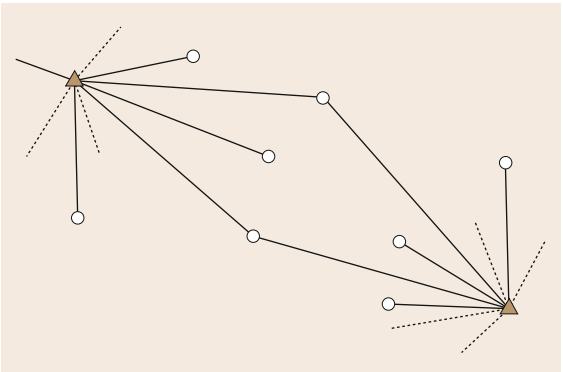

**Fig. 35.2** Geometry of rapid-static baselines: static ground points (*circles*) can be coordinated by the differential GNSS positioning mode via the measurement of 3-D baselines connected to base stations with known coordinates (*triangles*). One can see how logistically efficient this method of observing *radiating* baselines is when a GNSS receiver only needs to occupy the ground marks for short measurement sessions. Note the use of two base stations increases opportunities for quality control. Multiple base stations may or may not be operated simultaneously

The rapid-static technique is well suited for short-range applications such as establishing project-scale control and for certain types of land surveys (Sect. 35.2.3). The essential characteristics of rapid-static GNSS positioning are summarized in Table 35.4.

### 35.1.3 Kinematic Positioning

Table 35.5 lists some of the characteristics of *kinematic GNSS positioning*. We may distinguish between two forms of kinematic positioning. The first is when the coordinates of the moving GNSS receiver antenna's

**Table 35.4** Characteristics of rapid-static and conventional static GNSS positioning

| | Rapid-static GNSS surveying | Conventional static GNSS surveying |
|---|---|---|
| Datum | • Single base station<br>• Radiation of baseline vectors from single reference receiver | • Base station per baseline processing<br>• Datum station(s) in network adjustment of baselines |
| Inter-receiver distances | • Typically less than conventional static | • Tens of km |
| Observation session | • Few minutes to < 1 h; see *factors impacting on accuracy* | • One to several hours |
| Accuracy | • 1–2 cm horizontal, 2–3 cm vertical; over typical baseline lengths | • 0.5–1 parts-per-million (ppm) horizontal, 1–2 ppm vertical; i. e., centimeter-level accuracy over typical baseline lengths |
| GNSS hardware | • Multi-GNSS, multi-frequency receiver (preferred)<br>• Light-weight antenna, mounted on tripod | • Single-frequency GPS (lower performance); or multi-frequency receiver (preferred)<br>• Light-weight antenna, mounted on tripod |
| GNSS software | • Commercial off-the-shelf baseline processing software; automatic processing<br>• RINEX or proprietary data files<br>• Simplified functional model; *rapid AR capability* | • Commercial off-the-shelf baseline processing software; automatic processing<br>• RINEX or proprietary data files<br>• Simplified functional model |
| Estimated parameters | • Baseline vector<br>• Resolved ambiguities, i. e., ambiguity-fixed baseline solutions<br>• Quality control implemented via re-visit of ground marks | • Baseline vector<br>• Double-differenced, real-valued ambiguities<br>• Following network adjustment: individual receiver coordinates |
| Factors impacting on accuracy | • Baseline length<br>• Observation session length<br>• Quality of carrier-phase and pseudorange measurements<br>• Multi-frequency measurements<br>• Number of tracked satellites and geometry | • Baseline length<br>• Observation session length<br>• Quality of carrier-phase measurements |
| Applications | • Project control surveys<br>• Detail, as-built, and other post-processed surveys<br>• Alternative to terrestrial survey technology | • Project control surveys; and other post-processed surveys<br>• Alternative to terrestrial control survey technology |

**Table 35.5** Summary of precise GNSS positioning techniques – kinematic positioning

- Typical scenario: one mobile user receiver in single-baseline configuration; on a variety of land, marine, aerial, or spaceborne platforms
- Reference receiver may be operated by user or by third party, on a single project basis or as continually operated reference receiver; datum defined by reference receiver coordinates
- As with rapid-static surveys, user-reference receiver separations typically tens of kilometers, often < 10 km to ensure AR using geodetic-grade GNSS receivers with short observation sessions
- Single-epoch positioning using double-differenced *carrier-range* observable (double-differenced carrier phase with integer resolved ambiguities), also known as ambiguity-fixed solutions
- Options for re-initialization must be available if signal loss-of-lock on five or more satellites, and may include remaining stationary until ambiguities resolved again, return to previously surveyed static point, etc.
- Multi-frequency GNSS receivers, light-weight (portable) antennas
- Applications typically are the coordination of receiver antenna trajectories, for example, for mapping projects (road centerline surveys, aerial imaging/scanning), satellite orbit determination, hydrographic charting, etc.
- Model and data processing via commercial software; may also be undertaken in real-time mode (see below)
- Assuming multi-frequency user receiver, quality of solution is a function of baseline length (magnitude of residual differential biases), correctness of AR process, quality of measurements (i. e., multipath-free), number of tracked satellites, satellite-receiver geometry (i. e., Dilution of Precision measures)

**Fig. 35.3** Precise kinematic GNSS survey: the receiver is installed on a quad-bike with the antenna mounted upon on a pole, and the kinematic positioning task consists of determining coordinates of the antenna on a continuously sampled basis (e.g., once per second) as the bike as driven up and down the beach, to determine a dense network of heights with centimeter-level accuracy for beach erosion studies; note that the antenna height must be corrected for the fixed height of the top of the pole above the ground level (courtesy of Brad Morris)

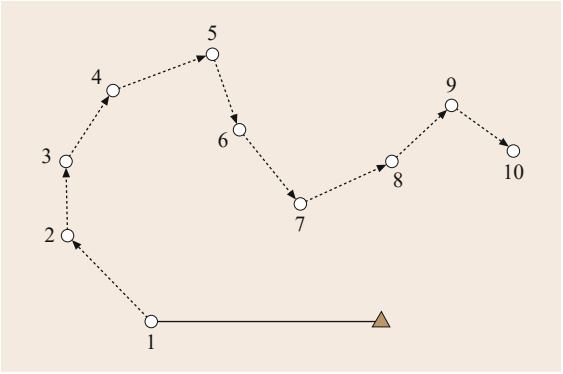

**Fig. 35.4** Progress of a *stop-&-go* GNSS survey: the first baseline is observed (known control mark to point 1), and once the ambiguities have been resolved (e.g., using the rapid-static positioning technique), the user receiver's antenna is then moved carefully from point 1 to point 2, then to point 3, and so on, making just a few seconds of measurements while stationary at the ground point (*circle*). Note the base station (*triangle*) operates continuously and the point coordinates are determined by the radiated baseline method (Fig. 35.2); the trajectory of the antenna is not of interest, only the coordinates of the stationary points 1–2–3–4...

trajectory is required (as in Fig. 35.3). The second category is a form of static positioning, but with the special case that the receiver continues to track satellites while it is moved from one static point to another.

The *stop-&-go* GNSS surveying technique deserves special consideration because the coordinates of the receiver are only of interest when it is stationary (the *stop* part); however the receiver continues to function while it is being moved (the *go* part) from one stationary setup to the next, as is indicated in Fig. 35.4.

The first step that needs to be performed in the survey is the initial AR in order that all subsequent single-epoch solutions are based on carrier-range positioning (Sects. 23.2 and 26.3). This technique is well suited to projects where many points close together have to be surveyed, and the terrain does not cause significant signal obstructions.

Instead of only coordinating the stationary points and disregarding the trajectory of the roving antenna, the objective of *kinematic* surveying is to determine the position of the antenna while it is in motion. In many other respects the technique is similar to the *stop-&-go* positioning technique. That is, the ambiguities must be resolved *before* starting the survey, and the ambiguities must be re-initialized *during* the survey when loss-of-signal-lock occurs which causes the ambiguity parameters to change from their initial values. Kinematic positioning invariably involves the determination of vectors radiating from a single (or small number of) base or reference station(s) (Fig. 35.2). Kinematic GNSS surveying techniques are appropriate for road centerline, topographic and hydrographic surveys, airborne applications, etc.

### 35.1.4 Real-Time Differential GNSS Positioning

*Real-time kinematic* (RTK) GNSS is a popular technique for many survey applications as there is no post-processing of GNSS measurement data (Sect. 26.3). The standard differential positioning scenario as before requires the use of a pair of GNSS receivers connected by a wireless data link (Table 35.6). Successful operation of RTK-GNSS systems using radio modem data links is typically limited to baseline lengths of 5–10 km due to radio range constraints. Wireless links over the mobile Internet do not have such distance restrictions. However, the inter-receiver distance over which *rapid* AR algorithms work reliably using dual-frequency GNSS instrumentation (with good sky visibility) may only be 20–30 km, and often less in the event of high ionospheric activity (Chap. 39). As with carrier-phase-based kinematic positioning in general, when signals are obstructed the AR algorithm has to be restarted in order to resolve the (new) ambiguity parameters. As this may take several tens of seconds, and if signal interruptions occur frequently, then this

**Table 35.6** Summary of precise GNSS positioning techniques – real-time differential positioning

- Rapid-static and kinematic may be conducted in real-time, and collectively these ambiguity-fixed, short-baseline approaches are known as *real-time kinematic* (RTK) techniques
- Operational constraints, reference receiver infrastructure requirements, and GNSS receiver specifications are as for rapid-static and kinematic GNSS surveys (see above)
- May distinguish between operational constraints for *single-base RTK* (with baseline lengths of a few tens of kilometers), and multiple reference receiver *network-RTK* with sparser reference receiver network surrounding user receiver (50–100 km spacing) [35.9]
- Additional infrastructure: networked reference receivers, analysis or network operations facility, and communications links (between reference receivers, and between reference receiver, or RTK service facility, and user receiver)
- Variety of wireless communication links, though increasingly via mobile Internet (terrestrial or satellite) channels; with interoperability afforded by use of industry standard data transmission messages and protocols such as Radio Technical Commission for Maritime Services (RTCM)
- Applications include all those that require precise coordinates in real time, to guide a machine or vehicle, for engineering or construction, and others
- Versatile high-accuracy GNSS positioning technique when supported by the necessary augmentation infrastructure
- Factors impacting quality are as for kinematic surveys, and in addition the reliability of the RTK communications link

*dead time* can result in RTK-GNSS being a comparatively inefficient positioning technique. The advantage over post-processed implementations of precise kinematic positioning is that when operated in real-time, the GNSS controller is able to alert the user in the event of the need for ambiguity re-initialization (i. e., new AR), or if there is an interruption in wireless communications from the reference receiver or RTK services center.

Most users subscribe to RTK-GNSS services rather than running their own reference receiver. Real-time networks of continuously operating reference stations (CORSs) have been established since the mid-1990s, and there are few signs of this trend slowing. One of the drivers for CORS investment, and the promotion of the use of RTK-GNSS, is the adoption of industry standard RTCM data message format and protocols (Annex A.1.3; [35.10]), ensuring interoperability between different brands of reference and user GNSS receivers. CORS installations typically comprise top-of-the-line receivers, with choke-rings antennas, capable of making multi-frequency, multi-GNSS measurements. The challenge is to install CORSs at sufficient density (minimum reference receiver separation) to permit single-base RTK with rapid AR (see schematic in Fig. 35.5). Note that this density of CORSs is the same as that for post-processed rapid-static and kinematic GNSS positioning using relative positioning principles.

RTK-GNSS implementations based on a network of reference stations (rather than a single reference station) are now common in many countries. Recall that one of the primary purposes of reference stations is to mitigate the impact on coordinate solutions of those systematic measurement biases and model errors that are spatially correlated [35.11, 12]. (The other is to provide the datum for differential positioning.) In the simplest configuration, it is assumed that in the case of two *nearby* GNSS receivers, when the measurements are made at the same time, and processed in an integrated observable model such as that produced by double-differencing measurements from a pair of receivers to a pair of GNSS satellites, there is no (or negligibly small) effect of atmospheric refraction biases and satellite orbit/clock errors on the baseline results (Sects. 21.3 and 26.1). Of course that assumption breaks down as the distance between the two GNSS receiver increases. Hence single-base RTK essentially requires

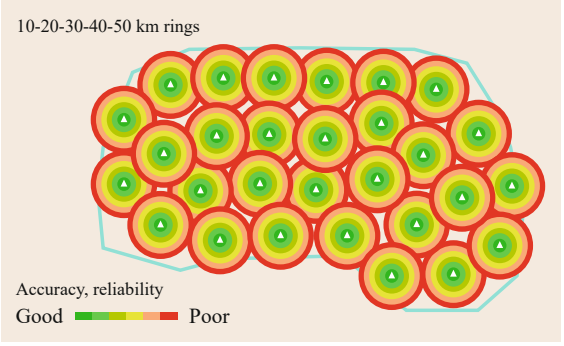

**Fig. 35.5** CORS infrastructure for single-base RTK – indicating the *packing* of a network of continuously operating reference stations to support single-baseline, rapid-static, and kinematic positioning, so as to provide complete coverage over an area. Note the closer the user receiver is to a CORS the more reliable the GNSS position solution. Ideally the distance should be no greater than a few tens of kilometers (hence the graduation in color of the rings around each CORS indicating varying solution quality, from *green* for the highest to *red* for the lowest)

**Table 35.7** Comparing single-baseline RTK and network-RTK GNSS positioning

| | Single-baseline RTK | Network-based RTK |
|---|---|---|
| CORS infrastructure | • User owned CORSs; or Service Provider (SP) owns CORS<br>• Many CORSs for full area coverage | • Service Provider (SP) owns CORSs; or licenses raw data from organization operating network of CORSs<br>• Evenly distributed CORSs across service area |
| Service provision | • User-operated; or SP<br>• RTCM v2 or v3 messages | • SP; or CORS operator<br>• RTCM v3 N-RTK messages; or VRS-based customized RTCM v2 messages |
| Inter-receiver distances | • Tens of kilometers, preferably < 10 km for most reliable operations and/or<br>• rapid on-the-fly AR | • 50–100 km CORS spacing across service area<br>• < 30–50 km user receiver to nearest CORS |
| Configuration | • Nearest CORS<br>• Owner-operated; or subscription to SP<br>• Typically direct user-CORS connection | • User located within cluster of 3–4 CORSs<br>• Subscription to SP<br>• Central network or operations server/facility |
| Modeling of spatially correlated biases | • Cancellation of satellite-specific and atmospheric biases in double-differenced measurement model, by assuming biases identical to those of nearest CORS<br>• RTCM messages are *calibration* of biases at CORS location | • Cluster of CORSs surrounding user receiver location used to derive bias *correction surface*<br>• RTCM messages carry all information necessary for computation of location-specific biases to be applied as corrections to user receiver measurements |
| Communication options | • Terrestrial: ultra-high frequency (UHF), very high frequency (VHF), MF beacons, digital broadcasts, mobile Internet, etc. | • Terrestrial: mobile Internet<br>• Satellite communications |
| Accuracy | • Centimeter-level horizontal accuracy; 2× worse for vertical | • Similar accuracy to RTK; though with higher solution reliability |
| GNSS hardware | • Single-frequency GPS (but distances shorter and/or longer AR process); or multi-frequency receiver (preferred)<br>• Light-weight antenna, mounted on bipod or pole, or moving platform | • Multi-GNSS, multi-frequency receiver (preferred)<br>• Same antenna and mounting options as RTK |
| Applications | • Engineering surveying, machine guidance, and control (in agriculture, mining, construction, port operations, etc.) | • Same as RTK but operations less constrained by distance to nearest CORS; increased reliability due to multi-CORS configuration |

the determination of baseline vectors radiating from the nearest RTK-capable reference station.

In contrast, a cluster of CORSs can be used to map the spatially correlated biases and errors across a CORS coverage area, and to apply these corrections to measurements at the user receiver location. This multi-CORS RTK-GNSS technique is often referred to as *network-RTK* (N-RTK), and its primary advantage from the point of view of the RT GNSS service providers is that the separation between user receivers and the surrounding CORSs can be of the order of 50–70 km or more [35.11–14]. The assumption that the systematic biases and model errors at the nearest CORS are the same as those at the user receiver location is replaced by the more realistic assumption that the biases and errors can be predicted at the user receiver location using a model of these biases and errors [35.15, 16].

N-RTK services can be supported by less dense CORS networks than single-base RTK services. Furthermore, the precise coordinates are not strictly determined relative to a single (or nearest) reference receiver, but has similarities to network-based (i. e., multi-station) static positioning. There are a number of implementations of N-RTK [35.14, 16, 24–26], of which the virtual reference station (VRS) scheme is the oldest and best known [35.15]. Some characteristics of RT-GNSS positioning are summarized in Table 35.7.

As a result of substantially more measurements and frequency-diversity, multi-constellation precise GNSS positioning will be able to be carried out with significantly greater distance-to-CORS than current N-RTK implementations – distances of over 100 km.

### 35.1.5 Precise Point Positioning

PPP (Chap. 25 and [35.19, 27–29]) is a GNSS carrier-phase-based positioning technique that can be used anywhere on the globe by a single user receiver – at

**Table 35.8** Summary of precise GNSS positioning techniques – precise point positioning

- Typical scenario: one static or mobile user receiver; the latter on a variety of land, marine, aerial or space platforms
- User GNSS receiver may be single-frequency or multi-frequency; the latter being preferred as such hardware is identical to survey-grade GNSS receivers used for differential carrier-phase-based positioning
- Requires precise satellite orbit and satellite clock information from an external source; post-processed orbit and clock information available in the form of several open standard formats such as Standard Product 3 (SP3; Annex A.2.1; [35.17]); RT streams use open RTCM-SSR messages (Annex A.1.3; [35.10]) or proprietary messages
- No reference receiver requirements for user positioning (although a sparse global network of reference receivers are needed for the computation of satellite orbits and clocks)
- Datum defined by reference frame in which orbits, clocks, biases and other parameters are computed; typically the International Terrestrial Reference Frame (ITRF) (Chaps. 2 and 36; [35.18])
- Real-time or post-processed software does not require reference receiver measurements; observation modeling is more sophisticated (and complete) as it must account for all systematic biases and model effects (those that may have been mitigated or eliminated in between-receiver data differencing)
- Dual-frequency PPP is capable of providing accurate position solutions at subdecimeter level for kinematic positioning and at subcentimeter level for static positioning [35.19, 20]. For single-frequency PPP the positioning accuracy lies at the decimeter level with high-end receivers [35.21] and for kinematic positioning with low-end receivers at the submeter level [35.22]. The high accuracy of dual-frequency PPP is achieved after a relatively long convergence time in the range of 20–40 min, while the decimeter level accuracy of single-frequency PPP is achieved in minutes [35.23]. Additional infrastructure, in the form of networked reference receivers similar to that for N-RTK operations, is necessary for rapid convergence or reliable AR
- Communication links for RT-PPP include geostationary satellite communications, mobile Internet, and downlink messages on navigation satellite signals
- Applications include all those that cannot be easily addressed using relative GNSS positioning techniques, including operations in remote and offshore areas
- Factors impacting quality are similar to those for kinematic surveys, such as satellite-receiver geometry, number of satellites tracked and measurements that are made, but also quality of the model information, algorithm and whether AR is successful (or even required)

least without direct co-processing of CORS measurements, or application of differential correction or model information generated from such measurements (Table 35.8). PPP offers, therefore, considerable flexibility, making it well suited for remote locations (on land and offshore) where there is an absence of GNSS CORS infrastructure.

PPP relies on accurate satellite orbit and clock error information that can be obtained from sources such as the International GNSS Service (Chap. 33), or a number of commercial service providers, and the explicit modeling of a number of measurement biases and system effects that are assumed to have been eliminated when using GNSS in relative positioning mode. PPP can be implemented in post-processed mode or in real-time. The former uses accurate orbit and clock products that are available – depending upon the product that is used – immediately or up to several weeks after the survey task is executed. As an alternative to doing their own processing, surveyors can submit RINEX data files to one of several web processing engines [35.6–8]. The latter uses RT orbit and clock data streams broadcast via the Internet (in the case of the IGS Real-Time Service – IGS-RTS [35.30, 31]), or satellite communications links. These streams may be in proprietary message formats or in the RTCM State Space Representation (SSR) format (Annex A.1.3; [35.10]).

PPP can be done with single- and multi-frequency receivers. Fast single-frequency PPP requires next to orbits, clocks, and differential code biases, also ionospheric maps [35.23, 32–34]. The best possible position accuracy, a few centimeters or better, is obtained by using carrier-phase measurements from dual-frequency receivers. However, single-frequency receivers can provide decimeter accuracy at a reduced cost for the receiver and generally reach this level of accuracy much faster (few minutes) than a dual-frequency receiver does [35.23]. The convergence of dual-frequency PPP is longer (20–40 min) than that of single-frequency PPP as it initially depends on the relatively noisy ionosphere-free linear combination of the code data. Of course, after some time, the ionosphere-free linear combination of the carrier-phase data kicks in for dual-frequency PPP and becomes the determining factor for its high positioning accuracy.

The relatively long convergence time to reach the subdecimeter positioning accuracy, is one of the weaknesses of PPP. The positioning concept of PPP-RTK aims to address these weaknesses by reducing convergence times and improving positioning accuracy [35.35, 36]. It extends the PPP concept by pro-

viding single-receiver users, next to the orbits and clocks, also information about the satellite-phase biases. This information enables recovery of the integer user-ambiguities, thus enabling single-receiver AR thereby reducing the convergence times as compared to that of PPP. At present various different mechanizations of PPP-RTK are under development [35.37–39]. When combined with atmospheric corrections, PPP-RTK is rivalling the speed of standard N-RTK (Table 35.7). This is a fertile area of GNSS research and substantial improvements in performance are expected.

## 35.2 Geodetic and Land Surveying

With the progressive refinement of GPS geodetic surveying techniques to make them easier to use, and to increase their versatility, it was inevitable that the application of GPS technology would extend to include land (see below), engineering (Sect. 35.3), and hydrographic surveying (Sect. 35.4).

### 35.2.1 Geodetic Survey Applications

Geodetic surveying was the first civilian application of precise GPS positioning [35.3, 4]. It is concerned with the establishment, maintenance, and densification of *geodetic datums* – across a range of scales from the global, regional, national, and state territory down to an individual project application (though these are sometimes referred to as *control surveys*, Sect. 35.2.3). Geodetic datums are realized by ground marks with known ellipsoidal coordinates that can be used by any surveyor or engineer as starting coordinates for subsequent precise surveys, to support mapping, surveying, construction, or engineering activities. Precise GPS static positioning (Sect. 35.1.1) revolutionized geodetic surveying because it was able to replace the traditional, slow, labor-intensive terrestrial surveying techniques.

There are several innovations of modern GNSS geodetic surveying methodology that bear mentioning. The first one is the near universal installation of permanent GNSS reference receivers, or CORSs. CORSs range from single-receiver installations to vast networks of CORSs across entire countries (as in Japan's GEONET [35.40], Sweden's SWEPOS [35.41]), regions (e.g., EUREF's permanent CORS network [35.42]), and globally (e.g., the IGS network [35.43]).

Figure 35.6 illustrates some of the CORS sites across the continent of Australia. Note that this is a non-homogeneous CORS networks, with different agencies and individuals being responsible for their operation. This is typical of many national CORS networks. In effect such networks consists of numerous *subnetworks* of CORSs, some established by the federal government agency responsible for geodesy, some by state government departments, and others by private companies, local government authorities, universities, and even individual users. Furthermore the subnetworks may have different equipment configurations, different types of antenna mounts, and monumentation; supporting different user groups with a variety classes of service.

Figure 35.7 shows a typical choke-ring antenna (Chap. 17) with and without radome, installed on two typical designs of geodetic-grade monuments: concrete pillars and rigid tripods. The CORS coordinate reference point may not be the electrical center of the antenna but instead a physical reference mark on the top of the stable monument. Not shown is the instrument cabinet where the receiver itself is housed (together with communications, batteries, and other ancillary equipment), power systems such as solar panels, lightning protection, additional pillars or witness marks, etc. CORS installations such as these are a considerable in-

**Fig. 35.6** GNSS CORS sites across Australia: an example of national CORS infrastructure that is non-homogeneous, with different owners and operators (*different colored dots*), to support a variety of GNSS positioning applications (and techniques), with an uneven distribution across the continent; note that private CORS sites operated by individual farmers, mining companies, universities, local council authorities, and others, are not shown (courtesy of Grant Hausler and ThinkSpatial)

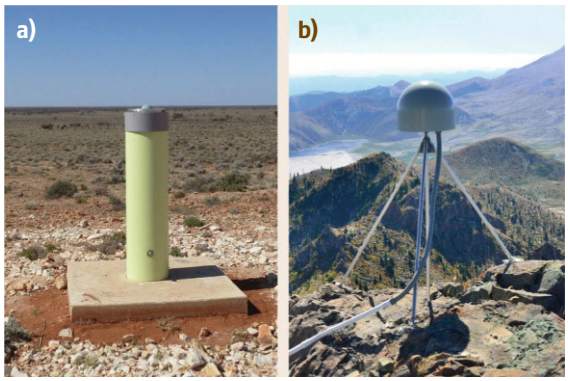

**Fig. 35.7a,b** Examples of geodetic-grade CORS installations: **(a)** on concrete pillar at Mulgathing, in South Australia, part of the AuScope national GNSS network (courtesy of Geoscience Australia); **(b)** drilled-braced monument at Coldwater Peak, part of the EarthScope Plate Boundary Observatory Mount St. Helens subnetwork (courtesy of Michael Gottlieb, UNAVCO)

vestment by an agency or organization in GNSS ground infrastructure.

The second innovation has been the availability of a variety of geodetic products and services, including those provided directly by the IGS (Chap. 33), by web services for GNSS measurement processing (Sect. 35.1.1), and by service providers for RT-GNSS positioning (Sect. 35.1.4), as well as the establishment of standardized data and transmission formats (Annex A) that support GNSS interoperability. This has also had an impact on GNSS measurement processing, allowing for the use of commercial software packages – as opposed to *scientific software* – for all but the most precise, long-baseline geodetic surveys.

The third concerns the nature of geodetic datums themselves. Increasingly national datums are aligned to, or defined by, the highest fidelity global geodetic datum: the International Terrestrial Reference Frame (ITRF; [35.18]). There are a number of reasons for this trend: (a) the global applicability of the ITRF, (b) the very precise set of coordinates and velocities of many GNSS CORSs (such as the IGS's network), (c) the ease of access via CORS tracking data and IGS geodetic products, (d) the well-defined datum epoch and documented maintenance procedures, and (e) its maintenance to the highest standards by the International Earth Rotation and Reference Systems Service (IERS; [35.44]).

Several GNSS geodetic surveying *methodologies* that can be used to distinguish these types of applications from routine engineering and mapping applications that rely on static and kinematic GNSS positioning techniques are summarized in Table 35.9. Note that geodetic surveying assumes the use of *geodetic-grade* multi-frequency, multi-GNSS receivers, with choke-ring or multipath-mitigating antennas, set-up on stable monumentation (Fig. 35.7).

The geodetic survey applications may, at first glance, appear simply as examples of static surveys; however modern geodesy recognizes that no object on the surface of the Earth has zero velocity with respect to the ITRF. The mission of modern geodesy is to determine and monitor the coordinates of sample points in order to improve our knowledge of geophysical processes that have ground motion/deformation signatures [35.45, 46].

*Ground deformation* surveys are undertaken to measure the change in the coordinates of stable points or monuments fixed to the Earth's surface. The points may move in a horizontal or vertical sense, or in three dimensions, with signature characteristics across a wide range of time and spatial scales, from continental motion of the order of millimeters or centimeters per year, to rapid ground shaking during an earthquake reaching magnitudes of many decimeters. There are a number of subcategories of deformation surveys, such as building/structural monitoring, ground subsidence (due to underground fluid extraction or mining) or inflation (due to build-up of magma below volcanoes), tide gauge stability monitoring, and local tectonic fault motion.

Given the sophistication of scientific GNSS analysis (Chaps. 34, 36, and 37), the computation of positions to subcentimeter accuracy may involve the determination of not only the geodetic coordinates of the GNSS receivers, but also improved estimates of receiver and satellite clock errors, signal biases, GNSS satellite orbits, atmospheric delay biases, and Earth rotation/orientation parameters. The continuous processing of measurements from hundreds of globally distributed CORSs, by a large number of organizations, coordinated by international geodesy initiatives, is a geodetic enterprise that defies easy partitioning into different geodetic surveying applications.

### 35.2.2 Land Surveying Operations

The goals of GNSS land, engineering, and hydrographic surveying operations are to coordinate many points on the ground, in the air, or on the sea as quickly as possible to the accuracy required by the client and with the coordinate information expressed in relation to a project, map, or geodetic datum.

It is possible to distinguish between three categories of *point coordination*. One is the task of determining coordinates of points or features that exist. Examples include control surveys, detail or topographic surveys, surveys of buildings and land boundaries, built struc-

**Table 35.9** Comments on GNSS geodetic surveying methodologies

| | |
|---|---|
| Field campaign surveys (baseline mode) | • Application: Densification of geodetic control across a local area<br>• Minimum of a pair of stationary GNSS receivers, operated in single-baseline mode, baseline lengths typically several tens of kilometers<br>• Conventional static positioning (Sect. 35.1.1), with observation sessions ranging from an hour to many hours<br>• Considerable redundancy through multiple occupations of monumented ground control points<br>• Single-baseline measurement processing using commercial software in post-processing mode<br>• Network solution through secondary adjustment of baselines, with known control point constraints applied to ensure consistency and connection to surrounding geodetic control, see Fig. 35.1. |
| Field campaign surveys (multistation mode) | • Applications:<br>– Establishment of a primary geodetic datum network across a large (national or continental) area<br>– Densification of datum across hundreds of kilometers<br>– Rapid datum maintenance geodetic surveys after major earthquake<br>– Multi-campaign GNSS surveys to detect small land or ice movement over periods of years<br>• Multiple receivers deployed across a network of monumented ground control points, in a multi-session mode, to ensure that all control points are occupied by GNSS receiver at least once (and ideally twice, or more)<br>• Static observation session lengths typically from several hours to 24 h (or even longer)<br>• Data post-processing options:<br>– Simultaneous processing of all observed data files in scientific software, with datum constraints applied directly (i. e., ITRF coordinates of some control points) and perhaps also indirectly (use of precise IGS satellite orbit products) – the most rigorous approach<br>– Use web-based processing services such as AUSPOS [35.8], OPUS [35.6], CRCS-PPP [35.7], etc., that link field surveys with surrounding IGS and/or national CORS – however not as rigorous as simultaneous processing of all campaign data in scenario above |
| Continuously Operating Reference Stations (CORS) | • Applications:<br>– *Active* geodetic control points realizing national datum; and possibly also supporting commercial RTK/N-RTK services<br>– Part of (national or international) network of observing stations, whose data is used to generate geodetic products such as coordinate time series, satellite orbits or clocks, ionospheric and tropospheric parameters, etc.<br>– Instrumentation primarily intended for monitoring tectonic motion, localized ground or structural deformation, etc.<br>• Observation data typically streamed to central data or analysis center, where data processing may be carried out in real-time, near-RT, or post-processed mode depending upon application<br>• CORS density may vary from several tens to several hundred (or even thousand) kilometers<br>• Data analysis may be via:<br>– Scientific software similar to that used for post-processing of field campaign data<br>– Specialized software for RT processing to geodetic modeling standard<br>– Commercial baseline or multi-station software to support RTK/N-RTK operations |

tures, etc. The second is determining the position of a moving object or platform, that is, its trajectory, as in the case of a land vehicle, an aircraft, or a ship. The third is to determine the location of a point that has a prespecified 3-D coordinate – as in set-out surveys on engineering construction sites, or way-points that must be navigated to. The latter two types of positioning are discussed in Sect. 35.3.

GNSS technology intended for use by surveyors and engineers needs to be largely automatic, reliable, and easy-to-operate. For high-productivity operations a commercial off-the-shelf package is preferred – receiver hardware, processing and control software, and ancillary instrumentation. The receiver signal tracking and processing electronics are essentially identical to geodetic-grade GNSS receivers, and hence are capable of the same measurement quality – although the choke-ring antenna is usually replaced by a light-weight survey antenna (Chap. 17). Furthermore there has been considerable product refinement in survey-grade GNSS receivers, which nowadays are compact, rugged, and come in a variety of form-factors. The most common instrument form-factor is a single unit (without cumbersome antenna or power cabling) containing receiver electronics, antenna, battery, wireless communications, and data memory, able to be placed on a survey pole or other survey instrument (Fig. 35.8), or on a moving platform (Fig. 35.3).

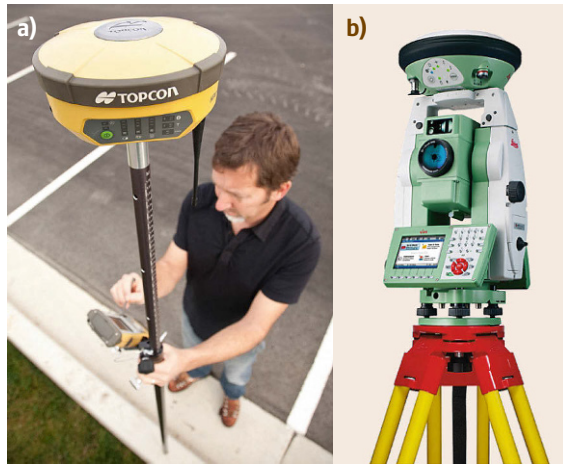

**Fig. 35.8a,b** Some examples of GNSS receiver form-factors for land surveying applications: **(a)** pole-mounted GNSS receiver as used by surveyors and engineers to determine coordinates of static points-of-interest (courtesy of Position Partners); **(b)** GNSS receiver mounted on top of a Total Station supporting integrated survey operation (courtesy of Leica Geosystems) ►

The typical field deployment requires the surveyor's GNSS receiver to move from one point whose coordinates are to be determined to another, and to continue this procedure until all points have been *visited*. The reference receiver remains set up on the point of known coordinate, and hence the 3-D baseline vectors radiate from that reference station to the points being surveyed, as in Fig. 35.2. This configuration is familiar to land surveyors, as *radiation* is the most common means of determining the coordinates of points – for example, by means of azimuth, distance and vertical angle measurement made from a Total Station instrument (Fig. 35.8) set up on a portable tripod over a fixed ground mark. In

**Table 35.10** GNSS land surveying applications and operational issues

| | |
|---|---|
| Control and deformation surveys | In a continuum of static positioning applications ranging from those that can be identified as geodetic surveying (Table 35.9), to local or project control with the following distinguishing characteristics:<br>● Generally employ static or rapid-static techniques (Table 35.4), using commercial data-processing software, although RTK/N-RTK mode sometimes used (though with more redundancy and greater care than typical kinematic surveys)<br>● Non-permanent ground marks (e.g., drillholes, nails in kerbs),<br>Datum typically construction project-based, although linked to the national datum at epoch of observation if using RTK/N-RTK<br>● Purpose is closely tied to nearby engineering or surveying activity<br>● Project extent is typically a few to tens of kilometers across<br>● Deformation surveys are associated with construction activities, or focused on built structures, and require either continuous surveys (or re-surveys at regular intervals) of critical points |
| Topographical surveys and mapping | The rapid determination of the coordinates of many natural surface points or constructed features, across a comparatively small area, with the following characteristics:<br>● *Direct* point coordination by GNSS, using rapid-static, stop-&-go, or kinematic surveying techniques (Sect. 35.1)<br>● *Indirect* mapping, where GNSS is used to determine the precise coordinates of a mapping sensor such as a digital camera or laser scanner<br>● Areal extent is a few hundred square meters to tens (and perhaps hundreds) of square kilometers<br>● Results not required in real-time, though RTK/N-RTK surveys may have lower operational costs<br>● Results may be presented in variety of forms suitable for import into computer aided design (CAD) or geographic information system (GIS) software |
| Cadastral surveys | Cadastral surveys address legal questions such as: where are the boundaries of land parcel, what rights and responsibilities are attached to a land parcel, and the creation of new land titles following subdivision or redevelopment, and hence have the following characteristics:<br>● Due to the considerable variety of national and state land titling and cadastral boundary systems, guidelines on what surveyors must measure, to what accuracy, and what information must be registered, will also vary with national or state jurisdiction<br>● There is considerable scope for use of GNSS surveying techniques for cadastral surveys of rural properties; use in urban areas is more problematic<br>● There are very few coordinate-based cadastres, hence GNSS-derived coordinates must be transformed into distances and bearings to be useful for cadastral mapping applications<br>● Survey project extent is typically a few hundreds of meters to perhaps a few kilometers across |

the GNSS configuration, the surveyor may not even be responsible for the operation of the reference receiver, and is merely using the RT corrections or the recorded data files (in the case of post-survey computations). Although the algorithms underlying Network-RTK take advantage of data from a network of CORSs, as far as the user is concerned the *packaging* of N-RTK messages is such that it mimics the RT processing of a baseline radiating from a nearby CORS to the user receiver (Table 35.7).

GNSS land and engineering surveying procedures are typically prescribed in national or state standards and recommendations, or contract guidelines, especially for cadastral surveys or datum control surveys (Table 35.10). These standards or guidelines may *suggest*, *recommend*, or *define* the hardware requirements, field observation procedures, ground mark design, quality assurance processes, and minimum and maximum thresholds for geometric constraints such as baseline lengths, network quality checks, number of tracked satellites, and so forth. Nowadays, because GNSS is an all-weather system available 24 h a day that does not require intervisibility between survey receiver and reference receiver(s), there is no longer the need to plan for the best time of day to conduct surveys so as to ensure adequate satellite geometry, or to carry out detailed reconnaissance of the survey area. It is beyond the scope of this chapter to delve into national standards or recommendations for GNSS land, engineering, and hydrographic surveying applications; however the reader is referred to documents such as [35.47–53].

### 35.2.3 Land Surveying and Mapping Applications

The range of land surveying and mapping applications is very broad (Table 35.10). However, GNSS is but one technology in the land surveyor's toolkit, best suited to clear sky view conditions that ensure that measurements can be made to as many GNSS satellites (with favorable geometry) as possible, and where the raison d'etre is the determination of position (i. e., coordinates). While the former is a constraint on the operating environment, the latter acknowledges there is a broader set of survey services than just point coordination, which include azimuth or alignment determination, horizontal or vertical offset measurement, and precise physical height (difference) measurement.

The complexity of land and engineering survey tasks requires professional judgement: (a) to select the appropriate technology and operational techniques, (b) to conduct or oversee the careful execution of the field survey, (c) to process measurements taking into account all errors and constraints, and (d) to generate the outputs required by the client. The reader is referred to land survey texts for details concerning surveying principles, technologies, and applications [35.54, 55].

*Control surveys* are similar to geodetic surveys (Sect. 35.2.1); however they are carried out at local or construction project scales [35.54, 55]. The objective is to determine the coordinates of ground control points referred to a project, mapping, or geodetic datum during a field survey campaign. These control points may be of a temporary nature, intended only to be used over a project lifetime, or established as permanent marks (Fig. 35.9). The control points would typically be used for subsequent project surveys for guiding construction, mapping terrain and structures, lower order surveys, or for monitoring ground or structural deformation.

*Deformation surveys* are a form of geodetic surveying in which the displacement of a GNSS receiver, relative to some *rest* position or position at some measurement epoch, is monitored over time (Sect. 35.2.1). The receiver may be mounted on a deforming engineered structure [35.56], or it may be set up on ground marks in areas of ground surface movement. The distinctions between geodetic deformation surveys and land deformation surveys are largely of a semantic nature; however there are a number of deformation survey scenarios that could be used to distinguish between geodetic, land, and engineering deformation survey applications. It is common to partition those deformation surveys that are sensitive to geophysical or natural processes, such as tectonic motion, volcanic activity, land uplift, or subsidence, from those that measure displacement of engineered structures or monitor deformation with anthropogenic sources such as underground fluid

**Fig. 35.9a,b** Establishing coordinates of control marks using GNSS: **(a)** setting up a GNSS receiver/antenna set up over rural control mark using a bipod; **(b)** GNSS receiver/antenna mounted on tripod to collect measurements for establishing geodetic control at a mine site (courtesy of Position Partners)

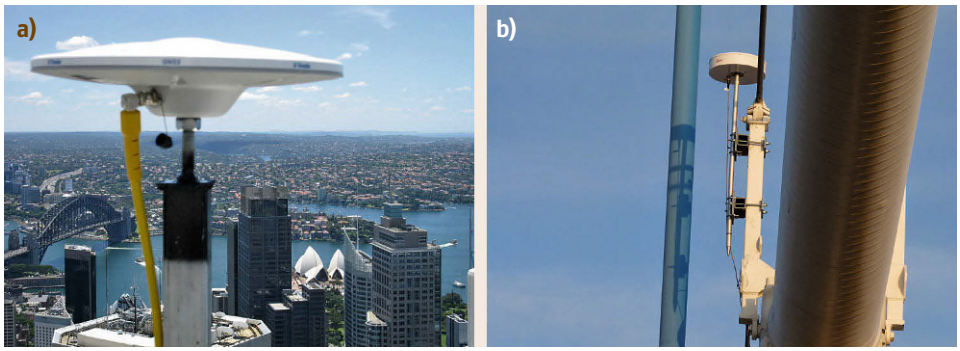

**Fig. 35.10a,b** GNSS installed on structures for displacement measurements: **(a)** on a tall building in Sydney, Australia (courtesy of Ultimate Positioning); **(b)** attached to support cables of the Severn Suspension Bridge, connecting Bristol to South Wales, UK (courtesy of Gethin Wyn Roberts & Chris J. Brown)

extraction and mining. The former may require more permanent monitoring systems, whereas the latter imply periodic measurement campaigns or monitoring that takes place only over a limited period of time.

Figure 35.10 shows two examples of GNSS installations for deformation monitoring – one on a tall building and the other on a cable suspension bridge. The mode of GNSS positioning may be continuous or episodic, and typically requires some form of time series analysis of computed coordinates in order to detect trends in changes in the coordinates or to determine spectral signatures of vibrating receivers. In addition, GNSS may only be one of a number of technologies that are used in such applications. Other instrumentation include inclinometers and accelerometers.

*Topographical surveys* are sometimes referred to as *detail surveys*, and are examples of small-area mapping [35.54, 55]. They are similar to surveys carried out using terrestrial survey technology such as Total Stations, except that line-of-sight visibility between reference point and survey point is not necessary. During such surveys the coordinates of ground features (natural and engineered) are determined, including the assumed locations of buried utilities, as well as sufficient sampled surface points to allow the terrain undulations to be modeled as gridded height values, triangulated irregular network points, or contour lines. The output of such surveys is a set of coordinates and feature attributes that permit the data to be exported to CAD or GIS software packages.

*Mapping surveys* are concerned with the determination of the coordinates of many points across an area for the purpose of describing the terrain, structure, or built environment in a *spatial* sense [35.54, 57]. Typically what results is a database of coordinates (the *where* information), attributes (the *what* information), and topology (the *how connected* information) of a sufficient number or density of natural or constructed features to ensure a representation of reality at the largest scale of interest. GNSS may be used to directly coordinate the feature to be mapped, or to determine the coordinates of the mapping, imaging, or laser scanning sensor over time, from which coordinates of *pixels* or *point-clouds* are derived in a secondary process.

*Cadastral surveys* are a special form of survey for the determination or marking-out of land property boundaries [35.58]. In some countries boundaries are defined by coordinates, and hence the survey task is to calculate where the *real* boundaries are with respect to physical structures such as fences, roads, or buildings. However in many countries land boundaries are defined by distance and azimuth of boundary lines as described in registered certificates of titles (in countries that use the Torrens System of title) or in deed documents (for countries that do not) [35.58]. They may also be depicted graphically in cadastral maps. In such cases the GNSS coordinates are used to derive distance and azimuth quantities, and are considered to be one form of evidence that can be used to reconstruct the original land parcel boundaries. GNSS land surveying techniques are particularly useful for rural cadastral surveys, or where new land property boundaries are established as a result of land redevelopment or infrastructure construction projects. [35.48] is an example of GNSS guidelines for cadastral surveying.

## 35.3 Engineering Surveying

Much of what is stated in Sect. 35.2 with regard to how GNSS is used for land surveying and mapping is also relevant to engineering surveying (see below) and hydrographic surveying (Sect. 35.4). The accuracy requirements are essentially the same, as is the receiver hardware. In addition, there is a reliance on service providers for a variety of augmentation services, and in some cases auxiliary data, to support centimeter-level positioning accuracy. There is an unrelenting drive by GNSS user equipment manufacturers to challenge current operational constraints in order to promote even greater uptake of GNSS technology for engineering applications. Hence some of the most significant innovations are occurring in the GNSS technology that addresses these applications.

Surveys for the construction of roads, bridges, buildings, tunnels, mines, and other structures are based on the same geometric principles and use similar field procedures as land surveying applications [35.53, 54]), and require: (a) the determination of the coordinates of existing ground marks or features, or (b) the identification of marks or points at predefined coordinates to guide construction or machinery. Surveyors are engaged on such projects at all phases of construction, including the original determination of land, building, or marine boundaries. This section focuses on terrestrial engineering applications. Section 35.4 discusses offshore engineering and charting applications.

### 35.3.1 Engineering Surveying Real-Time Operations

One defining characteristic of almost all GNSS engineering surveying applications is their demand for accurate positioning in real-time. In fact without such capability the application may at best not be cost-effective, or at worse not be feasible at all. RT precise positioning applications include: (a) precise navigation between predefined way-points, such as for vehicle guidance and control applications; (b) construction set-out of formwork, surfaces, and structures; (c) open-cut mining operations; (d) precision agriculture, especially so-called *control track farming*; and (e) rapid mobile mapping. In some cases GNSS is combined with other positioning/guidance technologies – such as laser or vision-based systems, or inertial measurement sensors – to ensure continuous positioning during short GNSS outages, or to provide additional platform orientation information.

RT-GNSS implies no delay between measurements made by the GNSS receiver and the coordinate information being generated from measurement processing. Of course there cannot be zero delay; however, it will be assumed that either a delay of one or more seconds is not critical, or computational techniques can be applied to predict position at predefined intervals. RT-GNSS positioning generally implies an *always-on* capability hence the operation of the reference receiver(s) and associated services, such as communications, computing facilities, power, etc., must be continuous, because in addition to high accuracy there is also an increased demand for high *integrity* – machine or vehicle guidance require reliable coordinate solutions.

The flexibility of RT-GNSS positioning is greatest when industry standards for data message transmission, such as those defined by RTCM (Annex A.1.3), are adopted, enabling GNSS receivers from different manufacturers to operate together using the same over-the-air transmissions. The value of industry standards is most obvious in RTK or N-RTK operations (Sect. 35.1.4).

The central role played by RT-GNSS service providers must be acknowledged. Some of the reasons why many users these days take advantage of RT-GNSS services are: (a) the need for continuous and reliable RT operations; (b) the widespread adoption of RTCM data transmission formats; and (c) the high cost/complexity of operating reference receivers. RT-GNSS service providers include private companies, academia, research institutions, and government agencies.

CORSs installed by RT-GNSS service providers typically consist of geodetic-grade receivers, with choke-ring antennas, capable of making multi-frequency, multi-GNSS measurements. RT-GNSS places considerable demands on communication links; between individual CORS receivers and (typically) a central server to manage the transmission of CORS measurements, and for transmission of correction messages to RT-GNSS users. Furthermore, the reference receivers should have the tracking capability to at least match that of the most sophisticated user receiver in order that, for example, RTCM data messages for all visible GNSS satellites and signals that could be used can be broadcast to users. Besides, CORS positioning infrastructure may be used to support GNSS geodesy applications (Sect. 35.2.1) – however the monument on which the GNSS antenna is fixed must be stable.

In contrast to multi-purpose or commercial CORS networks referred to above, there are many RTK systems installed by individual user/operators, especially in the precision agriculture and open-cut mining user segments. These users own several survey-grade GNSS receivers, operate one as a base station, install the other(s) on one (or more) agricultural or mine vehi-

**Table 35.11** GNSS engineering surveying applications and operational issues

| | |
|---|---|
| Construction surveys | Construction surveys support engineering and infrastructure projects, and have the following characteristics:<br>● GNSS is one technology used by engineers and surveyors on building/construction sites; other technologies must also be used and hence a seamless transfer of coordinates between different construction survey instrumentation is necessary<br>● The immediacy of the tasks on building/construction sites demands the use of real-time GNSS positioning techniques such as RTK/N-RTK; and with increased automation of construction processes there is the need to ensure integration of all types of GNSS positioning on construction sites<br>● Variety of positioning challenges, ranging from coordinating fixed points (similar to topographical surveys), determining coordinates of moving GNSS receiver trajectory, to navigating GNSS receiver to a predefined spatial coordinate<br>● Construction project datum is used, typically requiring the transformation of RTK/N-RTK generated coordinates into the project datum<br>● Survey extent is typically a few hundreds of meters to perhaps a few kilometers across |
| Construction and mining machinery automation | There is a trend to increased automation of construction and mining machinery automation, from human-in-the-loop implementations to full autonomous operation, implying:<br>● High-accuracy and high-integrity real-time GNSS positioning availability<br>● Centimeter-level accuracy, though with backup technology options when GNSS is unavailable<br>● Positioning typically is intended to navigate the vehicle to coordinated points, hence requiring adjustment of the vehicle's state from *current* coordinates to *target* coordinates<br>● Tight integration with guidance or control systems, and hence often factory-installed by the machine manufacturers themselves<br>● Coverage areas typically up to a few kilometers across |
| Agriculture | Similar to construction machinery automation applications, with the following unique characteristics:<br>● Coverage areas may be many kilometers across<br>● The conditions for RT-GNSS are typically more favorable with respect to sky visibility conditions<br>● The accuracy requirements may be more relaxed, ranging from meter-level for standard precision agriculture, to subdecimeter-level accuracy in the case of *control track farming*<br>● Horizontal positioning |
| Mapping | Mobile mapping applications are characterized by:<br>● Variety of platforms – terrestrial, airborne, marine<br>● Variety of mapping sensor technologies, ground sampling (or resolution), field-of-view, cost, operational constraints (e.g., height, range, speed, etc.)<br>● Accuracy requirements may be relaxed considerably, depending upon the mapping methodology that is used<br>● Real-time positioning is in general not essential<br>● Survey extent may vary from a few kilometers to many tens of kilometers across |

cle, and implement a *closed* RTK service via a UHF radio link between the receivers. Such a configuration is not optimal, for no other reason than the wasteful duplication of base stations across a coverage area. It is expected that, over time, such GNSS users will decommission their own base stations and instead subscribe to RT-GNSS services.

### 35.3.2 Engineering Surveying Applications

These type of surveys may be considered a subcategory of GNSS *land surveying applications* (Sect. 35.2.3), and are those that are: (a) undertaken on land, (b) associated with construction or mining activities, (c) limited to a project area, (d) constrained to a project time scale, (e) involve machinery, and (f) extensively use RT-GNSS techniques. Examples of engineering surveying applications are listed in Table 35.11, and discussed below.

*Construction surveys* address the different positioning requirements of civil engineers and building professionals during the construction phase for any engineered structure [35.54]. High-accuracy GNSS technology is used in place of traditional terrestrial surveying instrumentation for setting out of trenches or formwork for concrete pours, checking verticality (or horizontality) of construction, or measuring the dimensions of structural component, such as walls, beams, pipes, cables, and so on (Fig. 35.11). The utility of being able to do this in real-time is crucial in order that immediate action can be taken, whether in the form of routine execution of

**Fig. 35.11** GNSS as typically used by surveyors on construction sites: here is shown a pole-mounted GNSS receiver which is being used to either coordinate a point-of-interest or to mark a point whose coordinate is provided in order to set out formwork for concrete pouring, laying of cables, pipes, or services, etc.; typically operating in real-time mode (courtesy of Leica Geosystems)

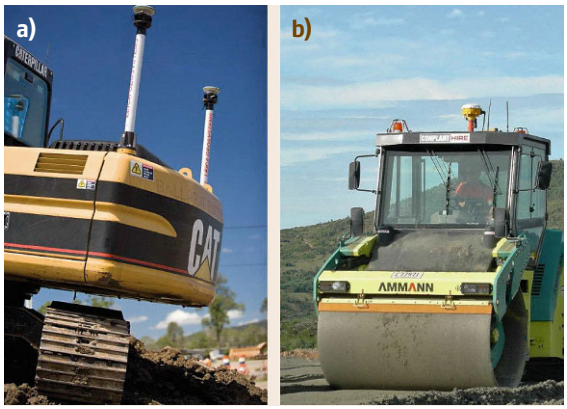

**Fig. 35.12a,b** GNSS receivers installed on construction machinery to guide excavations **(a)** and grading **(b)**. Note in **(a)** that two antennas/receivers are installed to allow for GNSS to determine not just position, but also orientation in 3-D so that the bulldozer blade may be manipulated to excavate an inclined design surface ((**a**) courtesy of Leica Geosystems, **(b)** courtesy of Ultimate Positioning)

engineering tasks or to allow for on-site modification or adjustment of construction plans. These surveys are, in many respects, the most demanding applications of high-accuracy GNSS technology because of the variable conditions on construction sites. For example, there may be significant shading of the sky, considerable vehicular and human traffic, dangerous/noisy/dirty conditions, variable wireless coverage, and a number of different coordinate datums, to name but a few. The engineering surveyor must be capable of executing their tasks in an often stressful and unpredictable environment. Furthermore, GNSS is but one tool at their disposal. However, there is a trend to increased *automation* of excavating, drilling, concreting, paving, laying of preformed slabs, erection of walls or formwork, removal of waste material, etc., which implies instantaneous guidance and/or control of heavy machinery using high-accuracy, high-integrity GNSS technology, possibly supplemented with laser, vision, and inertial systems to improve availability and reliability.

*Construction machinery automation* of graders, bulldozers, tractors, trucks, and specialized vehicles or machinery brings with it improvements in productivity [35.59]. This productivity can be measured in many ways, including faster and more accurate construction, longer work days, with fewer errors, smaller construction workforce, less injuries to workers, and reduced fuel use. Early examples of machine automation for construction environments are closely related to the technology supporting precision agriculture, especially *control traffic farming* [35.60, 61] where RT-GNSS is used to guide farm machinery with an accuracy that ensures the vehicle's wheel ruts are always in the same *track*. This requires subdecimeter, repeatable positioning accuracy, in real-time on a continuous basis. Construction equipment can be similarly *guided* along *tracks*, ensuring road centerlines are set out according to design coordinates, or the concreting of airport runways and taxiways is carried out very precisely in a vertical sense. This is in contrast to kinematic GNSS positioning as illustrated in Fig. 35.3, where the GNSS instrument is used to map the terrain as it actually is. Figure 35.12 shows GNSS receivers mounted on construction machinery.

Over the next decade the degree of autonomy of construction vehicles and machinery will increase significantly, and construction, mining, and agriculture will likely be the largest markets for high-accuracy GNSS positioning systems. Machine automation can be implemented in a variety of scenarios, from simply aiding the operator via in-cabin computer displays that show actual vehicle tracks and design lines or surfaces (Fig. 35.13) through radio-controlled machinery by operators who may not even be located on the site to fully autonomous robots that operate with no human intervention at all. These applications require centimeter-level positioning accuracy provided by RT-GNSS. However, the level of integrity may range from relatively low – with the operator merely informed when positioning is unavailable, who then controls the machinery manually – to very high integrity in the case of full machine automation. Yet even in this mode the addition of vision or scanning sensors can provide enough *situation-awareness* for an autonomous vehicle to respond to loss of GNSS positioning capability.

**Fig. 35.13** Inside cabin of GNSS-assisted machinery – one or more GNSS receivers/antennas (multiple antennas provide vehicle orientation information) are installed on construction machinery and real-time solutions for position (and perhaps orientation angles) of the reference point on the vehicle are displayed to the machinery operator on a controller device together with the planned trajectory of the machinery so that the excavation may be carried out according to design (courtesy of Ultimate Positioning)

*Mining survey applications* are subcategories of several GNSS land and engineering surveying applications [35.54, 55]. It must first be acknowledged that GNSS can only be used for open-cut mine operations, which are similar to construction project sites. On such sites the full range of surveying and positioning tasks are required: mapping, set-out, construction, volume surveys, machine guidance/control, and vehicle fleet management/tracking. As with construction site GNSS surveys, the area of operations is rather constrained – perhaps just a few kilometers across – and the dirty, dangerous, and typically extreme environmental conditions place heavy demands on technology. The challenge for RT-GNSS users in deep open-cut mines is that with increasing depth, the proportion of open sky that a GNSS receiver *sees* decreases rapidly. This is especially the case when surveyors or GNSS-guided machinery are working near steeply sloping mine walls. It was the need to increase the number of visible satellites under such conditions, beyond the available GPS constellation, which has driven the adoption of multi-GNSS receivers for such critical applications – initially GPS+GLONASS, but nowadays capable of tracking signals, and processing measurements, from other GNSS constellations.

### 35.3.3 Project Execution and Related Issues

The applications listed above imply operations over relatively small areas. GNSS must compete with terrestrial surveying technologies, and hence must be a cost-effective and easy-to-use technology. It should be used only in project environments that are optimal for rapid and reliable AR, and for which there is very good sky visibility. Unlike GNSS geodetic or land surveying projects, reconnaissance *prior* to the use of GNSS for engineering surveys is not carried out.

In addition, given the construction project scale of most engineering surveying applications, the issue of the coordinate datum is different to that for geodetic surveying, and perhaps even to land surveying. The datum is typically of local relevance, with coordinates often expressed in a horizontal map projection for ease of graphical display and spatial analysis. The vertical component is measured in terms of physical heights, not ellipsoidal heights (or height differences). Hence *horizontal surveys* are typically carried out, with *vertical surveys* often conducted using one of a number of lev-

**Fig. 35.14** Mobile mapping system (MMS) installed on a road vehicle. The system comprises multiple imaging sensors (cameras pointing forward, sideways, and backward), a laser scanner (on the top of the vehicle), a GNSS antenna (at the top of the van), and an inertial navigation system for platform orientation (box on rack next to laser scanner). Note also that this particular MMS is carrying additional sensors (mounted low to the ground) for radar imaging of the road surface and detection of cracks in pavement (courtesy of Charles Toth)

eling techniques, including the GNSS ellipsoidal height + geoid height-leveling method [35.62].

However, RTK/N-RTK operations imply that coordinates are determined in the datum defined by the coordinates of the CORSs – which typically are expressed in a national reference frame. In some instances, for example, at a mine, dam, and other large construction site the reference receivers are operated by the project surveyors, and the RTK/N-RTK settings may be adjusted to output GNSS coordinates in the local project datum or coordinate system. The situation regarding RT-PPP is more complex as the point positioning technique derives its datum from the precise GNSS satellite orbits, and these are invariably in a globally relevant, stable reference frame such as the ITRF [35.18]. In summary, for RT applications GNSS-derived coordinates may need to be transformed into the local project datum by the GNSS field instrumentation before they can be used by engineering surveyors, or by the machines that are guided by RT-GNSS systems.

With respect to GNSS-enabled *mapping* (Sect. 35.2.3), although the mapped points may be stationary, these days geospatial data acquisition is carried out from a moving platform (e.g., equipped with a camera or laser scanner) such as a vehicle (Fig. 35.14), aircraft (or unmanned aerial vehicle), or ship. Maximum flexibility is afforded by *post-survey* processing of recorded GNSS measurements. In addition, decimeter-level or lower accuracy is typically adequate allowing for relaxed instrument or field operational requirements. Furthermore the 3-D orientation or attitude of the mapping sensor is typically determined using inertial technology (Chap. 28). The operational guidelines, quality control procedures, and accuracy requirements for different mobile mapping platforms will vary considerably. It is beyond the scope of this chapter to discuss in detail the range of mobile mapping applications, the imaging and scanner technologies that are available, the mapping analysis methodologies that can be used, and the operational guidelines to be followed. Readers are referred to [35.63], and similar articles in geospatial magazines and international conference proceedings, for the latest developments in this rapidly evolving technological field.

## 35.4 Hydrographic Surveying

Much of what is stated in Sect. 35.3 with regard to how GNSS is used for engineering surveying and mapping is also relevant to hydrographic surveying in support of offshore engineering and sea floor charting. Offshore engineering associated with pipelines, undersea cables, breakwaters, harbor works, and freestanding structures has similar requirements for preconstruction surveys; for subsequent support or control of operations during the construction phase; and, finally, postconstruction *as-built* surveys. Furthermore, charting surveys require positioning of the moving platform, similar to terrestrial or aerial mapping, although the undersea imaging technologies are very different.

### 35.4.1 Hydrographic Surveying Applications

Although land, engineering, and offshore surveying share many geometric principles [35.53], the offshore operational environment is in many respects more challenging [35.64]. The environment is more corrosive, the marine platform (such as a ship, drill-rig, dredging vessel, small boat, or autonomous underwater vehicle) is in continuous motion, and the distances from marine receivers to shore-based reference stations may be longer than is the case for most land-based applications. On the other hand sky visibility is typically very good.

Prior to the introduction of GNSS, the techniques for offshore positioning were less accurate, more complex, and more expensive than those used on land. Invariably as the distance from shore increased, the positioning accuracy reduced, and the *electronic* positioning technology that could be used changed. The positioning technology was classified as *short-range*, *medium-range*, or *long-range*, referring to the distance over which transmitted terrestrial ranging signals could be detected [35.65, 66]. The introduction of the Transit Navy Navigation Satellite System (also often referred to as *Transit Doppler*) to the civilian community in 1964 [35.67, 68] made it possible to undertake hydrographic survey operations anywhere in the world, without relying on shore-based signal transmitters. The Transit Doppler system was retired in 1996, but GPS further revolutionized hydrographic surveying and maritime navigation. Nowadays, GNSS is used for all (surface) marine positioning requirements [35.66].

*Hydrographic surveying* operations can be partitioned into two general classes [35.64, 65]: (a) charting and (b) offshore engineering activities (Table 35.12). As with land-based mapping and surveying applications, some require RT positioning while others may be addressed using post-processed techniques.

*Charting* is an operation in which a mapping sensor aboard a ship, or towed *fish*, moves in a pattern that ensures an entire area of the seabed is imaged, or *illu-*

**Table 35.12** GNSS hydrographic surveying and marine applications

| | |
|---|---|
| Harbor and river operations | • Typical applications: small-scale surveys of river or harbor bed, positioning of buoys, cables or pipelines, vessel-docking maneuvers, etc.<br>• Scenarios vary: positioning vessel or structure; measuring vessel's trajectory; navigating to predefined locations<br>• If accuracy demands it, RTK/N-RTK techniques are used |
| Dredging | • Similar to land-based engineering surveys, requiring precise real-time spatial positioning of vessel-mounted excavating equipment<br>• Attitude of vessel may be determined using a GNSS multi-antenna system, although using an inertial system is a common option<br>• Typically conducted close to shore, permitting the use of standard RTK techniques |
| Offshore engineering | • Typical applications: construction of breakwaters, piers, shore defences, wind or tidal energy platforms, gas and oil-drilling platforms, pipelines, cable laying<br>• Operations will vary from being very close to land, to mid-ocean<br>• Accuracy requirements will vary considerably, hence there is a wide choice of GNSS positioning techniques<br>• Real-time positioning is typically required |
| Charting | • Can take place well offshore, for which differential kinematic positioning techniques may be impracticable<br>• Horizontal positioning accuracy is defined by international standards, and rarely requires the use of carrier-phase-based techniques<br>• Chart Datum is typically lowest astronomical tide, hence vertical (ellipsoidal) positioning of sonar sensor not required, although the vessel's heave motion is measured so as to correct raw depth measurements<br>• Real-time positioning is rarely a requirement for charting |

*minated*, by transmitted sound waves, and the reflected signals recorded – the acoustic sensor may be a side-scan sonar or an echo sounder [35.64, 69]. Much like an airborne or vehicle-mounted camera or laser scanner, the return signals are processed to generate a 3-D map of the (reflecting) surface (Fig. 35.15). As with other types of mapping, both the *position* and *orientation* of the sensor must be measured so that direct georeferencing techniques can be used. In the case of active mapping systems such as sonar or laser scanners, the position and orientation of both the signal transmitter and the signal receiver are required, while this requirement needs to be fulfilled only for the imaging sensor. Unlike land GNSS applications, for which there are no internationally recognized standards and recommendations on how to execute GNSS surveys, charting operations follow guidelines such as those from the International Hydrographic Organization (IHO; [35.70, 71]).

**Fig. 35.15** Multibeam sonar used to derive digital elevation model of seabed requires the position and orientation of sonar sensor attached to survey vessel so as to convert range measurements into coordinates of reflecting surface, which may be transformed into electronic nautical charts for navigation or to support offshore engineering (courtesy of Spain Hydrographic Service)

Surveys in support of *offshore engineering* are similar to construction surveys (Sect. 35.3). Offshore con-

**Fig. 35.16** Positioning of offshore cable laying ships and drill platforms is nowadays undertaken using GNSS technology (courtesy of Alf van Beem, after [35.72])

struction applications use identical GNSS surveying instrumentation and techniques to land-engineering surveys. GNSS is used to guide the placement of undersea pipelines or cables (Fig. 35.16), or the erection of offshore structures such as drill platforms, wind or tidal energy generating turbines, or breakwaters, and other river, harbor, or open ocean works. *Dredging*, for example, requires similar technology as does operator guidance of construction machinery (Fig. 35.13), as the objective is to excavate a channel, river, or portion of the seabed to some desired depth.

### 35.4.2 Operational Issues

There are several unique characteristics of hydrographic surveying worthy of mention. While high-accuracy marine positioning is still based on differential positioning principles, the challenge of operating well offshore, at long distances from GNSS reference stations, means that there is greater interest in using alternative high-accuracy positioning techniques for offshore positioning than is the case on land. Hence the offshore positioning market is an early adopter of PPP techniques, with several service providers transmitting satellite orbit and clock information to support RT-PPP [35.73–76].

Although many hydrographic and charting surveys are carried out near to shore, and even within a harbor, the coordinate datum is in general different to the land geodetic datum. Many offshore engineering surveys use a project datum (as do many onshore engineering projects). The IHO has mandated that the horizontal datum for all charting must be that of WGS84 [35.69, 77] – for all intents and purposes an ITRF-aligned datum. The guidelines for hydrographic surveys also tend to be internationally applicable [35.70, 71]. The RT-GNSS service providers who cater for the offshore surveying market are companies that operate on a global basis.

The seabed map is typically used for ship navigation, hence all underwater or exposed obstacles that pose a danger to maritime shipping should be accurately surveyed. There must be under-keel clearance of the traversing vessel, hence the vertical, or depth accuracy is required to be higher than the horizontal accuracy of any map feature. For all but the largest scale charts this implies a horizontal accuracy of no better than 5–10 m (and often much worse), while the depth accuracy requirement in rivers, harbors, and shipping channels may be at the submeter-level (and often higher). The *chart datum* is typically the Lowest Astronomical Tide [35.78].

# 36. Geodesy

Zuheir Altamimi, Richard Gross

Continuous geodetic observations are fundamental to characterize changes in space and time that affect the Earth system. The advent of global navigation satellite systems (GNSSs), starting with the Global Positioning System (GPS) in the early 1980s, has significantly increased the range of geodetic applications and their precision. Significant improvements have progressively been made in the GNSS software packages developed by research institutes, leading to the determination of high-precision geodetic parameters and their temporal variations. The proliferation of dense GNSS networks (local, national, continental and global), composed of continuously observing stations, allows for a variety of geodetic and Earth science applications. Most areas of science, Earth observation, georeferencing applications, and society at large, today depend on being able to determine positions to millimeter-level precision. Point positions, to be meaningful and fully exploitable, have to be determined and expressed in a well-defined reference frame. All current global and regional reference frames rely on the availability of the international terrestrial reference frame (ITRF), which is the most accurate realization of the international terrestrial reference system (ITRS). One of the major modern achievements in geodesy today is the ability to determine highly precise global and regional terrestrial reference frames based on GNSS observations, fully connected to the ITRF. This chapter describes the use and applications of GNSS in geodesy, focusing on its role in the International Association of Geodesy's (IAG's) global geodetic observing system (GGOS) for monitoring our planet in space and time, GNSS-based reference frame implementation, Earth rotation and sea level monitoring.

## 36.1 GNSS and IAG's Global Geodetic Observing System

Geodesy is the science of the Earth's rotation, gravity and shape, including their evolution in time [36.1, 2]. These properties of the Earth change in time because the Earth is a dynamic system – it has a fluid, mobile atmosphere and oceans, a continually changing global distribution of ice, snow, and water, a fluid core that is undergoing some type of hydromagnetic motion, a mantle both thermally convecting and rebounding from the glacial loading of the last ice age, and mobile tectonic plates (Chap. 37). In addition, external forces due to the gravitational attraction of the Sun, Moon, and planets also act upon the Earth. These internal dynamical pro-

cesses and external gravitational forces exert torques on the solid Earth, or displace its mass, thereby causing the Earth's rotation, gravity, and shape to change. Geodetic observing systems, including the space-geodetic techniques of very long baseline interferometry (VLBI), satellite laser ranging (SLR), global navigation satellite systems (GNSSs) like the US Global Positioning System (GPS), and the French Doppler orbitography and radio-positioning by integrated satellite (DORIS) system, provide the measurements of the Earth's rotation, gravity, and shape that are used to study the response of the Earth to these dynamical forces.

Observations of the Earth's variable rotation, gravity and shape also provide the basis for the realization of the reference systems that are required in order to assign coordinates to points and objects and thereby determine how those points and objects move in space and time (Fig. 36.1). The terrestrial reference frame (TRF) determined by geodetic measurements is the indispensable foundation for all sustainable Earth observations, in situ as well as airborne and spaceborne, and underpins all georeferenced data used by society. The TRF is therefore of fundamental importance to geodesy in particular, science in general, and society as a whole.

The global network of GNSS receivers is essential to determining the TRF. Of the different space-geodetic techniques, the GNSS network of observing stations is the densest. By colocating GNSS receivers with the stations of the other techniques it helps to integrate the separate technique-specific networks into one, integrated global observing system. GNSS also provides the means to access the TRF, allowing the absolute positions of GNSS receiver-equipped objects to be precisely given. Providing this ability to precisely position and navigate objects is one of the most important benefits of GNSS to science and society.

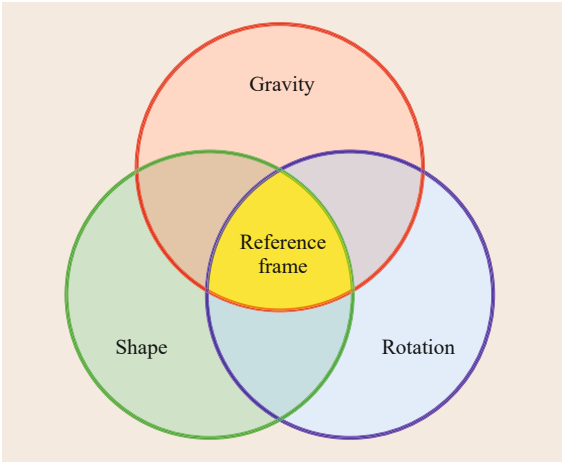

**Fig. 36.1** Reference frames are determined from observations of the Earth's rotation, gravity, and shape. Reference frames also provide the means to integrate the three pillars of geodesy (rotation, gravity, and shape). These pillars are not independent of each other but are connected to each other by the common geophysical processes causing them to change. But to relate changes in the individual pillars to each other the changes must be given in the same reference frame (after [36.3, 4])

### 36.1.1 The International Association of Geodesy

The International Association of Geodesy (IAG), a founding association of the International Union of Geodesy and Geophysics (IUGG), is the international scientific organization devoted to the advancement of geodesy [36.5]. Its origin dates to 1862 when the Prussian General Johann Jacob Baeyer formed the central European arc measurement project with the ultimate goal of precisely determining the size and shape of the Earth. Today, more than 150 y later, the IAG continues to pursue this goal by advancing geodetic theory through research and teaching, by collecting, analyzing, modeling and interpreting observational data, by stimulating technological development, and by providing a consistent representation of the shape, rotation, and gravity of the Earth and planets including their temporal variations.

The IAG accomplishes its mission through the activities of its operating components, including its commissions, intercommission committees, services, and the global geodetic observing system (GGOS). Commissions represent the major fields of activity in geodesy and represent the IAG in all relevant scientific matters, promoting the advancement of science, technology, and international cooperation in these fields. The four IAG commissions are:

1. Reference frames
2. Gravity field
3. Earth rotation and geodynamics
4. Positioning and applications.

Intercommission committees address scientific matters that involve all of the commissions. There is currently one intercommission committee, the intercommission committee on theory.

Services organize the collection and reduction of geodetic observations and generate the geodetic products needed for scientific research and societal applications. The 14 IAG services span the relevant geometric,

gravimetric, oceanographic, and related properties of the Earth. The geometric services of the IAG are the:

- International GNSS Service (IGS) (Chap. 33)
- International VLBI Service for Geodesy and Astrometry (IVS)
- International Laser Ranging Service (ILRS)
- International DORIS Service (IDS)
- International Earth Rotation and Reference Systems Service (IERS).

The gravimetric services of the IAG are the:

- International Gravity Field Service (IGFS)
- International Geoid Service (IGeS)
- International Gravimetric Bureau (BGI)
- International Center for Earth Tides (ICET)
- International Center for Global Earth Models (ICGEM)
- International Digital Elevation Model Service (IDEMS, to be confirmed).

The oceanographic services of the IAG are the:

- Permanent Service for Mean Sea Level (PSMSL)
- International Altimetry Service (IAS, to be confirmed).

The final service of the IAG, concerned with providing reference timescales, is the:

- Time Department of the International Bureau of Weights and Measures (BIPM).

### 36.1.2 The Global Geodetic Observing System

Recognizing the increasingly important role that geodesy plays in scientific research and societal applications, IAG established the global geodetic observing system (GGOS) in 2003, first as a project and then, in 2007, as a full component of the IAG. GGOS is meant to be *the* observing system of the IAG, organizing its technique-specific services under one unifying umbrella, thereby forming a comprehensive geodetic observing instrument integrating the hitherto separate pillars of geodesy (shape, rotation, and gravity) into one consistent observing system [36.6]. GGOS works with the other IAG components to provide unique, mutually consistent, and easily accessible geodetic constants, data and products for science and society. In addition, GGOS represents the IAG in the Group on Earth Observations (GEO) [36.7] and is IAG's contribution to the Global Earth Observation System of Systems (GEOSS) that is being constructed by GEO.

GGOS provides the basis on which future advances in geosciences can be built. By considering the Earth system as a whole (including the geosphere, hydrosphere, cryosphere, atmosphere and biosphere), monitoring Earth system components and their interactions by geodetic techniques and studying them from the geodetic point of view, the geodetic community provides the global geosciences community with a powerful tool consisting mainly of high-quality services, standards and references, and theoretical and observational innovations. The mission of GGOS is [36.5]:

1. *To provide the observations needed to monitor, map and understand changes in the Earth's shape, rotation and mass distribution*
2. *To provide the global frame of reference that is the fundamental backbone for measuring and consistently interpreting key global change processes and for many other scientific and societal applications*
3. *To benefit science and society by providing the foundation upon which advances in Earth and planetary system science and applications are built.*

The goals of GGOS are [36.5]:

1. *To be the primary source for all global geodetic information and expertise serving society and Earth system science*
2. *To actively promote, sustain, improve, and evolve the global geodetic infrastructure needed to meet Earth science and societal requirements*
3. *To coordinate the international geodetic services that are the main source of key parameters needed to realize a stable global frame of reference and to observe and study changes in the dynamic Earth system*
4. *To communicate and advocate the benefits of GGOS to user communities, policy makers, funding organizations, and society.*

In order to accomplish its mission and goals, GGOS depends upon the services, commissions, and intercommission committees of the IAG. The services provide the infrastructure, data and products on which all contributions of GGOS are based. The commissions and intercommission committees provide expertise and support for scientific development within GGOS. In summary, GGOS is IAG's central interface to the scientific community and to society in general.

### Organizational Structure

The components of GGOS are shown in Fig. 36.2. The governing components of GGOS are its consortium, coordinating board, and executive committee. These components serve as its steering committee, setting the strategic direction for GGOS. The coordinating office, like central bureaus of IAG services, oversees and coordinates the day-to-day activities of GGOS. It serves as the secretariat of GGOS and manages GGOS web services and outreach activities. The science panel is an independent, multidisciplinary advisory board. It provides scientific advice and support to GGOS to ensure that GGOS remains focused on relevant scientific and societal needs. The GGOS interagency committee (GIAC) is a forum for coordinating and supporting the development, implementation, and operation of the geodetic infrastructure that is owned by governmental institutions. Membership in GIAC is open to any governmental organization that contributes resources to the operation and development of space-geodetic observing systems.

### The Bureaus of GGOS

Along with the science panel and GIAC, the operating arms of GGOS are its bureaus and focus areas. GGOS currently has two bureaus: (1) The Bureau of Networks and Operations (2) The Bureau of Products and Standards.

*Bureau of Networks and Observations.* The goal of the Bureau of Networks and Operations (BNO) is to pursue the implementation of a network of space-geodetic observing systems of sufficient global distribution and capability that it will meet the needs of science and society as identified by GGOS [36.6]. To achieve this goal the Bureau works closely with the IAG services. In fact, the bureau is a consortium of service representatives supported by working groups, of which there are three:

1. *Working group on satellite missions* keeps GGOS informed about relevant satellite missions and supports GGOS in advocating for new missions that are needed to meet its goals.
2. *Working group on data and information systems* promotes the use of metadata standards and conventions for geodetic data and advocates for the interoperability of geodetic data centers.
3. *Working group on performance simulations and architectural trade-offs* uses simulations to assess the

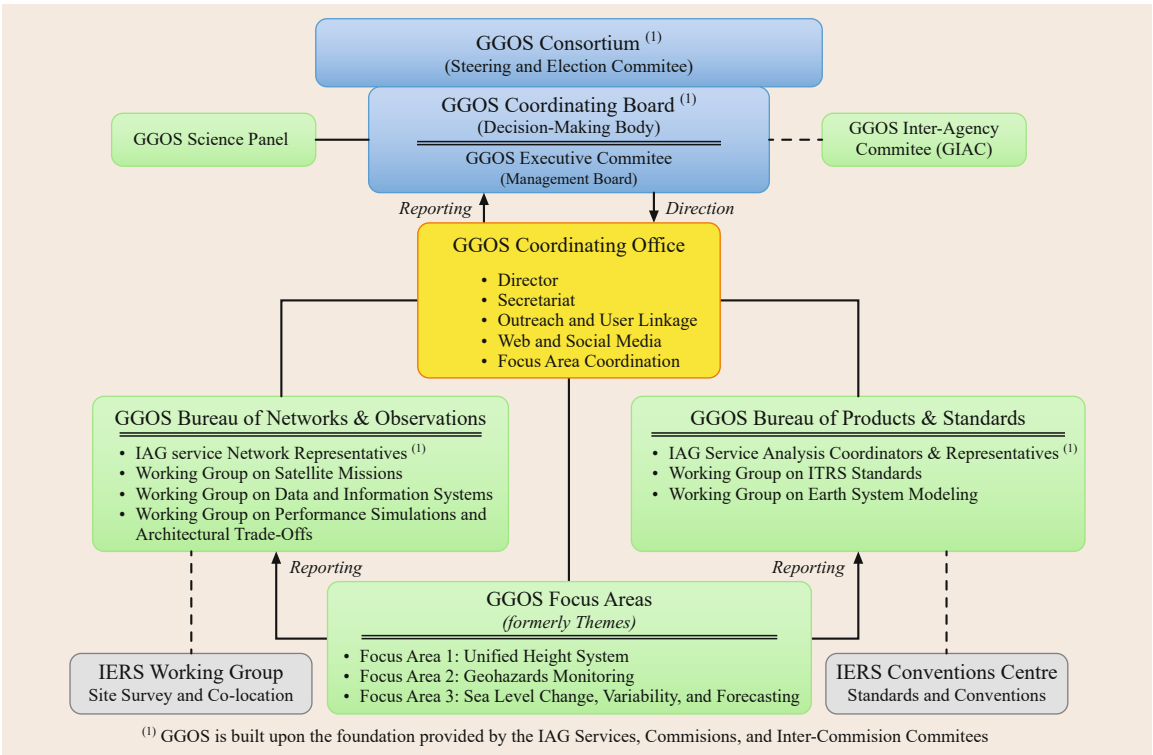

**Fig. 36.2** The organizational structure of GGOS showing its governing components in *blue*, coordinating component in *yellow*, operating components in *green*, and affiliated components in *gray* (Courtesy of IAG-GGOS, reproduced under the CC BY-ND 4.0 license)

impact on geodetic data and products of different ground station architectures and their evolution, different space-based architectures and their evolution, and trade-offs between the ground- and space-based architectures including requirements on ground and space ties.

In pursuit of its goal, the BNO also works with the IERS working group on site survey and colocation. This working group is striving to improve the accuracy of the measurements of the relative positions of the reference points of colocated space-geodetic stations.

*Bureau of Products and Standards.* The goal of the Bureau of Products and Standards (BPS) is to make sure that the same standards and conventions are used by all components of the IAG. When combining data and products from different analysis centers or from different observing systems it is critical that they be determined using the same standards and conventions. Otherwise, inconsistencies can be introduced that can limit the accuracy of the combined data and products. As a first step towards meeting its goal, the BPS is compiling an inventory of the standards and conventions used by the organizations that generate IAG data and products. To help achieve its goal, the BPS has two working groups:

1. *Working group on ITRS standards* is pursuing the establishment of a new ISO (International Organization for Standardization) standard on global geodetic reference systems like the ITRS.
2. *Working group on Earth system modeling* is developing an integrated Earth system model that will apply to all observation techniques and all pillars of geodesy (rotation, gravity, and shape).

In pursuit of its goal, the BPS works closely with the IERS conventions center, that component of the IERS that is responsible for maintaining the constants, standards, and conventional models used by the IERS.

### The Focus Areas of GGOS

GGOS focus areas are interdisciplinary in nature and address broad and critical issues that are important to science and society and that geodesy can contribute to but that need further development by or coordination within the geodetic community. GGOS currently has three focus areas:

1. Unified height system
2. Geohazards monitoring
3. Sea level change, variability and forecasting.

*Unified Height System.* The goal of a number of IAG working groups during the last few decades has been the unification of the more than 100 existing vertical reference systems. This involves defining and realizing a global reference level and determining the transformations between local height datums and the global, unified one. When this is achieved, all physical heights will be referred to the same global reference level. To aid in the realization of this goal, GGOS created a focus area, focus area 1, on the unified height system. To date, the activities of focus area 1 have been focused on determining a reliable value for the reference geopotential $W_0$ that can be used for the conventional reference level when realizing a global height system.

*Geohazards Monitoring.* Helping to mitigate the impact on human life and property of natural hazards such as earthquakes, volcanic eruptions, debris flows, landslides, land subsidence, tsunamis, floods, storm surges, hurricanes and extreme weather is one of the most important services that geodesy can provide to science and society. Since natural hazards often cause objects to be displaced and the Earth's surface to be deformed, GNSS plays a crucial role in this. For example, GNSS can be used to monitor the pre-eruptive deformation of volcanoes and the preseismic deformation of earthquake fault zones, aiding in the issuance of volcanic eruption and earthquake warnings. GNSS can also be used to rapidly estimate earthquake fault motion, aiding in the modeling of tsunami genesis and the issuance of tsunami warnings. GNSS observations are essential for understanding the processes causing the hazard, for assessing the risks of the hazard, for monitoring the development of the hazard, for deciding whether or not to issue an early warning, and to support rescue and damage assessment activities.

Recognizing the important role that geodetic observations play in disaster prevention and mitigation, GGOS created a focus area, focus area 2, on geohazards monitoring. The objective of focus area 2 is to improve the effectiveness of the geodetic community in supporting natural hazard identification, assessment, prioritization, prediction, and early warning. As an international organization, GGOS can be a very effective advocate for the role of geodesy in understanding and mitigating natural hazards. GGOS can also be an effective advocate for improving the geodetic data needed for natural hazards research including better spatial coverage, higher sampling rate, lower latency, and wider data availability, particularly of synthetic aperture radar (SAR) and GNSS data.

*Sea Level Change, Variability and Forecasting.* In 1990, 23% of the world's population lived both less

than 100 km from the coast and less than 100 m above sea level. Nearly a quarter of the world's population is therefore vulnerable to the effects of a rising sea level. Since the long-term average rate of sea level rise is only a few mm/y, mitigation efforts can be planned well in advance. But great demands are placed on geodetic observing systems because the sea level rise signal is so small. For example, the terrestrial reference frame, which should be at least an order of magnitude more accurate than the amplitude of the signal being measured, needs to be accurate and stable to within about 0.1 mm/y to support studies of sea level change. This makes sea level change studies one of the most demanding applications of geodetic observing systems.

Recognizing the important role that geodetic observations play in sea level change studies, GGOS created a focus area, focus area 3, on sea level change, variability, and forecasting. The objective of focus area 3 is to improve our understanding of the causes and consequences of sea level change through the application of geodetic measurements.

#### GGOS and Reference Frames

As discussed above, GGOS is built upon the foundation provided by the IAG services, commissions, and intercommission committees. The IAG services coordinate the acquisition and analysis of geodetic observations of the Earth's time varying gravity, rotation, and shape (Fig. 36.1). An important goal of GGOS is to advocate for the improvement of the global geodetic infrastructure, including the GNSS infrastructure, that provides the geodetic observations. One of the most scientifically and societally important applications of geodetic observations is their use for determining reference frames. This chapter of the GNSS Handbook discusses the use of geodetic observations, especially GNSS observations, to determine reference frames and to study changes in the rotation of the Earth. The use of geodetic observations to study changes in the shape of the Earth are discussed in the chapters in the Handbook concerned with precise positioning (Chap. 25), generation of orbit products (Chap. 34) and geodynamics (Chap. 37).

## 36.2 Global and Regional Reference Frames

This section is divided in four parts. The first part introduces the types of reference frame representations for a deformable Earth, taking into account all sorts of linear and nonlinear motions. The second part deals with global reference frames, focusing on the International Terrestrial Reference Frame (ITRF), its derivatives formed by the International GNSS Service (IGS) and the IGS contribution to the ITRF construction, describing the fundamental role of the IGS network in connecting the three other techniques: very long baseline interferometry (VLBI), satellite laser ranging (SLR) and Doppler orbitography radiopositioning integrated by satellite (DORIS). The third part details the GNSS-based global and regional reference frames and how these frames are linked to the global ITRF, through the usage of IGS products. The fourth part gives general guidelines on how to realize GNSS-based local, regional and global reference frames, fully consistent with and optimally aligned to the ITRF.

### 36.2.1 Reference Frame Representations for the Deformable Earth

The Earth is a complex dynamic system that undergoes deformations caused by various geophysical processes that should be taken into account when constructing a reference frame. The frame is implemented through a geodetic network anchored to the Earth's crust and therefore can be called crust-based frame. The expression of the instantaneous station position $\boldsymbol{X}(t)$, at epoch $t$, can be written as the sum of its regularized position $\boldsymbol{X}_{\mathrm{R}}(t)$ and high frequency geophysical variations $\Delta\boldsymbol{X}_i(t)$ (see IERS conventions [36.8], Chap. 4)

$$\boldsymbol{X}(t) = \boldsymbol{X}_{\mathrm{R}}(t) + \sum_i \Delta\boldsymbol{X}_i(t) \,, \tag{36.1}$$

and

$$\boldsymbol{X}_{\mathrm{R}}(t) = \boldsymbol{X}_{\mathrm{R}}(t_0) + \dot{\boldsymbol{X}}_{\mathrm{R}}(t - t_0) \,, \tag{36.2}$$

where $t_0$ is the reference epoch of the station position and $\dot{\boldsymbol{X}}_{\mathrm{R}}$ its linear velocity. $\boldsymbol{X}_{\mathrm{R}}(t)$ is introduced here in order to obtain a position with more regular time variation, after removing high-frequency time variations caused by geophysical processes using conventional corrections $\Delta\boldsymbol{X}_i(t)$.

Chapter 7 of the IERS conventions [36.8] provides a full description of the currently agreed-upon conventional models that go into $\Delta\boldsymbol{X}_i(t)$, such as Earth tide, ocean loading, atmospheric pressure, and so on, and used by the analysis centers (ACs) dealing with space geodesy data. In addition to these conventional recommended models, other geophysical phenomena have a large impact on space geodesy observations and therefore need to be taken into account in reference frame

implementation. We can categorize the resulting deformations of such phenomena at the surface of the deformable Earth into the following two types:

- Nearly linear motions that can be expressed in the mathematical geodesy formulation as constant with time. They are caused by two main types of processes: plate tectonics and glacial isostatic adjustment (GIA). Plate tectonics induce mainly horizontal motion, which is traditionally modeled via a rotation pole for each plate involving horizontal velocity components [36.9], while GIA implies horizontal and vertical deformations.
- Nonlinear motions that include periodic signals (e.g., annual, semi-annual or interannual) that are caused by nontidal loading effects due to the atmosphere, ocean circulation, terrestrial hydrology and ice melting [36.9]; ruptures provoked by earthquakes and volcanic eruptions; and slow transients or postseismic deformations.

Taking into account the above two types of motions, two categories of reference frame representations can be introduced: quasi-instantaneous reference frame and long-term or secular reference frame.

### Quasi-Instantaneous Reference Frames

A quasi-instantaneous frame gives access to average station positions, using short timespan of space geodesy observations: commonly one day, and up to one week. In this case station positions are only valid at the central epoch of the observations used. More than one week of observations could of course mathematically be used, but the resulting averaged station positions would then be biased by tectonic motion effects. Long time series of quasi-instantaneous frame solutions naturally contain all types of linear and nonlinear station motions. The analysis and accumulation (rigorous stacking) of long time series of quasi-instantaneous frame solutions permit not only the study of all types of linear and nonlinear station motions they naturally contain, but also the construction of a long-term secular frame, such as the ITRF.

Examples of quasi-instantaneous reference frames are daily or weekly solutions provided by the analysis and combination centers of the IAG services of the four space geodesy techniques. In the particular case of GNSS, in addition to IGS global solutions, local, national and regional solutions are also produced by research groups for scientific studies and by institutions in charge of the maintenance of national reference frames based on GNSS permanent networks. In general, IGS analysis center daily or weekly solutions are generated by estimating not only station positions and EOPs, but also orbits, clocks and eventually other parameters such as troposphere gradients. Local, national and regional solutions are generally computed by fixing IGS products (orbits, clocks and EOPs) where the main target is the estimation of station positions, using either a network approach (all stations are adjusted together) or precise point positioning approach, on a station-by-station basis. General guidelines are provided in Sect. 36.2.4 on how to express or align a GNSS solution into the ITRF.

### Long-Term Secular Reference Frames

A long-term or secular frame gives access to station positions at a given epoch $t_0$ and station linear velocities. Examples of long-term reference frames are the ITRF (Sect. 36.2.2) and a cumulative solution obtained by stacking time series of quasi-instantaneous reference frames. The choice of $t_0$ does not mathematically matter, but should be selected to be close to the central epoch of the stacked time series. The users can actually propagate station positions and their associated variances from the reference epoch $t_0$ to any other epoch $t$. For a given station with position vector $\boldsymbol{X}(t_0)$ at epoch $t_0$ and velocity vector $\dot{\boldsymbol{X}}$, its position $\boldsymbol{X}(t)$, at epoch $t$ is given by

$$\boldsymbol{X}(t) = \boldsymbol{X}(t_0) + \dot{\boldsymbol{X}}(t - t_0) \,, \tag{36.3}$$

and the variance propagation law gives its variance at epoch $t$ as

$$\begin{aligned} \operatorname{var}(\boldsymbol{X}(t)) = {} & \operatorname{var}(\boldsymbol{X}(t_0)) + 2(t - t_0)\operatorname{cov}(\boldsymbol{X}, \dot{\boldsymbol{X}}) \\ & + (t - t_0)^2 \operatorname{var}(\dot{\boldsymbol{X}}) \,. \end{aligned} \tag{36.4}$$

The stacking of time series of quasi-instantaneous reference frame solutions is usually operated using (36.3) – a type of equation where the unknowns are station positions $\boldsymbol{X}(t_0)$, and station velocities $\dot{\boldsymbol{X}}$. Equation (36.3) could also be generalized to include transformation parameters in order to account for possible reference frame differences between individual quasi-instantaneous reference frames themselves (which might not have the same origin, scale and/or orientation) and with respect to the stacked/combined long-term solution. Minimum constraints equations as described in Sect. 36.2.4 could also be added to the stacking model ((36.3)-type) in order to express a cumulative GNSS long-term solution in the ITRF.

### Geocenter Motion and Periodic Signals

A GNSS satellite, as any satellite, is theoretically orbiting around the center of gravity, or the center of mass (CM) of the total Earth system. Therefore in

theory, the instantaneous CM position reflects the natural origin of the inertial frame in which the satellite orbit is expressed. Analysis of satellite geodesy data have clearly indicated for about two decades that the network of stations attached to the Earth's crust and materializing the reference frame has detectable translational motion with respect to CM, known as the geocenter motion [36.10]. This motion is often defined as the motion of the CM with respect to the center of figure (CF) of the solid Earth surface [36.11] and is believed to be the crust response to various geophysical fluid displacements within the Earth system, such as the atmosphere, oceans, terrestrial hydrology and ice sheets. It is assumed to include tidal, nontidal and secular components. The tidal parts of the geocenter motion induced by the atmosphere and oceans, with an amplitude that may reach up to 1 cm, are included in the models recommended by the IERS conventions [36.8] to be taken into account a priori in the station displacement of space geodesy techniques. The nontidal part of the geocenter motion, with an amplitude of a few mm, manifests itself in the form of periodic signals: annual, semi- and interannual, and is quantified through data analysis of time series of station positions determined by space geodesy techniques, or through external geophysical models. The secular part, often called the geocenter velocity, is believed to be less than 1 mm/y [36.12]. The detailed review by [36.12] is the most extensive article describing the theory of the geocenter motion and its geophysical implications, as well as its quantification over different timescales.

There are basically three main methods for estimating the nonlinear geocenter motion components:

1. The translational
2. The degree-1 load-induced deformation
3. The inverse approaches.

The translational approach consists in estimating the three equatorial components of the CF, which is in fact approximated by the barycenter of the implied geodetic network, often called the center of network (CN), with respect to CM. The translational approach is called a kinematic approach when the degree-1 coefficients of the gravity field are estimated, which are proportional to the geocenter motion components [36.13]. It is also called a network shift approach when the seven- or six-parameter similarity (Helmert) transformation formula (see for instance (36.7)) is used to infer the three translation components between a time series of quasi-instantaneous frames and a secular long-term frame such as the ITRF. Indeed, the ITRF origin is defined by the long-term average of the SLR CM realization. Fitting a sine and/or a cosine function yields in fact the amplitude and phase of annual and/or semi-annual signals of the geocenter motion.

Although the SLR technique suffers from its poor spatiotemporal network, leading to the so-called *network effect* when using the translational approach [36.14], it is the most precise space geodetic technique for the geocenter nonlinear motion estimation.

The estimability of the geocenter motion by GNSS via the kinematic or network shift approaches faces intrinsic complications due to an inherent coupling of the GNSS orbit dynamic parameters; [36.15, 16] showed that the GNSS geocenter Z-component is strongly correlated to a particular parameter of the solar radiation pressure. In [36.17] it was demonstrated, via a collinearity diagnosis formalism, that the inability of GNSS, as opposed to SLR, to properly sense the location of the geocenter CM is mostly explained by the estimation, in the GNSS case, of epoch-wise station and satellite clock offsets simultaneously with tropospheric parameters.

The degree-1 approach was first introduced in [36.18], using the spherical harmonics formalism, to infer not only the translational geocenter motion, but also the accompanying load-induced crust deformation using GNSS (GPS) time series of quasi-instantaneous frames of a globally distributed network of stations. They in fact demonstrated that the translational components of the geocenter motion are functions of degree-1 coefficients of the associated load deformation. It was then shown in [36.19] that the truncated higher-degree terms of the harmonic expansion of the load-induced deformation alias significantly into the degree-1 terms, and therefore higher-degree terms, up to 50, must be included in the estimation, leading so to the so-called inverse approach. Many authors (as referenced in [36.11]) have expanded and improved the inverse approach and its application, using not only GNSS(GPS) data that suffer from the network sparseness in ocean areas, but also data-assimilated ocean bottom pressure (OBP) models as well as GRACE gravity data.

In addition to geophysical (load-induced) periodic signals that explain about half of the observed GNSS seasonal power, other signals are also frequent and detected in the GNSS residuals of station position time series, such as the GPS draconitic errors [36.20]. The GPS draconitic year (of 351.2 d), is the period for the GPS orbit constellation to repeat its orientation with respect to the Sun. Harmonic signals of this period have actually been observed in the power spectra of nearly all IGS products [36.21].

### 36.2.2 Global Terrestrial Reference Frames

Following the terminology adopted by the geodetic community since the advent of space geodesy, we distinguish between a terrestrial reference system (TRS) and a terrestrial reference frame (TRF). While the former has a mathematical and physical foundations for its definition and properties, the latter represents its numerical realization constructed upon space geodesy observations (hence with uncertainties) and is accessible to the users through numerical values (e.g., positions as a function of time of a network of Earth crust-based points). The main physical and mathematical properties of a TRS (at the theoretical level) or of a TRF (at the realization level) are the origin, the scale, the orientation and their time evolution. The latter is usually expressed through rates (time variations) of translations (origin components), scale and rotations (orientation parameters).

While the origin and the scale (having physical properties) are the most critical parameters of interest to Earth science applications, the orientation and its time variation are of least consequence because they are arbitrarily and conventionally defined. In fact adopting a given orientation of the three axes of the reference system is a matter of conventions and convenience and would not change the relative shape of the implied geodetic network used to create the reference system. Continuous and long-term space geodesy observations are crucial for realizing a TRS that is able to precisely characterize and model Earth surface movements, such as tectonic plate motion. In the absence of technique-specific systematic errors, and if all geophysical processes are accurately accounted for in geodetic analysis, TRF origin and scale should be stable over time, i. e., should not exhibit any drift or discontinuities over the entire timespan of the implied geodetic observations.

None of the space geodesy techniques is able to provide all the necessary parameters for the TRF definition (origin, scale and orientation). While satellite techniques are sensitive to the Earth center of mass (a natural TRF origin; the point around which a satellite orbits), VLBI (whose TRF origin is arbitrarily defined through some mathematical constraints) is not. The scale is dependent on the modeling of some physical parameters, and the absolute TRF orientation (unobservable by any technique) is arbitrarily or conventionally defined through specific constraints. The utility of multitechnique combinations is therefore recognized for reference frame determination, and in particular for accurate reference definition. In principle, the particular strengths of one observing method can compensate for weaknesses in others if the combination is properly constructed, suitable weights are found, and accurate local ties in colocation sites are available.

The key element of a multitechnique combined frame, as used for the ITRF, is the availability of a sufficient number of globally distributed colocation sites. A colocation site is defined by the requirement that two or more space geodetic distinct instruments are operating at the same location or at locations very close to one another, which are very precisely surveyed in three dimensions, using geodetic classical surveys or the GPS technique. Classical surveys are usually direction angles, distances, and spirit leveling measurements between instrument reference points or geodetic markers. Adjustments by least squares of local surveys are generally performed by national geodetic agencies operating space geodesy instruments, yielding differential coordinates (local ties) connecting the colocated instrument reference points.

Figure 36.3 shows the four-technique colocation site at Yarragadee (western Australia), with the modern 12 m VLBI radio-telescope that started its operation in 2011, the National Aeronautics and Space Administration (NASA) SLR MOBLAS 5 system, the DORIS beacon, the GNSS pillars (called YARR, YAR2, YAR3) and the Gravimeter hut for campaign gravimetry measurements.

Intermarker distance and accuracy of the local tie are the two main criteria that must be considered for the definition of a colocation site [36.22]. Given the need for local tie vectors to be precise at the 1 mm level, and considering the increase in atmospheric refraction as a function of increased station separation, the distances between geodetic markers at colocation sites should not exceed 1 km. In addition, repeated surveys of the marker footprint are necessary for long-term local tie stability. The typical uncertainty of the local ties used for the ITRF is 2–5 mm (sometimes larger than 5 mm for the less precise ties). From the ITRF experience,

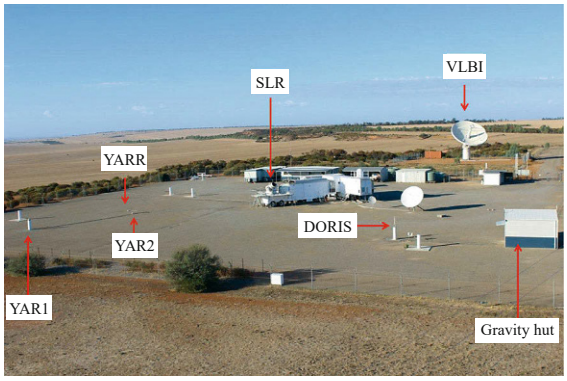

**Fig. 36.3** Yarragadee (western Australia) four-technique colocation site (courtesy of Geoscience Australia)

discrepancies between local ties and space geodesy estimates are frequent as discussed in the following section. However, discrepancies mean that either local ties or space geodesy estimates (or both) are imprecise or in error. One of the major local tie limitations is in fact to precisely determine the eccentricity between the external physical reference point used by the surveyors and the point referenced by space geodesy data analysts, for example the intersection of axes of VLBI or SLR telescopes, the DORIS beacon or the electrical GNSS antenna phase center [36.23]. The estimated uncertainty for each internal instrument offset is probably not better than 2 mm, and consequently, the overall local tie error would be at best 3 mm per component.

### The International Terrestrial Reference System (ITRS) and Frame (ITRF)

The international terrestrial reference system (ITRS) was developed by the geodetic community for the most demanding scientific applications under the auspices of the IERS. Following the IERS conventions and its updates [36.8, Ch. 4], the ITRS definition fulfills the following conditions:

1. It is geocentric, its origin being the center of mass for the whole Earth, including oceans and atmosphere.
2. The unit of length is the meter (SI). The scale is consistent with the geocentric coordinate time (TCG) for a geocentric local frame, in agreement with International Astronomical Union (IAU) and IUGG (1991) resolutions. This is obtained by appropriate relativistic modeling.
3. Its orientation was initially given by the Bureau International de l'Heure (BIH) orientation at 1984.0.
4. The time evolution of the orientation is ensured by using a no-net-rotation condition with regards to horizontal tectonic motions over the whole Earth.

The most accurate realizations of the ITRS is called the international terrestrial reference frame (ITRF). The implementation of the ITRF is fundamentally based on the rigorous combination of geodetic products of the main space geodetic techniques (GNSS, VLBI, SLR, and DORIS), through their colocated measuring instruments at a certain number of core sites. The ITRF combination model is based on the linearized form of the general similarity transformation formula, as it will be detailed below.

There is no single ITRF, but rather a series of updated and improved versions of ITRF. The versions are identified by the year associated with the date of last data used in the analysis, and should not be confused with the date of applicability. The most recent versions are ITRF97, ITRF2000, ITRF2005 and the ITRF2008 [36.24–26]. Generally, as time progresses, there is less need for frequent updates, because more time may be needed to make significant improvements through the addition of new data and improved models. However, to satisfy increasing accuracy requirements, the ITRF will continue to be updated to incorporate more advanced models for the time-dependent reference coordinates. Since the tracking network equipped with the instruments of those techniques is evolving and the period of data available increases with time, the ITRF is constantly being updated.

For more than ten years, initiated first by the IGS, analysis centers of the three other space geodesy techniques (VLBI, SLR, DORIS) have made available time series of station positions and Earth orientation parameters (EOPs) in SINEX (software independent exchange) format [36.27]. The power of times series of station positions, allowing the control not only of the station behavior and in particular to monitor nonlinear motion, but also the frame physical parameters (origin and scale), led the ITRF center to consider them as input for the ITRF generation, starting with the ITRF2005 [36.25]. In addition to station positions and velocities, ITRF2005 and ITRF2008 [36.26] integrate also consistent daily EOPs. The latter was already used by the IERS EOP center in order to improve the consistency of the IERS operational series of EOPs with the ITRF [36.28]. Up to the ITRF2008, the ITRF input time series solutions are provided on a weekly basis by the IAG international services of satellite techniques: the IGS [36.29], the ILRS [36.30] and the IDS [36.31], and on a daily (VLBI session-wise) basis by the IVS [36.32]. Each per-technique time series is already a combination of the individual analysis center solutions of that technique. As an example, the GNSS (mainly GPS) submitted solution to the ITRF2008 is a combination of the first reprocessed solutions by the IGS analysis centers and covers the time period 1997.0-2009.5 [36.33]. Note that a very small portion of Global'naya Navigatsionnaya Sputnikova Sistema (GLONASS) observations were used by some IGS ACs that contributed to the reprocessing effort. Starting on 19 August 2012, the IGS switched to daily integration and therefore daily IGS SINEX files will be used in the future ITRF solutions.

The procedure adopted for the ITRF formation involves two steps [36.25, 26, 34]:

1. Stacking the individual time series to estimate a long-term solution per technique comprising station positions at a reference epoch, station velocities and daily EOPs

2. Combining the resulting long-term solutions of the four techniques together with the local ties in colocation sites.

The main two equations of the combination model are given below. They involve a 14-parameter similarity transformation, station positions and velocities, and EOPs and are written as

$$\begin{cases} \boldsymbol{X}_{\mathrm{s}}^{i} & = \boldsymbol{X}_{\mathrm{c}}^{i} + (t_{\mathrm{s}}^{i} - t_0)\dot{\boldsymbol{X}}_{\mathrm{c}}^{i} \\ & \quad + \boldsymbol{T}_k + D_k \boldsymbol{X}_{\mathrm{c}}^{i} + \mathbf{R}_k \boldsymbol{X}_{\mathrm{c}}^{i} \\ & \quad + (t_{\mathrm{s}}^{i} - t_k)\left[\dot{\boldsymbol{T}}_k + \dot{D}_k \boldsymbol{X}_{\mathrm{c}}^{i} + \dot{\mathbf{R}}_k \boldsymbol{X}_{\mathrm{c}}^{i}\right] \\ \dot{\boldsymbol{X}}_{\mathrm{s}}^{i} & = \dot{\boldsymbol{X}}_{\mathrm{c}}^{i} + \dot{\boldsymbol{T}}_k + \dot{D}_k \boldsymbol{X}_{\mathrm{c}}^{i} + \dot{\mathbf{R}}_k \boldsymbol{X}_{\mathrm{c}}^{i} \,, \end{cases} \tag{36.5}$$

$$\begin{cases} x_{\mathrm{s}}^{\mathrm{p}} & = x_{\mathrm{c}}^{\mathrm{p}} + R_{yk} \\ y_{\mathrm{s}}^{\mathrm{p}} & = y_{\mathrm{c}}^{\mathrm{p}} + R_{xk} \\ UT_{\mathrm{s}} & = UT_{\mathrm{c}} - \frac{1}{f} R_{zk} \\ \dot{x}_{\mathrm{s}}^{\mathrm{p}} & = \dot{x}_{\mathrm{c}}^{\mathrm{p}} \\ \dot{y}_{\mathrm{s}}^{\mathrm{p}} & = \dot{y}_{\mathrm{c}}^{\mathrm{p}} \\ \mathrm{LOD}_{\mathrm{s}} & = \mathrm{LOD}_{\mathrm{c}} \,, \end{cases} \tag{36.6}$$

where for each point $i$, $\boldsymbol{X}_{\mathrm{s}}^{i}$ (at epoch $t_{\mathrm{s}}^{i}$) and $\dot{\boldsymbol{X}}_{\mathrm{s}}^{i}$ are positions and velocities of technique solution $s$ and $\boldsymbol{X}_{\mathrm{c}}^{i}$ (at epoch $t_0$) and $\dot{\boldsymbol{X}}_{\mathrm{c}}^{i}$ are those of the combined solution $c$. For each individual frame $k$, as implicitly defined by solution $s$, $D_k$ is the scale factor, $\boldsymbol{T}_k$ the translation vector and $\mathbf{R}_k$ the rotation matrix. The dotted parameters designate their derivatives with respect to time. The translation vector $\boldsymbol{T}_k$ is composed of three origin components, namely $T_x$, $T_y$, $T_z$, and the rotation matrix of three small rotation parameters: $R_x$, $R_y$, $R_z$, following the three axes, respectively $x$, $y$, $z$. $t_k$ is a conventionally selected epoch of the seven transformation parameters.

In addition to (36.5) involving station positions (and velocities), the EOPs are added by (36.6), making use of pole coordinates $x_{\mathrm{s}}^{\mathrm{p}}$, $y_{\mathrm{s}}^{\mathrm{p}}$ and universal time $\mathrm{UT}_{\mathrm{s}}$ as well as their daily rates $\dot{x}_{\mathrm{s}}^{\mathrm{p}}$, $\dot{y}_{\mathrm{s}}^{\mathrm{p}}$ and length-of-day $\mathrm{LOD}_{\mathrm{s}}$, where $f = 1.002737909350795$ is the conversion factor from universal time (UT) into sidereal time. The link between the combined frame and the EOPs is ensured via the three rotation parameters appearing in the first three lines of (36.6).

Note that (36.5) uses the linearized form of the general similarity transformation formula, neglecting second- and higher-order terms [36.8, 35].

In the first step of the ITRF construction, the first two lines of (36.5) and the entire (36.6) are used to estimate long-term solutions for each technique, by accumulating (rigorously stacking) the individual technique time series of station positions and EOPs. In the second step, the entire two equations are used to combine the long-term solutions obtained in step 1, together with local ties in colocation sites.

The number of colocation sites has evolved with time since the start of the ITRF combination activities in 1984, due to the decommission of certain historical sites for multiple reasons, and the appearance of a few new colocation sites. Figure 36.4 illustrates the distribution of the total number of VLBI, SLR and DORIS operating sites in 2015, as well as the IGS/GNSS colocated sites: IVS is managing a network of 49 radio telescopes located in 46 sites, ILRS 38 laser telescopes in 37 sites, IDS 53 beacons in 53 sites, and IGS more than 400 GNSS permanent, continuously operating receivers/antennas. All in all there are 90 colocated sites: 30 GNSS-SLR, 38 GNSS-VLBI and 43 GNSS-DORIS colocations. There are only 11 sites where VLBI and SLR are colocated, nine in the northern and only two in

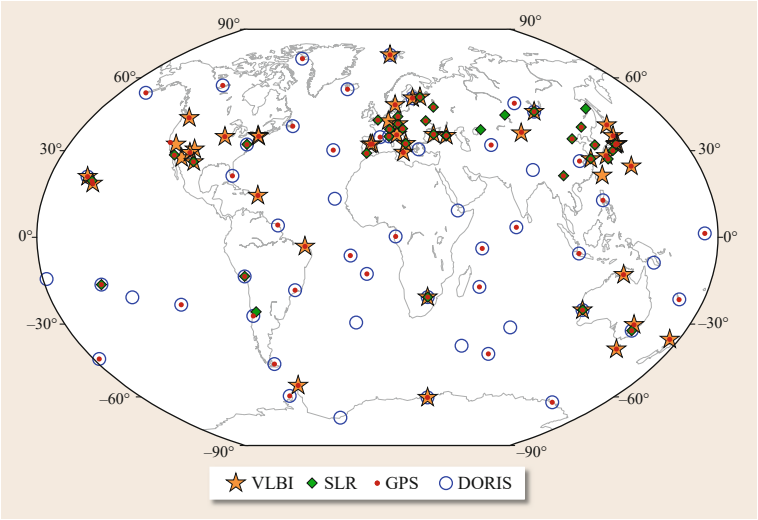

**Fig. 36.4** VLBI, SLR and DORIS sites and their colocations with GPS

the southern hemisphere. Unfortunately more than half of the VLBI and SLR instruments are old generation systems. As a consequence, the improvement of the underlying geodetic infrastructure of ITRF is an important goal of GGOS [36.6], discussed in the previous section. The low number, the nonoptimal coverage, and the low performance of some of the 11 VLBI-SLR colocation sites are significant limiting factors to ensuring a precise connection between these two techniques in the ITRF implementation. In fact, GNSS is playing a major role in connecting the three other techniques, given the fact that almost all SLR and VLBI sites, as well as 43 DORIS sites are colocated with permanent IGS stations. The drawback of this situation is that if there is any GNSS-related bias, this will contaminate the parameters that define the ITRF, primarily the origin and the scale that are determined by SLR and VLBI. There most probably are other technique-specific errors related to the mismodeling of the instrumental measurement reference points, not only for GPS [36.23], but also for the other techniques. Indeed, based on ITRF2008 results [36.26], tie discrepancies for 47, 43 and 34% of the total local tie vectors between GPS-VLBI, GPS-SLR and GPS-DORIS respectively are larger than 6 mm, corresponding to the level of scale agreement between VLBI and SLR solutions included in the ITRF2008 adjustment.

#### IGS Reference Frames and Their Relationship with the ITRF

The IGS products were integrated in the IERS combined products in 1992 and have contributed since then to the ITRF starting with ITRF91 [36.36]. All the IGS products are expressed in and are consistent with the ITRF frames. At the inception of its activities, the IGS used directly the ITRF frames to be the underlying frame of its products [36.37–39]. Following the methodology of [36.38, 40], the IGS started in 2000 to form its own, internally more consistent GPS-only frame, but still inheriting the ITRF definition in terms of origin, scale and orientation [36.41]. A more detailed history of IGS reference frame realizations can be found in [36.42, 43]. Starting with GPS week 1400 (5 November 2006), the IGS switched from relative to absolute model corrections to account for antenna phase center variations (PCV) [36.44]. At the same time, the IGS adopted directly the ITRF2005 [36.25] to form its specific frame called IGS05, composed of about 100 sites whose coordinates were corrected to account for relative to absolute PCV differences. In order to preserve the ITRF2005 origin, scale and orientation, the IGS05 was aligned to the ITRF2005 using 14-parameter similarity transformation [36.33]. In reality, among the 14 parameters, only the scale factor was significant, representing the mean of the height relative to absolute differences over the IGS05 stations. On 17 April 2011, the IGS generated and adopted the IGS08 frame [36.45], derived from ITRF2008. The IGS08 is composed of positions and velocities of a reference set of 232 stable GNSS stations extracted from ITRF2008, where corrections were applied to 65 stations to ITRF2008 positions in order to comply with the antenna calibration models used in present-day GNSS data analysis [36.23] (igs08.atx, in use since GPS week 1632). On 17 October 2012, the IGS updated the IGS08, called IGb08 [36.45], by adding about 36 stations in replacement of some decommissioned or dormant IGS08 stations. It should be noted that ITRF2008, IGS08 and IGb08 are however equivalent at the global level (sharing the same underlying origin, scale and orientation), although station-dependent position differences can exist.

### 36.2.3 GNSS-Based Reference Frames and Their Relationship with the ITRF

This section deals with reference frames that are built using GNSS data only, but are nominally aligned with the ITRF in origin, scale and orientation. The first subsection presents the GNSS-specific frames that are implemented by the different GNSS providers and in which the broadcast orbits are expressed. The second subsection discusses the regional reference frames that are also based on GNSS data only, while aligned to the ITRF via common processed stations. The third subsection develops general and mathematical guidelines on how to optimally align global or regional frames to the ITRF using IGS products.

#### GNSS-Specific Reference Frames

In order to ensure the integrity of any GNSS system and to precisely determine satellite orbits of its constellation, a specific reference frame has to be defined and maintained over time. The computed orbits are then transmitted to the users via the GNSS navigation message that allow determination of the user location, which will be expressed in the reference frame of that of the used orbits. The GNSS systems and frames in existence with publicly available information and publications are WGS84 for GPS, whose newest realization is designated as G1674 [36.46], PZ-90 for GLONASS whose latest realization is PS-90.11 [36.47] introduced in early 2014, CGCS2000 for COMPASS [36.48], the Galileo terrestrial reference frame (GTRF) for Galileo where the first series of its realization is described in [36.49], the newest one being designated as GTRF14v01, and the Japanese

geodetic system (JGS) for quasi-zenith satellite system (QZSS), which is believed to be consistent with or close to the newest Japanese geodetic datum 2011 (JGD2011) that was revised after the 2011 Tohoku Earthquake [36.50].

In an effort to ensure the interoperability of timing and geodetic references among the different GNSSs, working group D of the International Committee on GNSS (ICG) is actively interacting with the GNSS providers toward a more rigorous and accurate alignment of the GNSSs to a common time reference and to the ITRF. To our best knowledge, all recent and up-to-date realizations of all GNSS-specific geodetic reference systems are believed to be aligned to ITRF2008. However, almost all these realizations, except the GTRF series, are based on GNSS data with short timespans, most often a few days or one week of observations. While the GTRF series are aligned to the current ITRF version at the few millimeter level in both positions and velocities, the other GNSS-specific frames are obtained via the adjustment of station positions at the central epoch of the observations used, with no velocity estimates to account for time variations. Depending on the selected reference epoch of the adjusted positions of the control stations, the impact of, for example, tectonic motion will be at the few centimeter per year level. If we consider a scenario of 10 y before a new update of the control station positions is made, with no plate motion model applied, a 20–70 cm position error will be accumulated and mapped into the computed orbits, depending on the station locations. Consequently, we believe that the current realizations of GNSS-specific frames agree to each other and with the ITRF2008 at the few decimeter level. However, this level of agreement is certainly well below the inherent and typical uncertainty of the broadcast orbits. Over a ten-month period, [36.51] analyzed signal-in-space ranging errors (SISREs) for all current GNSS systems and showed that the global average SISRE values amount to 0.7 m (GPS), 1.5 m (BeiDou), 1.6 m (Galileo), 1.9 m (GLONASS), and 0.6 m (QZSS). As a consequence, the position of a real-time user, with single or multi-GNSS capabilities, is at the level of 1–2 m accuracy.

A way forward to improving the consistency of GNSS-specific frames at the few millimeter level is to follow the GTRF example, or to disclose data to the IGS of a subset of stations used in the ground segment, as it was the case of 11 stations of the National Geospatial Intelligence Agency (NGA) for the US Department of Defense, which were included in the ITRF2008 [36.26, 46]. The remaining challenge rests, however, in improving the intrinsic accuracy of the broadcast orbits of all GNSS constellations.

### Regional and National Terrestrial Reference Frames

Since the start of the ITRF development, together with the advent of GNSS positioning performance, significant effort was and is still undertaken by national mapping agencies to redefine and modernize continental and national geodetic systems, so that they are compatible with the global ITRF.

The structure of IAG commission 1 (reference frames) includes a subcommission 1.3 dealing with the definitions and realizations of regional reference frames and their connection to the global ITRF. The commission offers a home for service-like activities addressing theoretical and technical key common issues of interest to regional organizations. Six regional organizations are part of IAG subcommission 1.3, distributed to cover all continents (AFREF for Africa, NAREF and SIRGAS for North and South Americas, EUREF for Europe, APREF for Asia and Pacific, and SCAR for Antarctica).

Regional reference systems and frames are defined with respect to the ITRS/ITRF, realized and maintained by the IAG regional entities; the best known and advanced ones are ETRS89 for Europe, NAD83 for North America, and SIRGAS for South America. These regional entities usually play a major role in redefining regional and national geodetic systems and their relationship to the ITRF. In addition, many countries have already redefined or are in the process of redefining their geodetic systems, directly connected to the ITRF, using their national permanent GNSS networks. The main purpose of regional and national reference frames is for georeferencing applications with centimeter precision and accuracy. There are three main categories of implementation of these reference frames:

1. Station positions at a given epoch, eventually updated more or less frequently. This is the case, for example, for NAD83 [36.52, 53] and SIRGAS [36.54] for North and South America respectively, and GDA94 for Australia [36.55]
2. Station positions and minimized velocities. This is the case of ETRS89 for Europe where velocities are minimized by removing the angular velocity of the Eurasian plate when transforming from ITRF to ETRS89 realization [36.56]
3. Station positions and deformation model corrections. A case example is the New Zealand geodetic datum 2000 (NZGD2000) [36.57] where a deformation model is elaborated to correct coordinates for the effect of regional-scale tectonic movements for all geodetic reference points. The accumulated displacements estimated by the deformation model allow the computation of station coordinates as if

they were observed at the fixed reference epoch of 2000.0.

### 36.2.4 General Guidelines for GNSS-Based Reference Frame Implementation

By design, the ITRF is to be regarded as a common global standard that provides the most accurate frame definition: long-term averages of the origin, scale and orientation, necessary for the consistency and interoperability of Earth science and societal applications. In the meantime, with the proliferation of dense GNSS networks at the local, national, continental and global levels, it is obviously impossible to include all worldwide permanent GNSS stations in the IGS (and consequently) in the ITRF networks. It becomes however desirable to express all local, national, continental and global GNSS network solutions in the ITRF.

In order to access the ITRF, it can be used directly, via its products (station positions and velocities), but also indirectly, using IGS products. In the following we describe general guidelines that allow the efficient expression of a GNSS-based solution of station positions in the ITRF, using IGS products (orbits, clocks and EOPs). This method, based on the equations of minimum constraints (MC) (see for instance [36.34, 58]), is described below for the case of an epoch solution (as a materialization of a quasi-instantaneous reference frame), involving one day or one week of GNSS observations. It can of course be applied to any kind of network (being global or regional) not only for positions, but also for velocities. It comprises the following steps:

1. Selection of a reference set of known ITRF/IGS stations and collecting their GNSS observation data provided in Receiver INdependent EXchange (RINEX) format from IGS data centers, covering the timespan (one day or one week) of the implied observations. It is highly advised to select a set of ITRF/IGS stations that are as homogeneously and globally distributed as possible, in order to achieve the best and an accurate expression in the ITRF.
2. Processing user station data together with the selected ITRF/IGS ones, using the preferred GNSS software. In this step, IGS orbits, clocks and EOPs should be fixed to the values consistent with the associated ITRF/IGS frame (ITRFyy, IGSyy). Fixing or tightly constraining ITRF/IGS reference station coordinates should by all means be avoided. Doing so would potentially introduce distortion in the solution due to possible outdated ITRF/IGS station coordinates after some events, such as earthquakes or equipment changes. Moreover, as the ITRF is a secular linear frame, fixing or tightly constraining ITRF/IGS reference station coordinates would also inhibit the geophysical signal embedded in the transformed solution one may want to preserve.
3. Propagation of the selected ITRF/IGS station positions ($\boldsymbol{X}_\mathrm{I}$) at the central epoch ($t_\mathrm{c}$) of the employed GNSS observations, using

$$\boldsymbol{X}_\mathrm{I}(t_\mathrm{c}) = \boldsymbol{X}_\mathrm{I}(t_0) + \dot{\boldsymbol{X}}_\mathrm{I} \cdot (t_\mathrm{c} - t_0) \,,$$

where $\boldsymbol{X}_\mathrm{I}(t_0)$ are the ITRF/IGS station positions at epoch $t_0$ and $\dot{\boldsymbol{X}}_\mathrm{I}$ are their linear velocities.
4. Application of minimum constraints approach [36.34, 35], detailed below, which is believed to be implemented in all major scientific software packages. The derived solution will be expressed in the ITRF/IGS frame that is consistent with the used orbits.
5. Comparison of the estimated ITRF/IGS reference station positions to the official published values, propagated at epoch $t_\mathrm{c}$ in step 3, by fitting a similarity transformation of three, four or seven parameters selected in the MC application and checking for consistency. The estimated transformation parameters should all be zero. In addition, if large discrepancies (postfit residuals of the similarity transformation) are found for some stations (exceeding a certain threshold, say 1–2 cm, but depending on the targeted accuracy), these stations should be rejected from the ITRF/IGS reference set and the processing chain should be iterated. Care should also be taken in the time interval of the validity of the used IGS/ITRF coordinates, taking into account station position discontinuities.

The starting point of the MC concept is based on the seven-parameter similarity transformation between any two reference systems or frames. Therefore, the linearized relationship between any space geodesy TRF solution, for example GNSS-based solution ($\boldsymbol{X}_\mathrm{G}$) and the ITRF ($\boldsymbol{X}_\mathrm{I}$), over selected reference set of common stations, can be written as

$$\boldsymbol{X}_\mathrm{I} = \boldsymbol{X}_\mathrm{G} + \mathbf{A}\boldsymbol{\theta} \,, \tag{36.7}$$

where the design matrix $\mathbf{A}$ is a stacked matrix made from elementary 3-row matrices

$$\mathbf{A}^i = \begin{pmatrix} 1 & 0 & 0 & x_\mathrm{a}^i & 0 & z_\mathrm{a}^i & -y_\mathrm{a}^i \\ 0 & 1 & 0 & y_\mathrm{a}^i & -z_\mathrm{a}^i & 0 & x_\mathrm{a}^i \\ 0 & 0 & 1 & z_\mathrm{a}^i & y_\mathrm{a}^i & -x_\mathrm{a}^i & 0 \end{pmatrix} \tag{36.8}$$

with $i = 1 \ldots n$ for a total of $n$ sites, and where $\boldsymbol{\theta} = (T_x, T_y, T_z, D, R_x, R_y, R_z)^\top$ is the vector of seven transformation parameters. $T_x, T_y, T_z$ are the three translation

components, $D$ is the scale factor, and $R_x$, $R_y$, $R_z$ are the three rotation parameters. The approximate coordinates $x_a^i$, $y_a^i$, $z_a^i$ of point $i$, appearing in the design matrix $\mathbf{A}$ can be taken from the ITRF/IGS reference solution. Note that (36.7) is only valid at the same and common epoch of the two station position sets ($\boldsymbol{X}_I$ and $\boldsymbol{X}_G$). It can also be generalized to 14 parameters when station velocities are involved in the process; see [36.24] for more details. Note also that the design matrix $\mathbf{A}$ can be reduced to the columns corresponding to the frame parameters of interest, e.g., columns 1, 2 and 3 for the origin components; 5, 6 and 7 for the orientation parameters. In case of a regional network, applying the MC approach on the three translation components (i. e., $\mathbf{A}$ is reduced to the three first columns) can be sufficient. It is however advisable to evaluate at least the following three options: translation, translation and scale, all seven parameters.

The unweighted least squares expression of (36.7) yields for $\boldsymbol{\theta}$

$$\boldsymbol{\theta} = \overbrace{(\mathbf{A}^\top\mathbf{A})^{-1}\mathbf{A}^\top}^{\mathbf{B}}(\boldsymbol{X}_I - \boldsymbol{X}_G)\,. \tag{36.9}$$

The approach of MC consists in using the matrix $\mathbf{B} = (\mathbf{A}^\top\mathbf{A})^{-1}\mathbf{A}^\top$ in such a way that $\boldsymbol{X}_G$ will be expressed in the same frame as the ITRF solution $\boldsymbol{X}_I$. Therefore to have $\boldsymbol{X}_G$ expressed in the ITRF at a certain $\boldsymbol{\Sigma}_\theta$ level, an MC equation can be written as

$$\mathbf{B}(\boldsymbol{X}_I - \boldsymbol{X}_G) = \mathbf{0}\,(\boldsymbol{\Sigma}_\theta)\,, \tag{36.10}$$

where $\boldsymbol{\Sigma}_\theta$ is the variance matrix at which (36.10) is satisfied. It is a diagonal matrix containing small variances (to be selected at the user level) for each one of the seven transformation parameters. It is suggested to use 0.1 mm for translation parameters and equivalent amounts (i. e., 0.1 mm divided by the Earth radius) for the scale and orientation parameters.

In terms of normal equations, we can then write

$$\mathbf{B}^\top\boldsymbol{\Sigma}_\theta^{-1}\mathbf{B}(\boldsymbol{X}_I - \boldsymbol{X}_G) = \mathbf{0}\,. \tag{36.11}$$

The initial normal equation system of a GNSS-based solution before adding any kind of constraints can be written as

$$\mathbf{N}(\Delta\boldsymbol{X}) = \boldsymbol{K}\,, \tag{36.12}$$

where $\Delta\boldsymbol{X} = \boldsymbol{X} - \boldsymbol{X}_{apr}$, with $\boldsymbol{X}$ being the unknown vector, $\boldsymbol{X}_{apr}$ is the vector of a priori values, $\mathbf{N}$ is the unconstrained normal matrix and $\boldsymbol{K}$ is the right-hand side vector.

By fixing the IGS products (orbits, clocks and EOPs), the normal equation system (36.12) becomes invertible, but the underlying TRF could be far from that of the ITRF, i. e., defined at the level of the orbit precision (a few cm). The same normal equation system can also be obtained after removing classical constraints applied to a given GNSS-based solution.

Selecting a subset of ITRF stations ($\boldsymbol{X}_I$), the MC equation becomes

$$\mathbf{B}^\top\boldsymbol{\Sigma}_\theta^{-1}\mathbf{B}(\Delta\boldsymbol{X}) = \mathbf{B}^\top\boldsymbol{\Sigma}_\theta^{-1}\mathbf{B}(\boldsymbol{X}_I - \boldsymbol{X}_{apr})\,. \tag{36.13}$$

Note that the right-hand side of (36.13) vanishes if the a priori values are taken from the ITRF/IGS selected solution.

Cumulating (36.12) and (36.13) yields

$$\begin{aligned}&(\mathbf{N} + \mathbf{B}^\top\boldsymbol{\Sigma}_\theta^{-1}\mathbf{B})(\Delta\boldsymbol{X})\\ &\quad = \boldsymbol{K} + \mathbf{B}^\top\boldsymbol{\Sigma}_\theta^{-1}\mathbf{B}(\boldsymbol{X}_I - \boldsymbol{X}_{apr})\,.\end{aligned} \tag{36.14}$$

The minimally constrained solution, expressed in the ITRF upon the selected stations is then

$$\begin{aligned}\boldsymbol{X} = {}& \boldsymbol{X}_{apr} + (\mathbf{N} + \mathbf{B}^\top\boldsymbol{\Sigma}_\theta^{-1}\mathbf{B})^{-1}\\ &\times (\boldsymbol{K} + \mathbf{B}^\mathrm{T}\boldsymbol{\Sigma}_\theta^{-1}\mathbf{B}(\boldsymbol{X}_I - \boldsymbol{X}_{apr}))\,.\end{aligned} \tag{36.15}$$

### 36.2.5 GNSS, Reference Frame and Sea Level Monitoring

Because of its ramifications around climate change and global warming, sea level monitoring requires the most stringent continuous geodetic observations that can only be addressed within the context of a global and stable reference frame. Two main data streams are used to infer sea level rise and its spatial and temporal variability: tide gage records and satellite altimetry data. The former dataset requires precise quantification of land vertical motion where tide gages are located, and the latter dataset imposes the precise knowledge of satellite orbits in a well-defined global reference frame. Both methods greatly benefit from the availability of GNSS observations. GNSS is the technique of choice to infer vertical crustal motion due to its ease of use and its connection to the ITRF through IGS products. Data collected by GPS receivers on board altimetry satellites and by ground-based receivers, together with DORIS and SLR data are used to precisely determine satellite orbits [36.59, 60].

To fully exploit tide gage records and accurately determine land vertical motion, it has been demonstrated that the GNSS processing strategy, together with the availability of an accurate reference frame are the main two limiting factors for improving our understanding of regional sea level variability in space and time. The processing strategy includes precise orbit determination of the GNSS satellites, an optimal

treatment of GNSS terrestrial observations and an advanced method of reference frame determination. Using an improved processing strategy and GPS data spanning 10 y at tide gages, [36.61] determined vertical velocities, based on ITRF2005, with uncertainties several times smaller than the 1–3 mm/y associated with global sea level change. The same authors have also shown that GPS-based land motion corrections at tide gages and expressed in ITRF2005 perform much better than glacial isostatic adjustment (GIA) model predictions, both on the global and the regional scale. These results suggest that GNSS measurements are more appropriate than GIA models to capture localized vertical motions associated with, for example, plate tectonics, volcanism, sediment compaction, or underground fluid extraction.

Precise orbit determination (POD) is one of the main critical issues for an accurate determination of global sea level variability using altimetry data of ocean surface satellite topography missions (OSTM), such as TOPEX-Poseidon, and Jason-1 and 2. These missions carry onboard three tracking systems (DORIS, GPS and SLR) to meet the requirement of better than 1.5 cm radial accuracy for the operational orbit included in the geophysical data record products [36.60]. One of the main long-period error sources of POD is the stability of the origin of the reference frame, and in particular its $z$-component. In [36.62] it was shown that the difference between using an old reference frame called CSR95 (compatible with ITRF2000) of the Center for Space Research of the University of Texas at Austin, and ITRF2005 in orbit computation caused a change in the estimated mean sea level trend of $-0.26$ mm/y for the period from 1993 to 2002. The primary cause was shown to be the drift in the $z$-component of the origin between the two frames of 1.8 mm/y that also affected the regional sea level rates at the high latitudes by $\pm 1.5$ mm/y. The review article [36.60] gives a summary of the different levels of performance of POD estimates as determined by different groups, using data of the three satellite techniques. They reported in particular that the 1 cm goal is met by both Jason-1 and 2 GPS-based reduced-dynamic orbits.

## 36.3 Earth Rotation, Polar Motion, and Nutation

Observations of the Earth's rotation show that while the Earth rotates about its axis once a day, it does not do so uniformly. Instead, the rate of rotation fluctuates by as much as a millisecond a day. The Earth wobbles as it rotates because its mass is not balanced about its rotation axis, and the Earth precesses and nutates in space. These variations in the Earth's rotation are caused by processes acting within the interior of the Earth such as glacial isostatic adjustment and core-mantle interaction torques, by processes acting at the surface of the Earth such as fluctuations in the transport of mass within the atmosphere and oceans, and by processes acting external to the Earth such as torques due to the gravitational attraction of the Sun, Moon, and planets [36.63–67].

In principle, only three time-dependent parameters, the Euler angles, are needed to fully characterize the varying orientation of the Earth in space. However, by convention, five parameters are actually used: two precession and nutation parameters that give the location of the reference pole in the space-fixed celestial frame, two polar motion parameters that give the location of the reference pole in the body-fixed terrestrial frame, and a spin parameter that gives the angular rotation of the Earth about the reference axis. The advantage of using five parameters instead of three is that with five parameters the externally forced precession/nutation motion of the Earth is largely separated from its internally excited wobbling motion, also known as polar motion.

Routine measurements of the Earth's time-varying rotation are currently provided by the space-geodetic techniques of satellite and lunar laser ranging (SLR and LLR), very long baseline interferometry (VLBI), global navigation satellite systems (GNSSs) like the global positioning system (GPS), and Doppler orbitography and radio positioning integrated by satellite (DORIS). Each of these techniques has its own unique strengths and weaknesses in its ability to determine the five Earth orientation parameters (EOPs). Not only is each technique sensitive to a different subset and/or linear combination of the Earth orientation parameters, but also the averaging time for their determination is different, as is the interval between observations and the precision with which they can be determined.

Because of the large number of Earth orbiting satellites that transmit GNSS signals and the large number of ground stations that receive them, continuous, uninterrupted measurements of the Earth's rotation are provided by GNSS. In addition, because the raw observables can be rapidly analyzed, GNSS can provide measurements of the Earth's rotation in near-real time. In this section, the contribution of GNSS to monitoring the rotational behavior of the Earth and to understanding the causes of the observed variations is discussed.

### 36.3.1 Theory of the Earth's Rotation

Changes in the rotation of the solid Earth are usually studied by applying the principle of conservation of angular momentum, which requires that changes in the rotation vector of the solid Earth are manifestations of either torques acting on the solid Earth or of changes in the mass distribution within the solid Earth that alter its inertia tensor. Angular momentum is transferred between the solid Earth and the fluid regions (the underlying liquid metallic core and the overlying hydrosphere and atmosphere) with which it is in contact; concomitant torques are due to hydrodynamic or magnetohydrodynamic stresses acting at the fluid/solid Earth interfaces. Using the principle of the conservation of angular momentum the equations governing small variations in both the rate of rotation and in the position of the rotation vector with respect to the Earth's crust can be derived [36.67–70].

Within a rotating, body-fixed reference frame, the equation that relates changes in the angular momentum $\boldsymbol{L}(t)$ of a rotating body to the external torques $\boldsymbol{\tau}(t)$ acting on the body is [36.71]

$$\frac{\partial}{\partial t}[\boldsymbol{h}(t)+\mathbb{I}(t)\cdot\boldsymbol{\omega}(t)] + \boldsymbol{\omega}(t)\times[\boldsymbol{h}(t)+\mathbb{I}(t)\cdot\boldsymbol{\omega}(t)] = \boldsymbol{\tau}(t)\,, \quad (36.16)$$

where $\boldsymbol{\omega}(t)$ is the angular velocity of the body with respect to inertial space and where $\boldsymbol{L}(t)$ has been written as the sum of two terms: (1) that part $\boldsymbol{h}(t)$ due to motion relative to the rotating reference frame, and (2) that part due to changes in the inertia tensor $\mathbb{I}(t)$ of the body caused by changes in the distribution of mass.

The Earth's rotation deviates only slightly from a state of uniform rotation, the deviation being a few parts in $10^8$ in speed, corresponding to changes of a few milliseconds (ms) in the length of the day, and about a part in $10^6$ in the orientation of the rotation axis relative to the crust of the Earth, corresponding to a variation of several hundred milliarcseconds (mas) in polar motion. Such small deviations in rotation are studied by linearizing (36.16).

Let the Earth be initially uniformly rotating about its figure axis and orient the body-fixed reference frame so that its $z$-axis is aligned with the figure axis. Under a small perturbation to this initial state, the initial relative angular momentum $\boldsymbol{h}_\mathrm{o}$ (which is zero because there is initially no relative angular momentum) will be perturbed to $\boldsymbol{h}_\mathrm{o}+\Delta\boldsymbol{h}$, the initial inertia tensor $\mathbb{I}_\mathrm{o}$ will be perturbed to $\mathbb{I}_\mathrm{o}+\Delta\mathbb{I}$, and the initial angular velocity vector $\boldsymbol{\omega}_\mathrm{o}$ will be perturbed to $\boldsymbol{\omega}_\mathrm{o}+\Delta\boldsymbol{\omega}$. Keeping terms to first order in small quantities and making a number of other assumptions including assuming that the Earth is axisymmetric, that the oceans remain in equilibrium as the rotation of the solid Earth changes, that the core is not coupled to the mantle, and that the rotational variations occur on timescales much longer than a day, then the Cartesian components of the linearized version of (36.16) can be written as [36.67]

$$\frac{1}{\sigma_\mathrm{o}}\frac{\partial m_x(t)}{\partial t}+m_y(t)=\chi_y(t)-\frac{1}{\Omega}\frac{\partial\chi_x(t)}{\partial t} \quad (36.17)$$

$$\frac{1}{\sigma_\mathrm{o}}\frac{\partial m_y(t)}{\partial t}-m_x(t)=-\chi_x(t)-\frac{1}{\Omega}\frac{\partial\chi_y(t)}{\partial t} \quad (36.18)$$

$$m_z(t)=-\chi_z(t)\,, \quad (36.19)$$

where $\Omega$ is the mean angular velocity of the Earth (rad/s), $\sigma_\mathrm{o}$ is the observed complex-valued frequency of the Chandler wobble (rad/s), and the dimensionless $m_i$ are related to the elements of the perturbed rotation vector

$$\boldsymbol{\omega}(t)=\boldsymbol{\omega}_\mathrm{o}(t)+\Delta\boldsymbol{\omega}(t) = \Omega\,\hat{\boldsymbol{z}}+\Omega\,[m_x(t)\,\hat{\boldsymbol{x}}+m_y(t)\,\hat{\boldsymbol{y}}+m_z(t)\,\hat{\boldsymbol{z}}]\,, \quad (36.20)$$

with the hat denoting a vector of unit length.

The dimensionless $\chi_i(t)$ in (36.17)–(36.19) are known as excitation functions and are functions of the perturbed inertia tensor (kg-m$^2$) and relative angular momentum (kg-m$^2$/s) that are exciting the changes in the Earth's rotation [36.67]

$$\chi_x(t)=\frac{1.608[\Delta h_x(t)+0.684\,\Omega\,\Delta I_{xz}(t)]}{(C-A')\Omega}\,, \quad (36.21)$$

$$\chi_y(t)=\frac{1.608[\Delta h_y(t)+0.684\,\Omega\,\Delta I_{yz}(t)]}{(C-A')\Omega}\,, \quad (36.22)$$

$$\chi_z(t)=\frac{0.997}{C_\mathrm{m}\Omega}[\Delta h_z(t)+0.750\,\Omega\,\Delta I_{zz}(t)]\,, \quad (36.23)$$

where $C$ is the axial principal moment of inertia of the entire Earth, $C_\mathrm{m}$ is that of just the crust and mantle, and $A'$ is the average $(A+B)/2$ of the equatorial principal moments of inertia of the entire Earth.

The numerical coefficients of the inertia tensor terms in (36.21)–(36.23) are functions of load Love numbers [36.67], so (36.21)–(36.23) are valid for processes like atmospheric surface pressure variations that load the solid Earth causing it to deform. For processes that do not load the solid Earth, like earthquakes, the coefficients 0.684 in (36.21)–(36.22) and 0.750 in (36.23) should be set to 1.0.

### 36.3.2 Length-of-Day

Equations (36.19) and (36.23) relate changes in the axial component of the Earth's angular velocity to changes

in both the axial component of relative angular momentum and in the $zz$-element of the inertia tensor. But GNSS observations do not give changes in the axial component of the Earth's angular velocity. Instead, they give changes in the length of the day. The length of the day is the rotational period of the Earth. Changes $\Delta\Lambda(t)$ in the length of the day are related to the time rate-of-change of the difference (UT1 – TAI) between Universal Time UT1 and atomic time TAI and to changes $\Delta\omega_z(t) = \Omega\, m_z(t)$ in the axial component of the Earth's angular velocity [36.67]

$$\frac{\Delta\Lambda(t)}{\Lambda_o} = -\frac{\mathrm{d}(\mathrm{UT1}-\mathrm{TAI})}{\mathrm{d}t} = -\frac{\Delta\omega_z(t)}{\Omega} = -m_z(t)\,, \tag{36.24}$$

where $\Lambda_o$ is the nominal length-of-day (LOD) of 86 400 s. GNSS-observed changes in the length of the day are therefore related to the processes causing the length-of-day to change by

$$\frac{\Delta\Lambda(t)}{\Lambda_o} = \frac{0.997}{C_m\Omega}[\Delta h_z(t) + 0.750\,\Omega\,\Delta I_{zz}(t)]\,. \tag{36.25}$$

Figure 36.5 shows the changes in the length of the day $\Delta\Lambda(t)$ measured by GNSS during March 1997 to June 2014. Like a spinning ice skater whose speed of rotation increases as the skater's arms are brought closer to the body, the speed of the Earth's rotation increases and the length of the day decreases if its mass is brought closer to its axis of rotation. Conversely, the speed of the Earth's rotation decreases and the length of the day increases if its mass is moved away from the rotation axis. Observations of the length of the day like those shown in Fig. 36.5 show that it consists mainly of:

1. A linear trend of rate +1.8 ms/cy (not evident in Fig. 36.5 because of the shortness of the record)
2. Decadal variations having an amplitude of a few milliseconds
3. Tidal variations having an amplitude of about 1 ms
4. Seasonal variations having an amplitude of about 0.5 ms
5. Smaller amplitude variations occurring on all measurable timescales.

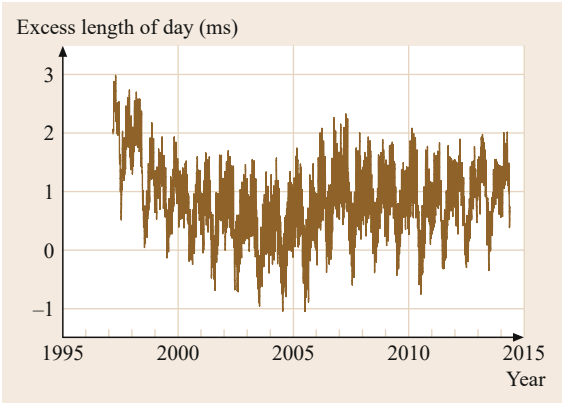

**Fig. 36.5** Observed excess length-of-day values in milliseconds (ms) spanning March 1997 to June 2014 from the IGS final combined series. The excess length-of-day is the amount by which the length-of-day is longer (positive values) or shorter (negative values) than the nominal length-of-day of 86 400 s

A number of different dynamical Earth processes are responsible for the changes in the length of the day shown in Fig. 36.5. Tidal forces due to the changing gravitational attraction of the Sun, Moon, and planets deform the solid and fluid regions of the Earth, causing the Earth's rotation to change by causing its inertia tensor to change. In fact, solid-body tides, caused by the tidal forces acting on the solid Earth, are the dominant cause of length-of-day variations on intraseasonal to interannual timescales. Ocean tides, caused by the tidal forces acting on the oceans, are the dominant cause of subdaily length-of-day variations and contribute to length-of-day variations at longer periods.

Figure 36.6 shows a spectrum of the GNSS-observed length-of-day variations that are shown in Fig. 36.5. Peaks at the tidal frequencies are clearly evident. Nontidal variations in the length of the day occurring on timescales of a few days to a few years are predominantly caused by variations in the zonal atmospheric winds, with variations in atmospheric surface pressure, oceanic currents and bottom pressure, and water stored on land contributing much less. On longer timescales, decadal variations as large as a few milliseconds in the length of the day are caused by interactions between the fluid outer core and solid mantle of the Earth, and a secular trend of +1.8 ms/cy in the length of the day is caused by a combination of tidal dissipation in the Earth-Moon system (+2.3 ms/cy) and by glacial isostatic adjustment (–0.5 ms/cy). See [36.67] for a review of these and other causes of length-of-day changes.

### 36.3.3 Polar Motion

Equations (36.17)–(36.18) and (36.21)–(36.22) relate changes in the equatorial components of the Earth's angular velocity to changes in both the equatorial components of relative angular momentum and in the $xz$- and $yz$-elements of the inertia tensor. But GNSS observations do not give changes in the equatorial com-

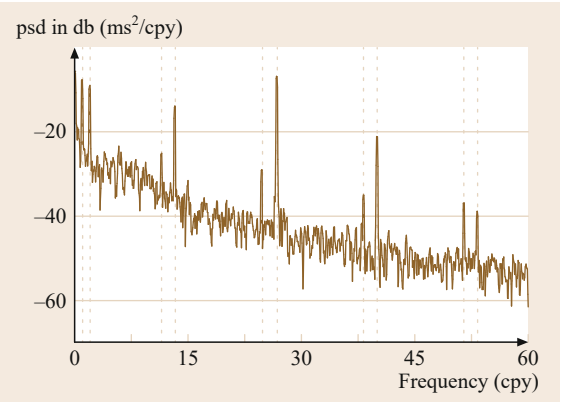

**Fig. 36.6** Power spectral density (psd) estimates in decibels (db) computed by the multitaper method of the IGS Final combined length-of-day measurements spanning March 1997 to June 2014. *Vertical dashed lines* indicate the frequencies of the annual (1 cycle/y (cpy)) and semiannual (2 cpy) LOD variations and of the largest tidal variations in the monthly (13 cpy), fortnightly (27 cpy), termensual (40 cpy), and 7 d (51 cpy) tidal bands

ponents of the Earth's angular velocity. Instead, they give changes in the terrestrial position of the celestial intermediate pole (CIP). The CIP is the intermediate reference pole whose use allows the separation of nutation from wobble. The equatorial components of the Earth's angular velocity are related to the GNSS-observed position of the CIP in the terrestrial reference frame $\boldsymbol{p}(t) = p_x(t) - \mathrm{j}\, p_y(t)$, where the negative sign accounts for $p_y(t)$ being conventionally positive toward 90° West longitude, by [36.67]

$$\boldsymbol{m}(t) = \boldsymbol{p}(t) - \frac{\mathrm{j}}{\Omega}\,\frac{\mathrm{d}\boldsymbol{p}(t)}{\mathrm{d}t}\,, \qquad (36.26)$$

where $\boldsymbol{m}(t) = m_x(t) + \mathrm{j}\, m_y(t)$ and j is the imaginary unit $\sqrt{-1}$. By combining (36.26) with (36.17)–(36.18) it can be shown that the GNSS-observed polar motion parameters $p_x(t)$ and $p_y(t)$ are related to the polar motion excitation functions $\boldsymbol{\chi}(t) = \chi_x(t) + \mathrm{j}\,\chi_y(t)$ by

$$\boldsymbol{p}(t) + \frac{\mathrm{j}}{\sigma_\mathrm{o}}\,\frac{\mathrm{d}\boldsymbol{p}(t)}{\mathrm{d}t} = \boldsymbol{\chi}(t) = \frac{1.608[\Delta\boldsymbol{h}(t) + 0.684\,\Omega\,\Delta\mathbb{I}(t)]}{(C - A')\Omega}\,, \qquad (36.27)$$

where in this equation $\Delta\boldsymbol{h}(t) = \Delta h_x(t) + \mathrm{j}\,\Delta h_y(t)$ and $\Delta\mathbb{I}(t) = \Delta I_{xz}(t) + \mathrm{j}\,\Delta I_{yz}(t)$.

Figures 36.7a and 36.7b show the $x$- and $y$-components of polar motion, $p_x(t)$ and $p_y(t)$ respectively, measured by GNSS during July 1996 to June 2014. Much like the wobble of an unbalanced

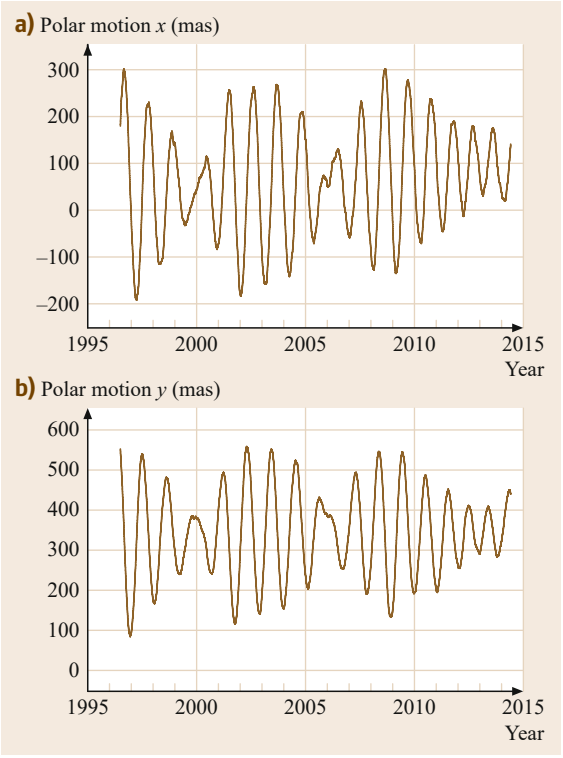

**Fig. 36.7** The $x$-component **(a)** and $y$-component **(b)** of observed polar motion values in milliarcseconds (mas) spanning July 1996 to June 2014 from the IGS final combined series. The readily apparent beat pattern is caused by the 12-month annual and 14-month Chandler wobbles, which have similar amplitudes, constructively and destructively interfering with each other

automobile tire, the Earth wobbles because the mass of the Earth is not balanced about its rotation axis. In the absence of excitation, the Earth would eventually stop wobbling because of dissipation processes in the oceans and solid, but not rigid, crust and mantle. But as long as mass continues to be horizontally transported towards or away from the poles the Earth will continue to wobble. Observations like those shown in Figs. 36.7a and 36.7b show that polar motion consists mainly of:

1. A forced annual wobble having a nearly constant amplitude of about 100 mas
2. The free Chandler wobble having a period of about 433 d and a variable amplitude ranging from about 100–200 mas
3. Quasiperiodic variations on decadal timescales having amplitudes of about 30 mas known as the Markowitz wobble
4. A linear trend having a rate of about 3.5 mas/y and a direction towards 79° West longitude

5. Smaller amplitude variations occurring on all measurable timescales.

One of the great strengths of GNSS in measuring changes in the Earth's rotation is that it can measure not only the polar motion parameters themselves but also their time rate-of-change. By combining polar motion and polar motion-rate measurements according to the left-hand side of (36.27), GNSS allows direct measurements of the polar motion excitation functions to be made. These directly measured excitation functions can then be compared to models of, say, atmospheric and oceanic excitation to study the causes of the observed polar motion. Figure 36.8 shows a spectrum of the polar motion excitation functions determined from the GNSS-observed polar motion and polar motion-rate measurements. Like the changes in the length of the day, a number of different dynamical Earth processes are responsible for exciting polar motion. Because the tidal potential is symmetric about the polar axis, tidal deformations of the solid Earth do not cause it to wobble. But because ocean basins are asymmetrically distributed about the Earth, ocean tides do cause the Earth to wobble and small peaks at the fortnightly tidal frequencies are clearly evident in Fig. 36.8.

The annual wobble is a forced motion of the Earth that has been shown to be largely caused by the annual appearance of a high atmospheric pressure system over Siberia every winter [36.63]. This Siberian high-pressure system annually loads the Siberian crust, causing the Earth to wobble with an annual period. The Chandler wobble on the other hand is not a forced motion of the Earth, but is instead a free resonant motion of the Earth that occurs because the Earth is not rotating about its figure axis, the axis about which the Earth's mass is balanced. The Chandler wobble would freely decay with an exponential time constant of about 68 y if no mechanism or mechanisms were acting to excite it. Using atmospheric and oceanic general circulation models, it has been shown that the sum of atmospheric surface pressure and ocean-bottom pressure variations are the primary source of excitation of the Chandler wobble, with ocean-bottom pressure variations being about twice as effective as atmospheric pressure variations over land. On the longest timescales, the trend in the pole path has been shown to be caused by a combination of the viscoelastic response of the Earth to past changes in ice sheet mass and the elastic response of the Earth to present-day changes [36.72]; see [36.67] for a review of these and other causes of polar motion.

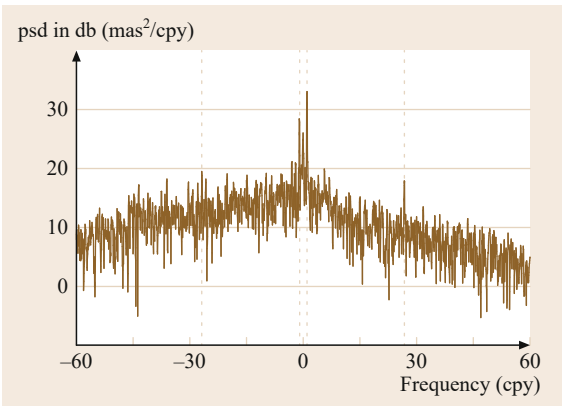

**Fig. 36.8** Power spectral density (psd) estimates in decibels (db) computed by the multitaper method of the polar motion excitation functions $\chi(t)$ spanning July 1996 to June 2014 formed by using (36.27) to combine the IGS final combined polar motion and polar-motion-rate measurements. *Vertical dashed lines* indicate the prograde and retrograde frequencies of the annual excitation ($\pm 1$ cycle/y (cpy)) and of the fortnightly tidal term ($\pm 27$ cpy). The retrograde component of polar motion excitation is represented by negative frequencies, the prograde component by positive frequencies

## 36.3.4 Nutation

Because of their great distance, the radio reference sources observed by VLBI exhibit negligible motion in the sky and can therefore be used to realize an inertial, celestial reference frame. This allows VLBI to determine all five of the Earth orientation parameters that are conventionally used to fully characterize the orientation of the Earth in space, including the two nutation parameters. But because the large nongravitational forces acting on artificial Earth-orbiting satellites cannot be accurately modeled [36.54], the orbits of satellites cannot be used to realize an inertial reference frame. Thus satellite techniques like GNSS can determine only a subset of the five EOPs. In particular, because of correlations between satellite orbital elements and both UT1 and the two nutation parameters, these Earth orientation parameters cannot be determined by satellite techniques like GNSS. However, their rate-of-change can be determined.

The rate-of-change of UT1, or length-of-day (36.24), was first routinely estimated from GPS data in June 1992 by the Center for Orbit Determination in Europe (CODE) analysis center. In [36.73] it was subsequently argued that there was no fundamental difference between estimating rates in UT1 and rates in nutation and that consequently GNSS should also be able to measure the rate-of-change of nutation.

They showed that the uncertainty in GNSS-measured nutation rates should grow linearly with the period of the nutation term and that GNSS should therefore be able to measure the rates of nutation terms having short periods. Using 3.5 y of GNSS data they were able to estimate the rates of 34 nutation terms having periods between four and 16 d.

# 37. Geodynamics

Jeff Freymueller

Geodynamic studies rely on measurement of motions over time, such as displacements, displacement time series, or velocities for those sites that move steadily with time. Global navigation satellite systems (GNSSs) are widely used for geodynamics research, including studies of tectonic plate motions and plate boundary deformation, earthquakes and seismology, volcano deformation, surface loading deformation, and glacial isostatic adjustment. GNSS is an ideal tool for these studies because it can provide time series of millimeter-precision positions using inexpensive, portable and easily deployed equipment. This chapter illustrates and summarizes the important concepts and the basic computational models used to relate active processes within the Earth to surface deformation that can be observed using GNSS. These include conceptual models for the earthquake cycle, elastic dislocation theory, the Mogi volcanic source model, and surface loading computations. The chapter also summarizes important research results in all of these topics. Rapid and real-time applications of GNSS to use surface deformation for earthquake and tsunami warning are growing, and are likely to become even more important in the future, as will multi-GNSS observations to provide greater measurement accuracy.

## 37.1 GNSS for Geodynamics

The use of geodetic positioning to study tectonic movements began nearly a century before the global navigation satellite system (GNSS) era (see [37.1] for a description), and most of the models at the core of tectonic geodesy were developed or proposed during the pre-GNSS era. The earliest studies were for displacements caused by large earthquakes, which were the only tectonic motions large enough to be observed at that time. Displacements measured from repeat triangulation before and after the 1906 San Francisco earthquake were the basis for the elastic rebound hypothesis [37.2, 3], and supported *Gilbert*'s proposal that earthquakes were the result of a sudden release of strain that was built up over a long period of time [37.4]. This century-old finding remains at the core of our understanding of the relation between tectonics and earthquakes.

The earliest GNSS studies in the 1980s were carried out in an environment in which modern space geodesy had just demonstrated its full range of capabilities, although not yet its present level of accuracy. The computational tools needed to apply surface deformation to tectonic, volcanic, and other studies already existed. All that was needed was a measurement tool that could provide spatially and temporally dense measurements of surface deformation. That was provided by the first GNSS system, the global positioning system (GPS). This chapter describes how a variety of geodynamic problems can be studied using GNSS-derived displacements and velocities, and introduces the key interpretive concepts and models.

Today, data from thousands of GNSS stations are used by researchers around the world (Fig. 37.1). High-accuracy satellite orbits are available from the International GNSS Service (IGS, Chap. 33), and the stations that contribute to the IGS tracking network form a reference network that any researcher can use to determine station positions in the International Terrestrial Reference Frame (ITRF) (Chap. 36; [37.5]). Modern studies on tectonic geodesy are based on displacements or velocities derived from time series of site positions expressed in the ITRF, on regional to global scales.

The numerical tools used to relate motion and deformation of points on the surface to plate motions, fault slip, volcanic inflation, and changing surface loads are not specific to GNSS. In that sense, the specific measurement tool is not unique, and displacements or velocities measured by very long baseline interferometry (VLBI), satellite laser ranging (SLR), GNSS or terrestrial techniques can be used interchangeably as long as measurement uncertainties are well known. However, GNSS is the critical space geodetic technique for geodynamic studies because the instrumentation is portable, inexpensive, and easy to operate, allowing GNSS networks to be deployed at a scope and on a scale that would be impossible for other geodetic techniques. Both spatial density of measurements and measurement accuracy are critical for the application of GNSS to geodynamics.

Geodynamic studies using GNSS can be grouped into several broad categories, each detailed in a section of this chapter:

- Rigid plate motion (Sect. 37.3)
- Plate boundary deformation (Sect. 37.4)
- Earthquakes and seismology (Sect. 37.5)
- Volcano deformation (Sect. 37.6)
- Surface loading deformation including glacial isostatic adjustment (GIA) (Sect. 37.7).

In each case, the development of GNSS over the last three decades has revolutionized our view of these topics. Models that allow us to relate these geodetic measurements to the causes of deformation are just as important as the measurements themselves. While mathematical derivations of the deformation models are beyond the scope of this handbook, this chapter provides references and recommendations for further reading on each topic. Derivations and detailed exploration of many of the physical models used here are provided in [37.6].

### 37.1.1 Accuracy Requirements

GNSS accuracy requirements for geodynamic studies depend on the expected magnitude of the displacements or rates of motion, so the types of geodynamic problems addressed by the community have expanded as the accuracy of GNSS measurements has improved. Study of the displacements caused by large earthquakes (displacements of decimeters to meters) long predated the development of GNSS, and measurement of the relative motions of the major tectonic plates (velocities of centimeters per year) was within the reach of 1980s VLBI and SLR, and the earliest GNSS studies. Many current studies focus on problems involving displacements of millimeters or velocities of millimeters per year, which were too small to measure accurately early in the GNSS era. We can expect that future improvements in GNSS accuracy will continue to open up new doors for studying geodynamic phenomena.

For many geodynamic problems, relative position accuracy is the most relevant requirement. Consider the case of a single isolated and very long fault (a fault is a fracture surface within the Earth that experiences relative motion across it; faults are often approximately

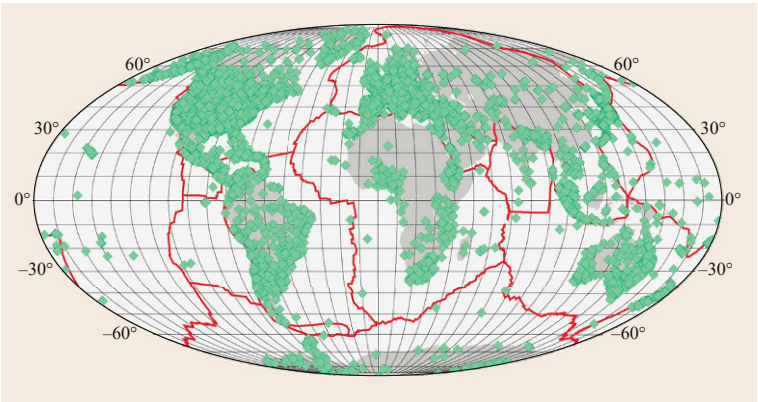

**Fig. 37.1** A compilation of global continuous GNSS sites, as of 2014. *Diamonds* indicate locations of continuous GNSS sites for which data are nominally available (some countries restrict access to data from their GPS sites for legal reasons)

planar over local scales). What is most relevant for this problem is the motion of one side of the fault relative to the other. It is this relative motion that creates geologic structure and offsets, and the displacement or slip rate of the fault can be derived from a series of relative position measurements. The absolute position or motion in a geocentric frame is not strictly needed to address this problem, which is why significant advances were made in the pre-GNSS era. The accuracy required depends on the rate of motion across the fault. Ideally, the relative velocities of GNSS sites (within the local network) should be determined with a precision equal to a few percent of the fault slip rate, but useful information can still be gleaned from measurements with a lower signal-to-noise ratio (SNR).

When larger regions are considered, then the importance of a stable geocentric reference frame increases. All tectonic motions (at any scale) can be described by rotations about a geocentric axis; locally, they may be approximated in terms of linear velocities. For such studies, a stable external reference frame such as ITRF makes it possible to separate local-scale rotations and motions from large-scale rotations. For tectonic studies, displacements or velocities and their uncertainties are frequently displayed in a plate-fixed frame derived by subtracting a rigid body rotation from ITRF so that they represent motions relative to a certain stable tectonic plate.

### 37.1.2 Today's GNSS Accuracy

The distinction between the accuracy of relative positions/velocities and absolute geocentric positions/velocities is important because the accuracy of GNSS in these two modes is quite different. We can measure relative motions much more precisely than we can relate them to a geocentric reference frame. Analysis of continuous GNSS sites within tens or hundreds of meters of each other using a baseline solution approach has demonstrated that relative velocities between two GNSS antennas can be measured to within a small fraction of 1 mm/yr, potentially $\approx 0.1$ mm/yr [37.7]. *Bennett* et al. [37.8] argued that relative velocity accuracy at the submillimeter per year level could be achieved over regions of several 100 km in size. The limiting potential velocity accuracy at larger scales and absolute velocity accuracy depend on two factors: the intrinsic accuracy and long-term stability of the ITRF, and the error in accessing the ITRF (the error for the user to express their solution in the ITRF). The first error is presently on the order of 0.5 mm/yr for velocities, and is discussed in more detail in Chap. 36. One of the principal objectives of the International Association of Geodesy's Global Geodetic Observing System (GGOS) project is to improve the accuracy and long-term stability of the ITRF to the level of 1 mm for positions and 0.1 mm/yr for velocities. The error in accessing the ITRF depends on the number of ITRF reference stations used by the user and the choice of reference stations, and is not easy to quantify in general. Overall, the realistic accuracy of station velocities globally probably remains at the level of $\approx 1$ mm/yr.

The precision and accuracy of site velocities estimated from GNSS time series depends on the noise characteristics of the GNSS positions. Many studies have demonstrated that GNSS positioning errors are correlated in time. Thus, estimates of site velocities or displacements (and especially their uncertainties) need to account for these time correlations either through a correlated noise model or empirical variance scaling. Assuming that each day's position errors are uncorrelated, white noise leads to over-optimistic uncertainties in displacements and especially velocities. The impact on velocities is particularly important because the error spectrum includes components that are correlated over a long time period.

The most robust estimates of the continuous GNSS position noise spectrum come from studies that use

a maximum likelihood estimate (MLE) method to fit an error model to the time series. One drawback of this approach is that it is very time consuming for long time series, but *Bos* et al. [37.9] have developed a fast method that well approximates the full MLE estimation, and is not sensitive to gaps in the data. *Hackl* et al. [37.10] and *Santamaría-Gómez* et al. [37.11] developed empirical approximations to the noise model. All of these studies found that the noise in GNSS time series can be described as a combination of white noise and flicker noise, which is a power law noise with power proportional to $f^{-1}$, where $f$ is frequency. Assuming measurements were sampled evenly in time (e.g., daily or weekly), if the noise in the time series was purely white noise, the velocity standard deviation would decrease approximately as $(1/T^{3/2})$, where $T$ is the duration of the time series. The impact of the time correlations is that the actual uncertainty (standard deviation) in the velocities decreases approximately as $(1/T)$. *Santamaría-Gómez* et al. [37.11] presented empirical relations for the velocity uncertainty based on their noise model. Based on these studies, site velocities can be as precise as $\approx 0.1$ mm/yr for the horizontal and $\approx 0.3$–$0.5$ mm/yr for the vertical; velocity accuracy, however, depends on the accuracy of the orientation and frame origin of the ITRF reference frame, the details of how the user accesses the ITRF, and on the magnitude of any slowly varying systematic errors in the GNSS positions.

Today's GNSS accuracy is sufficient for the study of the problems emphasized in this chapter, although the present SNR ratio can be too low for small or slow signals, such as slow-moving faults or small volcanic intrusions. GNSS random errors and periodic systematic errors remain significant compared to the size of many loading signals. Transient deformation signals of all sizes have been identified over the last decade or so, and other instrumentation demonstrates that there are transients that produce deformation too small to resolve with the present GNSS accuracy level. It is likely that smaller and smaller geodynamic signals will be amenable to study as GNSS accuracy continues to improve.

Accuracy of real-time (within seconds) or near real-time (within minutes) GNSS positioning lags well behind the accuracy of post-processed positions. This is due to two main factors:

- The lower quality of real-time orbit and clock products needed for GNSS positioning.
- The difference in positioning accuracy between epoch-wise kinematic positions and static daily positions.

The gap in quality of products is closing, and that trend is likely to continue. The difference between epoch-wise kinematic and daily positions remains large. However, the error spectrum for kinematic positions is complex due to the effects of multipath and other errors that cannot be averaged in time, and different kinematic and real-time geodynamic applications require accuracy of ground motions at different frequency bands. Some applications are sensitive to the error at periods of one to a few epochs (e.g., time-dependent coseismic slip inversions), while others are sensitive to error at a particular frequency (e.g., study of seismic surface waves). The desired sample rate depends on the intended scientific application for the data. For example, the estimation of earthquake rupture models is currently limited to frequencies below $\approx 1$ Hz because of limits in our ability to know the seismic velocity structure and calculate wave seismic waveforms. However, there is considerable information contained in seismic waveforms in the range of 1–10 Hz, so GNSS recording to 10 Hz could have considerable scientific value. This will be discussed in more detail for the problem of earthquake ground motions in Sect. 37.5.2.

### 37.1.3 Accuracy Limitations and Error Sources

Accuracy limitations on geodynamic studies using GNSS include the accuracy and self-consistency of the ITRF and the extent to which ITRF represents a truly geocentric frame. The ITRF is discussed in detail in Chap. 36, and only a brief summary will be presented here. The ITRF is designed to be a geocentric frame with its origin at the center of mass (CM) of the Earth system (CM frame). ITRF is a secular frame by design, and is parameterized in terms of a piecewise linear model for site position as a function of time. In terms of velocities, its present level of accuracy is thought to be $\approx 0.5$ mm/yr. Important limitations to the accuracy of ITRF, and thus of GNSS positions expressed in ITRF, include the remaining systematic errors in the various space geodetic techniques, the number of co-location sites between multiple space geodetic techniques, the small number and limited accuracy of survey ties between techniques at the co-location stations, the observing site geometry of some other techniques (notably SLR), and unmodeled position offsets in the time series due to earthquakes or equipment changes. Earthquakes that occur after the definition of a given ITRF may cause displacements or nonlinear motions at certain sites, which make the ITRF positions for those sites inaccurate after such events.

The biggest question about the ITRF for geodynamic studies is how well the frame origin accurately reflects the geocenter. The frame origin of ITRF on

secular timescales is intended to be the CM of the entire Earth system, including fluids, and is thus termed a CM frame. Some geophysical models are computed in a frame with origin at the center of mass of the solid Earth (CE). The geometric center of the Earth can also be defined in terms of the center of figure of the Earth surface (CF). See [37.12] for a full description of different frames. The centroid of a sufficiently dense geodetic network should be a reasonable approximation of CF, which makes it relatively simple to define a CF frame on any timescale. Rigorous definition of a CM frame on nonsecular timescales requires detailed knowledge of the redistribution of mass within the Earth and on its surface. *Dong* et al. [37.12] argued that the current ITRF frame origin reflects CM on secular timescales, but CF on seasonal or shorter timescales. The ITRF is realized using geodetic observations and datum constraints, and thus might deviate from an ideal secular CM frame due to measurement errors, incorrect assumptions in the datum constraints, or weakness in the observing geometry of SLR (SLR defines the frame origin).

There is no universal agreement about the magnitude of any frame origin error or its cause, but several studies have made estimates of or estimated bounds on the size of potential biases. These studies agree that the largest component of any bias is likely to be in the $T_z$ translation rate (along the spin axis). Studies using GNSS data and an assumption of rigid motions of plate interiors estimate the size of the $T_z$ frame origin bias (rate) for ITRF2008 to be in the range of 0.5–1.1 mm/yr [37.13, 14]. *Wu* et al. [37.15] estimated a smaller bound on the $T_z$ frame origin bias, 0.5 mm/yr, using a combination of surface velocities, GRACE and ocean bottom pressure data. The sign of the estimated $T_z$ bias is consistent across all recent studies; this suggests that the ITRF2008 frame origin may have a small negative $T_z$ rate bias (meaning that $z$ velocities in ITRF are too large). However, the estimated uncertainty of the $T_z$ bias ranges from 0.1 to 1 mm/yr in different studies, so the significance of these findings remains under investigation.

Frame origin biases impact geodynamic studies in direct and indirect ways. A nonzero frame origin bias will bias estimates of plate motion and will induce apparent internal deformation of the plates. It affects vertical velocities and quantities derived from those, and uncertainty in the frame accuracy is a major limitation in the use of GNSS data for studying small signals like sea level change.

In addition, systematic errors still remain in the GNSS position time series. Some residual systematic errors result from inadequate modeling of tropospheric path delays or other models removed from the data (ionosphere, tidal loading, etc.). These residual errors vary likely on a day-to-day or week-to-week basis, and add short-term noise to the position time series. Prominent periodic systematic errors are found at the draconitic frequency of $1.04\,\mathrm{yr}^{-1}$ (and its overtones), which corresponds to the period needed for a repeat of the position of the Sun relative to the GPS orbital nodes, $\approx 351$ d [37.16]. Draconitic harmonic errors are present in current IGS GPS products and time series [37.11, 17]. Their period has led to speculation that solar radiation pressure models may be responsible for these errors, and [37.18] demonstrated that draconitic periodic errors are substantially reduced when improved solar radiation pressure models are used. *Griffiths* and *Ray* [37.19] showed that errors at that period also could be caused by errors in subdaily Earth orientation parameter (EOP) models, and *King* and *Watson* [37.20] demonstrated that multipath also can cause spurious periodic signals aliased to the same frequencies. *Amiri-Simkooei* [37.21] estimated mean amplitudes for the draconitic variations (1.4, 1.3, 2.8 mm, respectively) for north, east and up, although this estimate could be affected by leakage from the nearby annual period. *Zou* et al. [37.22] argued that the amplitude is likely to be smaller, closer to $\approx 1$ mm/yr, based on agreement of GPS and GRACE seasonal variations. The draconitic errors have only a minor impact on the estimation of site displacements or velocities, but must be considered when interpreting seasonal periodic deformation, for example, from seasonal surface loading.

## 37.2 History and Establishment of GNSS Networks for Geodynamics

### 37.2.1 Campaign GPS Networks

It first became possible to use GPS for positioning in the early 1980s, once four or more satellites could be tracked simultaneously. The initial test phase of the GPS satellite constellation was optimized to maximize the time for which four satellites were visible over the southwestern United States, using the first seven operational satellites. GPS measurement campaigns for geodynamic studies began soon after, with measurements in California and in Iceland beginning by 1985. Measurement campaigns had spread worldwide by the end of the 1980s, despite the still-incomplete satellite constellation. GPS campaigns were integrated into the

European WEGENER (Working Group of European Geoscientists for the Establishment of Networks for Earth-Science Research) project beginning in the late 1980s, first focused on the Eastern Mediterranean and later extended to the whole of Europe [37.23]. GPS campaigns spanning most of Europe were organized beginning in 1989 by the EUREF project for a combination of geodetic and geodynamic objectives [37.24].

Campaign networks refer to networks of survey points that are measured episodically using GNSS instruments (Fig. 37.2). Although some campaign networks covered large areas, most tend to be spatially dense and limited in total extent, with ≈ 10–100 measurement points spaced kilometers to tens of kilometers apart. In the 1980s and 1990, it was common to occupy each site for five consecutive days or more, although with improvements in GNSS accuracy it has become more common for each survey to occupy a site for 2–3 days, or sometimes only one. Repeat surveys for such networks are commonly on a yearly or once every few years basis.

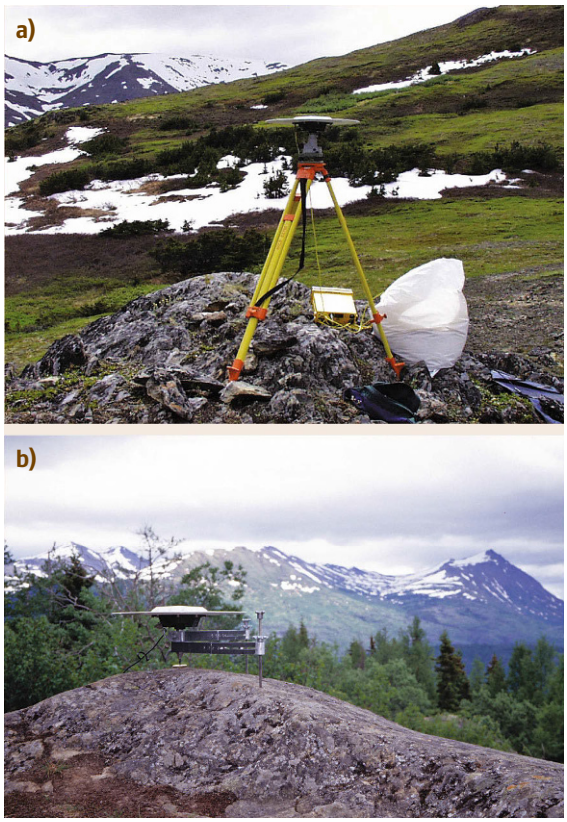

**Fig. 37.2a,b** Two examples of campaign GNSS sites, both from Alaska (USA). **(a)** A site setup on a tripod, with a Trimble 4000 SSE receiver and TRM22020.00+GP antenna, and a plastic bag to keep the receiver dry while deployed. **(b)** A site using the same type of antenna setup on a spike mount, a ≈ 13 cm high centering device (courtesy of Jeff Freymueller)

The early 1990s mark the beginning of the modern era of GPS campaigns. Today, many groups maintain processed time series of GPS/GNSS data extending back to 1991 or 1992, while most of the data from the past are no longer used. The dividing line in time is determined by the development of a global tracking network sufficient to determine satellite orbits (and clock delay parameters) worldwide. The first dense and truly global network was deployed in January–February 1991 in the GIG 1991 campaign [37.25], and this was followed in the summer of 1992 by the IGS epoch 1992 campaign (Fig. 37.3). These temporary global campaigns, which involved the cooperation of numerous research groups and agencies worldwide, demonstrated the need for a permanent global network, which quickly led the way to the development of the IGS network (Fig. 37.3c) using a similar cooperative model [37.26].

Today, campaign GNSS surveys continue to be used to make measurements at high spatial density, often as a supplement to or densification of continuous networks. The advantage of this approach is that a large number of sites can be measured over a short time and for a very low cost compared to continuous GNSS installations. The main disadvantage is that these measurements are sparse in time, which means that time-varying signals are difficult or impossible to resolve. Campaign networks can also be prone to setup errors, and because equipment used at each site often changes, there can be additional systematic biases on each survey. Nevertheless, many important scientific results have been derived from such data. Campaign measurements often provide crucial information after large earthquakes, because in addition to measurements made by scientists, land surveyors have surveyed a large number of survey markers; re-measurement of these points can provide extremely dense earthquake displacement fields [37.27, 28].

### 37.2.2 Continuous GNSS Networks for Geodynamics

The first regional continuous GNSS networks for geodynamics began to develop in 1990. In southern California, the permanent GPS geodynamic array (PGGA) began with the deployment of four stations starting in early 1990 and expanded to nine sites over the next few years (Fig. 37.4). A small continuous GPS network with ≈ 1000 km spacing was established across Japan at about the same time [37.29]. These networks were established with the primary goal of measur-

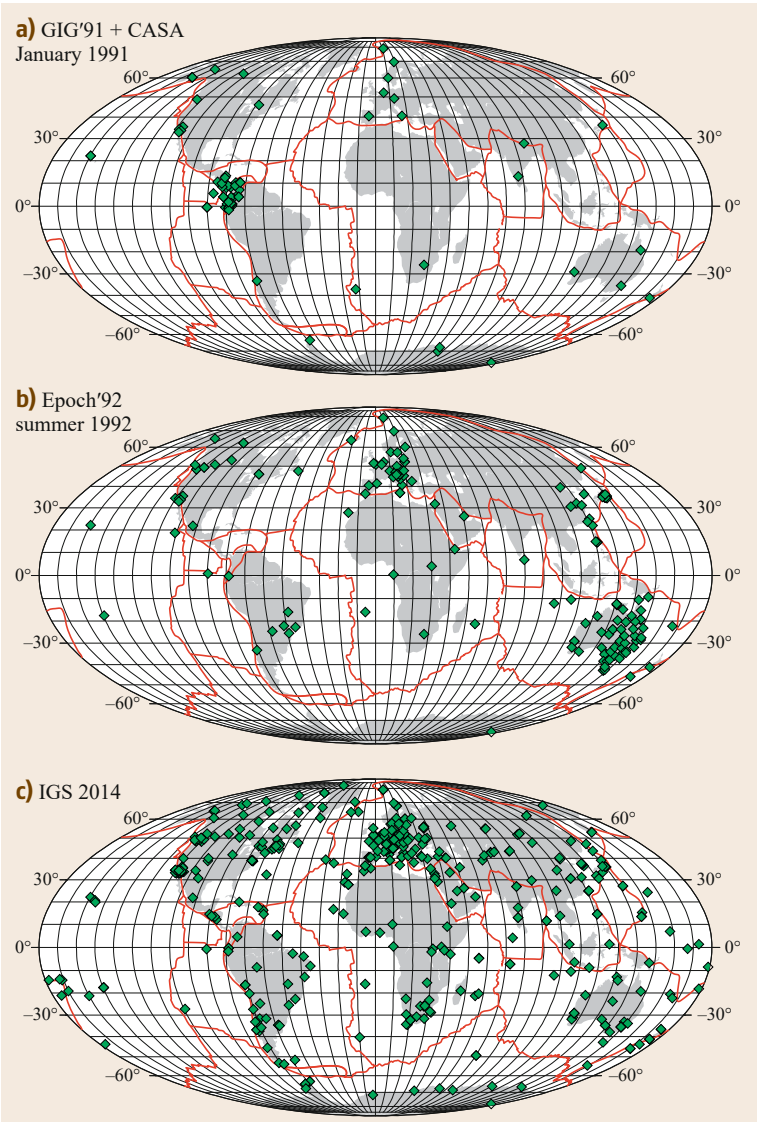

**Fig. 37.3a–c** Development of the global tracking network, with sites indicated by *diamonds*. **(a)** Temporary network setup for the GIG+CASA91 campaign, January–February 1991, **(b)** temporary global network for the IGS Epoch 1992 campaign, summer 1992, **(c)** IGS network as of 2014

ing deformation related to tectonic processes, rather than for purely geodetic objectives such as mapping, datum, or reference frame definition. Shortly afterward, in 1993, the BIFROST (Baseline Inferences from Fennoscandian Rebound Observations, Sealevel, and Tectonics) project established a continuous network in Scandinavia for studying GIA [37.30, 31]. These early networks successfully demonstrated the possibility and utility of measuring deformation on a daily basis. Although it may seem remarkable today, at the time the big question was whether it would be possible to process so much data on a daily basis!

The June 30, 1992 Landers earthquake in California demonstrated the power of continuous observations. Earthquake displacements were determined from the continuous data within several days after the earthquake, rapid work for the time, and the continuous stations provided some of the first precise records of postseismic transient deformation following a large earthquake [37.32, 33]. The existence of the continuous network also provided a critical backbone for campaign studies of the coseismic and postseismic deformation [37.34, 35]. This prompted additional densification of the continuous GNSS network in both southern and northern California.

Two damaging earthquakes in 1994 and 1995 provided the impetus for a dramatic expansion of continuous GNSS networks for geodynamic studies (Figs. 37.4

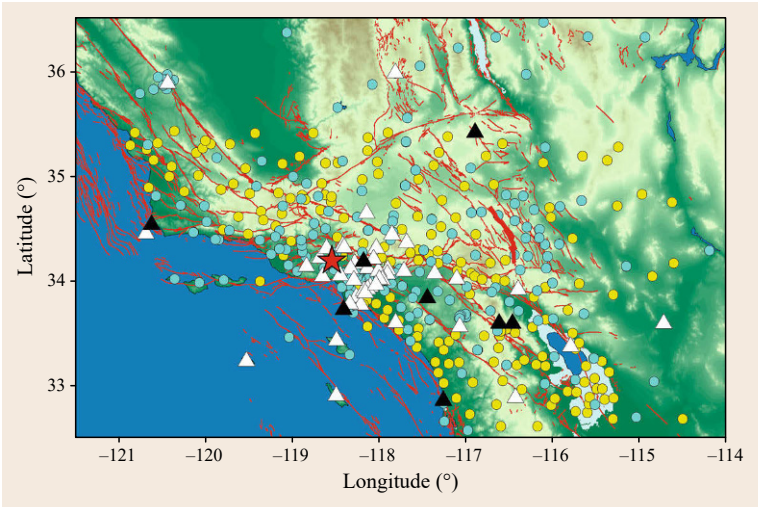

**Fig. 37.4** Development of the SCIGN network in southern California, USA. *Black triangles* are the PGGA sites as of January 1994, the time of the Northridge earthquake. *White triangles* show the additional sites added after that event. *Yellow circles* show the additional sites of the SCIGN network (built 1997–2002), and *blue circles* show sites added after completion of the SCIGN network. *Thin red lines* are active faults. The *thick red line* is the rupture zone of the 1992 Landers earthquake, and the *red star* shows the location of the Northridge earthquake

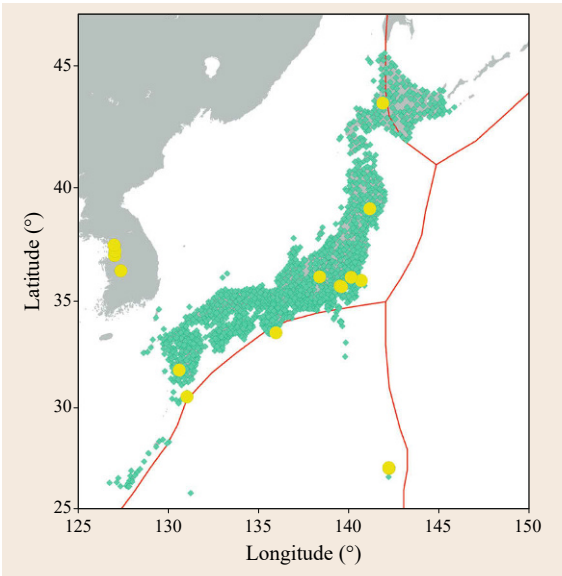

**Fig. 37.5** The GEONET GNSS network in Japan. GEONET sites are shown by *green diamonds*. Sites from Japan and Korea that are contributed to the IGS network (Fig. 37.3c) are shown by *large yellow circles*. *Red lines* show a simplified view of the major plate boundaries (Japan is a region of complex deformation)

and 37.5). The Northridge earthquake on 17 January 1994 was a magnitude 6.7 earthquake that struck suburban Los Angeles, CA, USA. It killed 57 people, injured more than 5000, and caused more than $20 billion of economic damage. The earthquake spurred an expansion of the PGGA to ≈ 57 stations within 2 years of the earthquake and later to ≈ 250 stations (as the southern California integrated GPS network or SCIGN) [37.36]. SCIGN was followed by the plate boundary observatory (PBO) network, which spanned the entire deforming zone of the western United States [37.36], comprising ≈ 1100 stations GNSS stations including about half of the former SCIGN network, and further densification in California as part of the California real time network (Fig. 37.4).

Exactly 1 year after Northridge, the devastating Kobe (or great Hanshin) earthquake struck in Japan. This magnitude 7.3 earthquake killed more than 6000 people and caused approximately $100 billion (10 trillion yen) in damage. In response, the Japanese government deployed the ≈ 1000 station GEONET GNSS network [37.37] across the entire country within roughly a year (Fig. 37.5). Today there are ≈ 1200 GEONET stations in Japan operated by the Geospatial Information Authority of Japan (GSI), plus several hundreds GNSS stations operated by universities or other agencies. GEONET was revolutionary in that it provided for the first time dense continuous GNSS data spanning an entire complex plate boundary. GEONET data have revealed not only steady strain within the plate boundary zone, but also a wide variety of transient deformation signals, seasonal deformation due to surface loading, and deformation due to a large number of earthquakes, including the magnitude 9.0 Great East Japan earthquake of March 2011.

Similar networks now exist across much of the world, amounting to many thousands of GNSS stations. As of January 2014, processed time series for more than 12 000 stations where, for example, provided by the Nevada Geodetic Laboratory of the University of Nevada Reno (Fig. 37.1).

### 37.2.3 The Importance of Global Networks

A cooperative global network was developed in parallel to these regional networks under the auspices of the IGS (Chap. 33). The IGS was originally named the *International GPS Service for Geodynamics*, and is presently called the *International GNSS Service (IGS)*. The name changes reflect both the development of other GNSS systems and the broadening of the applications of the IGS beyond geodynamic studies. The IGS network is an essential utility that enables global GNSS geodesy and is the backbone for the ITRF.

The global IGS network (Fig. 37.3c) is the glue that holds together regional networks and provides the orbit and clock products that are needed to analyze the wealth of global GNSS data. The IGS network expanded rapidly over 1992–1994 and slowly but steadily since then. Today, IGS analysis centers use as many as several hundred GNSS sites in their solutions to produce the best possible orbit and clock products, as well as a daily IGS combined network position solution that is the basis for the GNSS contribution to the ITRF. Researchers around the world use subsets of the IGS network to connect their own data to a global reference system; it functions as a global geodetic backbone to which all other data are attached.

## 37.3 Rigid Plate Motions

Plate tectonic theory developed in the 1960s and revolutionized our thinking about the Earth. The classic theory posits that Earth's crust is divided into a set of plates that move relative to each other, that each plate is rigid, and that all deformation occurs within narrow zones at the plate boundaries. The last of these postulates has been substantially modified with the recognition that plate boundary zones can be very broad, spanning up to $\approx 1000$ km in the continents.

The motion of a rigid plate on the surface of a sphere is a rotation about a geocentric axis, and can be described by an angular velocity vector. Relative plate motions, or the motions between a pairs of plates, are also described by a rotation about a geocentric axis, and thus by an angular velocity vector. Plate motions can be estimated by determining the set of plate angular velocities in ITRF [37.5, 38], or the set of relative plate angular velocities [37.13]. The geodetic reference frame origin must be coincident with the geocenter for this description to be accurate, and [37.13] also estimated a frame origin bias in ITRF along with the plate motions.

The earliest plate models estimated from the last few million years of geologic data featured a small number of major plates (10–20). Today the number of major and minor plates is reckoned to be several times larger. Detailed models of broad deforming areas such as western North America suggest that plate tectonic-like models may apply even down to the scale of blocks with dimensions of tens of kilometers [37.39]. A further discussion of plate boundary zones appears in the next section.

Chemically, the Earth is divided into three main layers that are chemically distinct, the crust, mantle, and core. However, the boundaries in mechanical properties of the Earth do not coincide with the chemical composition boundaries. The moving plates define the lithosphere, which includes the crust and a portion of the mantle (Fig. 37.6). The plates move over the asthenosphere, which is hotter and more hydrated than the mantle lithosphere. In the simplest description, the lithosphere behaves as an elastic material while the asthenosphere is viscoelastic, which means that over very long times it behaves as a fluid. The entire mantle is viscoelastic, but the viscosity of the asthenosphere is lower than that of the deeper parts of the mantle; this allows plates to move relatively easily. The asthenosphere is likely more hydrated than the rest of the mantle, explaining its relative weakness. The existence of broad plate boundary zones indicates that the lithosphere is not perfectly elastic, but does accumulates some permanent deformation. Nevertheless, there remains a very large contrast in properties between lithosphere and asthenosphere, and over the timescales of geodetic measurements we can usually apply the simple mechanical model of elastic lithosphere over viscoelastic asthenosphere. The thickness of the lithosphere varies considerably, from $\approx 50$ km within areas of active or recent tectonic deformation to $> 100$ km in stable continental interiors.

Given the angular velocity of a plate, the horizontal velocity $\boldsymbol{v}$ of a geodetic site fixed to the crust (Fig. 37.7) is the vector cross product of the plate angular velocity $\boldsymbol{\omega}$ and the geocentric site position $\boldsymbol{r}$

$$\boldsymbol{v} = \boldsymbol{\omega} \times \boldsymbol{r} \,. \tag{37.1}$$

Although there are three components to the vector $\boldsymbol{v}$, when it is expressed in the local east–north-up coordinate system defined at the site, the up component

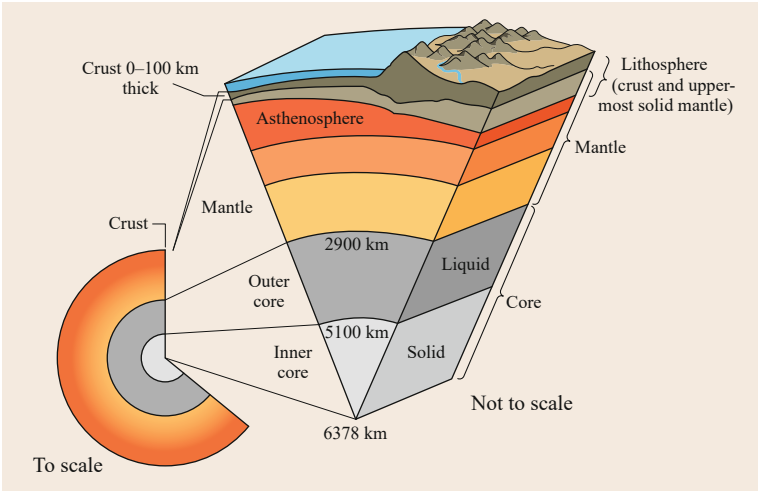

**Fig. 37.6** A depth section of the Earth, showing both chemical (crust, mantle, core) and mechanical layering (lithosphere, asthenosphere, mantle). The tectonic plates are pieces of the lithosphere, which consists of the crust and the coldest part of the uppermost mantle (courtesy of United States Geological Survey (USGS)/Wikimedia Commons)

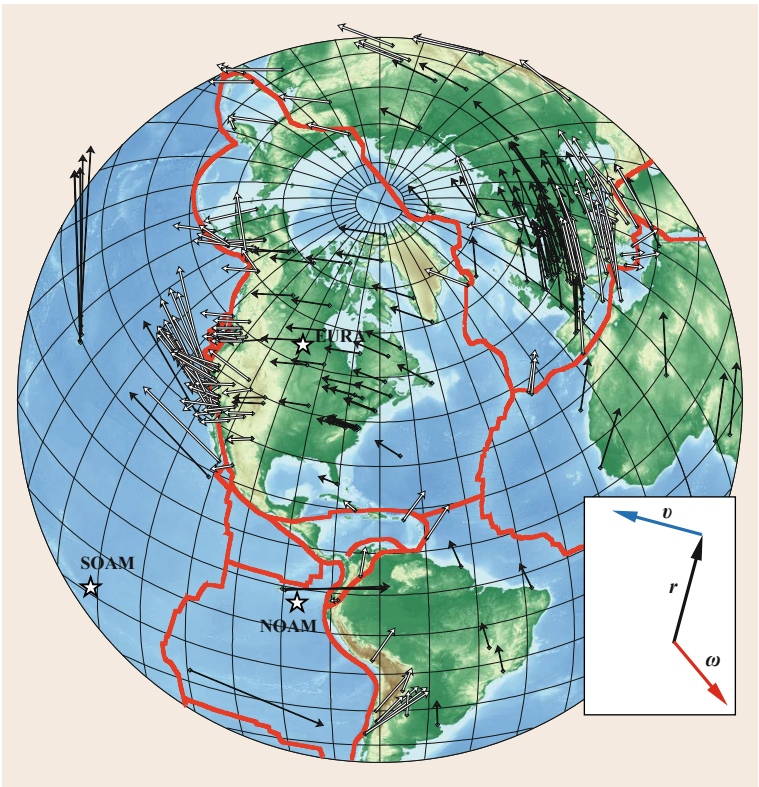

**Fig. 37.7** Rigid plate motions and plate boundary zones. GNSS velocities in ITRF are from [37.13]. *Black vectors* are sites located within stable plate interiors, and *white vectors* are sites within plate boundary zones. *Stars* indicate the poles of rotation for the north American (NOAM), South American (SOAM) and Eurasian (EURA) plates. The *inset* illustrates the geometry of the cross product used to compute plate motions from the plate angular velocity. The site velocity vector is placed at the location of the site (after [37.40])

$v_{up}$ is always zero. The simple plate tectonic model predicts that all motion is horizontal, and this approximation is good for the plate interiors, leaving aside isostatic effects. It is often convenient to describe the angular velocity in terms of a pole of rotation and angular rotation speed. The pole of rotation is the projection of the angular velocity vector onto the surface of the Earth. Given (37.1), the horizontal velocity vectors $\boldsymbol{v}_{\text{horiz}}$ will rotate about the pole (Fig. 37.7). The angular speed is simply the magnitude of the angular velocity vector $|\boldsymbol{\omega}|$. We can use (37.1) and the same angular velocity to describe the motion of rigid plates over geologic timescales (millions of years), and also over geodetic timescales (years). However, over geodetic timescales we also need to account for variations in deformation due to the behavior of faults

in the earthquake cycle, which will be addressed in Sect. 37.4.

It is much easier for us to visualize motions in terms of the linear velocity vector, rather than in terms of angular velocities. Over a small area, the motion of plates sometimes may be approximated by linear velocities. We can use (37.1) to evaluate the validity of this approximation, by computing the derivatives of the linear velocity $\boldsymbol{v}$ with respect to the angular velocity $\boldsymbol{\omega}$ and the position vector $\boldsymbol{r}$. When the pole of rotation is far from a given point, the velocity vectors change only slowly with changes in position $\boldsymbol{r}$, and the linear velocity can provide an accurate description of plate motions over a region of hundreds of kilometers in size. However, close to the pole of rotation velocities change significantly in magnitude and orientation over small distances.

Although the mathematical relation between plate angular velocities and geodetic site velocities is very simple, there are two main sources of complexity in defining a geodetic plate motion model. First, it must be recognized which sites are representative of the stable plate interior. This task can be challenging because plate boundary zones can be very broad so that the boundary of a stable plate may be drawn incorrectly, and because some plates undergo internal deformation on short timescales due to, for example, GIA. For example, the African continent was often described as a single plate in the past, despite the extension across the East African rift system, and has since been subdivided into at least two plates. Although small, the horizontal motions due to GIA (Sect. 37.7.5) from the deglaciation after last glacial maximum (LGM) within regions that are geologically stable over the long term are significant enough to bias estimates of plate motion for the North American plate [37.41] and parts of Eurasia. Second, the plate motion model assumes that the origin of the reference frame for velocities and the geocentric axis of plate motions is identical. If plate motions are truly horizontal, then the axis of rotation for plate motions should represent a center of figure (CF) coordinate system. ITRF is intended to represent a CM of Earth system coordinate system, and any velocity bias between the two systems will map into errors in the estimated plate motions as well as apparent internal deformation of the plates.

Dense velocity fields from GNSS can be used to test whether plate interiors are rigid. Most such studies have found that once regions of known tectonic activity or significant GIA signals have been masked out, the internal deformation of plate interiors is comparable to or smaller than the noise level in the GNSS velocities [37.13, 38, 42]. As the accuracy of GNSS velocities has improved, the upper limit on internal deformation of the plates has shrunk, with the most recent results suggesting plate rigidity to be within $\approx 0.3$–$0.4\,\mathrm{mm/yr}$ or smaller.

Until recently, geodetic estimates of plate motions [37.38, 43] could not distinguish any significant difference between plate motions today (measured with geodesy) and plate motions averaged over recent geological timescales (a few million years), for most plate pairs. However, *Argus* et al. [37.13] showed that the differences between geodetic and geologic estimates of plate motions are statistically significant given the high precision of today's measurements. This implies that changes in plate motions of a few to several percent have occurred over the last 3 million years, most notably the reduction in angular speed of the Nazca plate relative to South America [37.44]. Nevertheless, plate motions over the last few decades are similar to geologic estimates of plate motions.

## 37.4 Plate Boundary Deformation and the Earthquake Cycle

Although the original hypothesis of plate tectonics held that all plates were rigid and nondeforming, it was recognized from an early stage that in some areas seismicity and active tectonics were distributed across large areas, rather than being confined to narrow plate boundaries. These broad deforming regions are termed *plate boundary zones*, and are particularly common for plate boundaries involving continental crust [37.45]. Western North America and Eastern Asia are two examples of broad plate boundary zones (Fig. 37.8). Many active faults take up motion within these plate boundary zones.

The idea of an earthquake cycle is the key concept for relating geodesy to tectonics and earthquakes (see [37.47] for a full description). This concept derives from the hypotheses of Reid and Gilbert, combined with a modern understanding of plate tectonics and the frictional behavior of faults. Earthquake cycle models describe how a steady driving stress on a fault leads to a buildup of stress and strain, which will eventually result in sudden slip on the fault in an earthquake (Fig. 37.9). A basic premise of most earthquake cycle models is the hypothesis that the parts of the fault that slip during earthquakes are frictionally locked during most of the time between earthquakes. The shallow part of a fault may not slip at all for decades or centuries, and then slip a large amount suddenly in an earthquake.

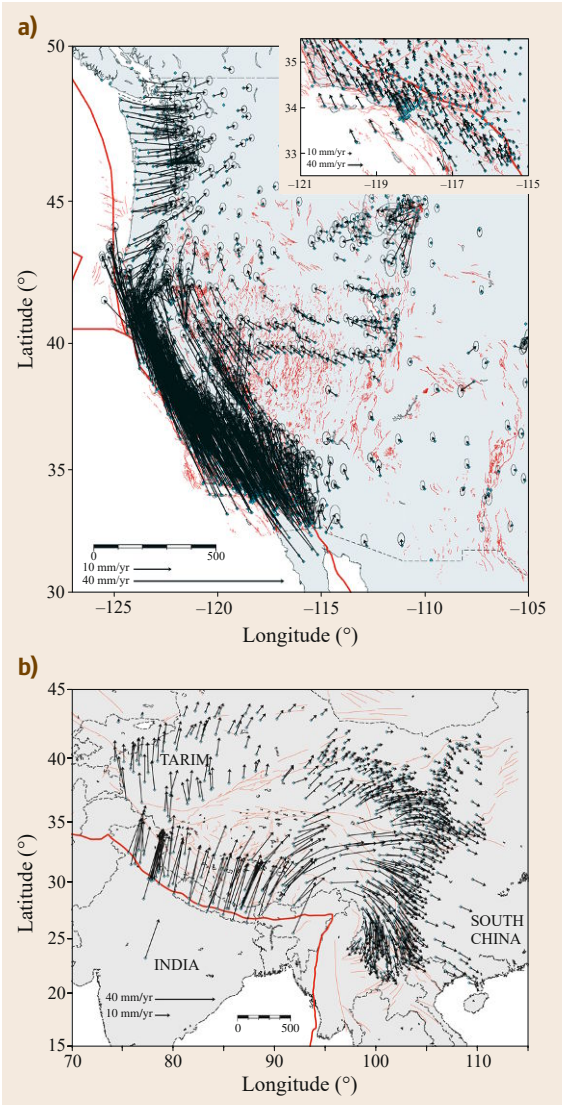

**Fig. 37.8a,b** Two examples of plate boundary deformation zones. **(a)** North America, showing velocities relative to the North American plate, from the University NAVSTAR Consortium (UNAVCO) PBO velocity solution. The *inset* shows details of the velocity field in southern California. **(b)** India–Eurasia, showing velocities relative to the Eurasian plate (after [37.46]). *Thin red lines* indicate active faults, and *thick red lines* show the major plate boundaries. (after [37.40])

Plate motions do not stop because shallow locked faults remain locked, so the variations in fault slip over the earthquake cycle result in deformation in the surrounding material.

Earthquake cycle models suggest that there are characteristic and complementary deformation patterns

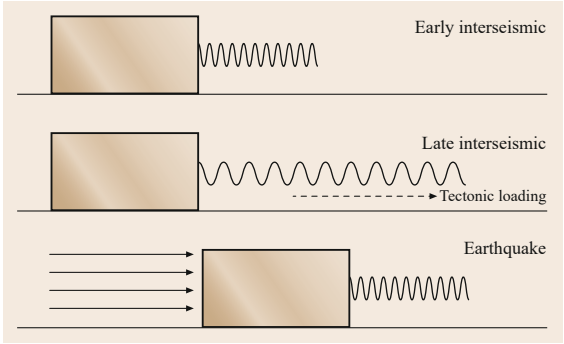

**Fig. 37.9** Conceptual sketch for the earthquake cycle, based on a one-dimensional spring slider. The fault is represented by a block frictionally coupled to the surface, and the force of friction resists motion. The spring represents the elastic medium surrounding the fault. Tectonic loading steadily and slowly extends the spring, but the block does not move as long as the elastic force exerted by the spring remains smaller than the frictional force. When the elastic force exceeds the frictional force, the block accelerates because the sliding friction is lower than the static friction; this motion also compresses the spring, which reduces the elastic force and causes the block to decelerate and then stop again

between earthquakes (the interseismic phase) and during earthquakes (the coseismic phase). *Savage* and *Burford* [37.48] proposed a simple interseismic deformation model for a strike slip fault, and *Savage* [37.49] proposed a similar model for interseismic deformation at subduction zones. Repeated geodetic measurements after large earthquakes demonstrated the existence of a transient postseismic phase of deformation, during which deformation is distinctly different from that observed before the earthquake [37.50, 51]. These basic models have held up remarkably well over the last few decades, as the amount and quality of deformation data has exploded due to the development of GNSS. The GNSS era has seen some elaboration on these basic models, and has revealed a number of new slow and transient slip phenomena, but largely has confirmed rather than altered the basic principles of these models.

### 37.4.1 Plate Boundary Zones

In a plate boundary zone between two plates, the cumulative deformation across the entire zone corresponds to the total relative plate motion. This deformation is generally accommodated by a slip on a network of active faults, and often there are large nondeforming blocks surrounded by regions of more intense deformation (the term *block* is used in several ways in the geological literature, but in this case it simply means

a piece of lithosphere that is rigid and nondeforming). These features most likely develop because of pre-existing variations in the strength of the lithosphere, such as variations in rock types, pre-existing faults from an earlier phase of deformation, and so on (the continental lithosphere is extremely heterogeneous). For example, in the case of Western North America, the Sierra Nevada-great valley (SNGV) block or microplate separates the strike-slip faulting of the San Andreas fault system on its western border from the largely extensional basin and range region to its east (Fig. 37.8a). The broad plate boundary zone in Eastern Asia includes the nondeforming south China and Tarim blocks (Fig. 37.8b). Both examples shown in Fig. 37.8 involve at least three major plates, and multiple smaller blocks whose long-term motion can be described in a similar way to that of rigid plate motions.

Ignoring deformation due to the earthquake cycle for the moment, the motion of any point within a plate boundary zone can be described using (37.1), where the angular velocity is now a function of space, $\boldsymbol{\omega}(\boldsymbol{r})$. Over most of the Earth's surface, the rigid plate–microplate description of (37.1) seems to apply until the size of the blocks approaches the thickness of the lithosphere, a few tens of kilometers, and perhaps down to even smaller length scales. See [37.45, 52] for a full discussion from this point of view.

If the entire surface can be represented by a set of rigid blocks or plates, then the angular velocity $\boldsymbol{\omega}(\boldsymbol{r})$ will be constant within each block or plate, and will have a discontinuity across each block boundary. Alternatively, the deformation of plate boundary zones can be described using a continuous deformation model. *Haines* and *Holt* [37.53] showed that displacements, strains, and rotations could all be described in terms of the spatially variable angular velocity $\boldsymbol{\omega}(\boldsymbol{r})$ and can be determined uniquely from this function and appropriate boundary conditions. They represented the continuous function $\boldsymbol{\omega}(\boldsymbol{r})$ using spline functions that pass through a set of grid points; this allows the continuous function to be approximated by a discrete set of values that can be estimated from GNSS site velocities. Their approach allows for simple integration of nongeodetic data such as seismic estimates of strain rate from time-averaged earthquake moment tensors or geologic fault slip rates.

### 37.4.2 Earthquake Cycle Deformation

Most permanent deformation in the shallow part of the crust occurs through slip on faults. Faults are fracture surfaces within the Earth on which the two sides have been displaced. Real faults have rough surfaces with *topography* over all length scales [37.54], but faults are often approximately planar, at least over local scales. With the exception of faults that are nearly vertical, the fault orientation generally changes slowly with depth. This section will deal with a simple geophysical approximation of a fault, in which minor deviations in fault geometry are ignored if they do not produce observable effects in surface deformation measured with GNSS. In this simple approach, we will assume that faults cut through the entire lithosphere, so that the relative motions of the two sides of the fault are taken up entirely through slip on the fault. Over a very long time (many earthquake cycles), the total slip on the fault at all depths must be equal, and this long-term average slip rate should correspond to the rate estimated by measuring long-term offsets of geological features.

Over shorter timescales, fault slip is not uniform in time or with depth. If all faults slipped at a steady rate equal to their long-term slip rate, then there would be essentially no shallow earthquakes. Earthquakes (Sect. 37.5) result from abrupt slip on faults. Large earthquakes within the continental crust rupture only a limited depth range, from at or near the surface to a lower limit that is usually no deeper than 10–20 km. Within this depth range, the frictional contact of the two sides of the fault is sufficient to prevent fault slip for long periods of time. However, the deeper parts of the fault continue to creep or shear steadily. This results in a steady buildup of elastic stress and strain in the surrounding material. Earthquakes result when the shear stress acting on the fault surface exceeds the force of friction and causes the fault to begin slipping (Fig. 37.9). For most Earth materials at the pressure and temperature conditions of the shallow crust, the initiation of fault slip causes the coefficient of friction of the fault surface to decrease, which leads to an acceleration of slip (an earthquake) and further reduction of the coefficient of friction. However, with increasing slip the elastic driving stresses are reduced, and when the driving stress drops below the frictional force again, the fault decelerates and then stops moving, and the earthquake stops. The buildup of stress and strain over time and the earthquakes that result from it are linked together as the earthquake cycle. See [37.47] for a more complete discussion of fault friction and its evolution through time, and the earthquake cycle.

Surface deformation observable by GNSS results from all phases of the earthquake cycle. Earthquakes and their effects, the coseismic phase of the earthquake cycle, are described in Sect. 37.5. The period between earthquakes is termed the interseismic phase of the earthquake cycle, and will be described in the current section. The postseismic phase of the earthquake cycle describes transient processes that occur immediately after large earthquakes, and will be discussed in Sect. 37.5.5.

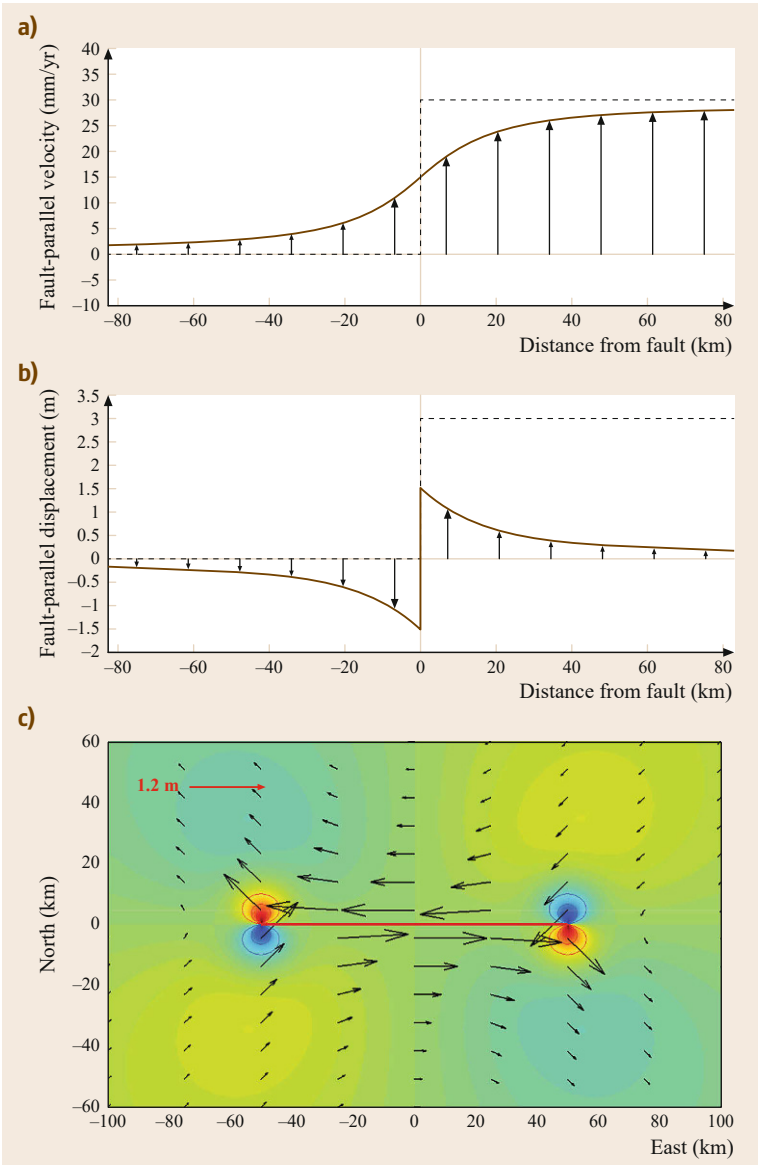

**Fig. 37.10a–c** Deformation surrounding a locked fault in the interseismic and coseismic phases of a simple elastic earthquake cycle. The fault in this model is a long strike slip fault (*left-lateral*) with a slip rate of 30 mm/yr, which has an earthquake after 100 years with 3 m slip. Panels a and b represent fault-normal profiles taken through the origin. **(a)** During the interseismic period, the fault is locked from the surface to 15 km depth and slipping steadily below that. The interseismic deformation pattern is shown by the *arrows* and *solid line*, relative to the far field on the left side of the fault. Compared to the uniform block motion that would result if the fault slipped uniformly at all depths (*dashed line*), the elastic response of the Earth spreads the fault shear over a broad area. **(b)** The coseismic displacement is antisymmetric about the fault, with maximum displacement at the fault (each side moves by half the coseismic slip, in opposite directions). The sum of 100 years of interseismic deformation and the coseismic displacement is a uniform block motion, shown by the *dotted line*. **(c)** A map view of the coseismic displacements from 3 m of displacement on a section of the fault. The rupture zone is shown in *red*. The colors show the vertical displacement pattern, *red* for uplift and *blue* for subsidence, with contours drawn every 5 cm (maximum vertical displacements are 21 cm)

During the interseismic period, surface deformation results from the contrast between the lack of slip at shallow depth and the steady slip at greater depth. The slip deficit is defined as the difference between the slip occurring on a part of the fault and the slip expected based on the long-term slip rate. If a part of a fault has been creeping steadily at the long-term slip rate, it will have a slip deficit of zero. Slip deficit changes with time, accumulating between earthquakes and being reduced by earthquakes. For a fully locked fault, slip deficit accumulates at the long-term slip rate. This is the model (Fig. 37.10) first proposed by *Savage* and *Burford* [37.48] in which the deeper part of the fault zone creeps continuously at the long-term fault slip rate (no slip deficit), while the shallow part of the fault zone remains completely stuck by friction except in earthquakes. They represented this numerically by a planar elastic dislocation embedded in an elastic half-space that slips steadily from a locking depth $d$ to infinite depth.

Deformation in the interseismic phase of the earthquake cycle can be computed using a superposition of steady slip on the entire fault at the long-term fault slip rate with backward slip on parts of the fault that represents the slip deficit rate [37.48, 49]. The observed surface deformation is computed by adding the surface

deformation of each of these two components together. Steady slip at the long-term faultslip rate results in the plate or block motion described by (37.1) or a local linear velocity approximation of that equation. The component due to the backward slip can be computed using elastic dislocation theory [37.55]. The elastic and viscoelastic models used to compute this deformation are explored in detail in [37.6], and their application to modeling GNSS velocity data is discussed in more detail in [37.52] and [37.40], for example. A brief description for the simplest case follows below.

For the case of a very long strike-slip fault, a two-dimensional approximation is adequate when the distance from a location to the fault is small as compared to the distance to an end of the fault. For this case, the velocity depends only on the distance from the fault. *Savage* and *Burford* [37.48] showed that the velocity $v$ of a GNSS site located a distance $x$ from the fault is

$$v = \frac{s}{\pi}\left(\arctan\frac{x-x_\mathrm{f}}{d_1} - \arctan\frac{x-x_\mathrm{f}}{d_2}\right), \tag{37.2}$$

where $s$ is the long-term average slip rate, and the fault located at $x_\mathrm{f}$ slips from depths $d_1$ to $d_2$. If we let $d_2 \to \infty$ and denote the upper limit of fault slip $d_1$ by the locking depth $D$, then (37.2) simplifies to

$$v = \frac{s}{\pi}\arctan\frac{x-x_\mathrm{f}}{D}\,. \tag{37.3}$$

In this simple model, the fault is fully locked (no slip) from the surface to the locking depth, and is slipping at the long-term slip rate below that depth. The locking depth $D$ thus correlates with the maximum depth of earthquake slip, usually 10–20 km for faults within the continental crust. This simple function represents the sum of the two parts of the superposition mentioned above, expressed in a reference frame in which the velocity is zero at the fault ($x = x_\mathrm{f}$). This equation can be transformed into a version relative to the far field on one side of the fault or the other by adding or subtracting $s/2$, which is the velocity predicted by (37.3) as $x$ goes to positive or negative infinity.

Figure 37.10 illustrates the two components of the superposition. The profiles shown in the upper two panels are fault-normal profiles through the midpoint of the fault, so that a two-dimensional approximation holds. Steady motion at the long-term slip rate would result in a velocity profile that looks like a step function across the fault. The elastic deformation due to the shallow locked fault is the difference between the solid and dashed lines, equal to $\pm s/2$ at the fault, and decaying to zero in the far field. The locking depth controls how much of this elastic strain is concentrated close to the fault. About 50% of the elastic deformation is found within 1 locking depth from the fault, and 90% of the elastic deformation occurs within $\approx 6.3$ locking depths from the fault.

### 37.4.3 Elastic Block Modeling

Elastic block modeling provides a way to combine the plate-like description of (37.1) and the elastic strain included in (37.3) for any network of faults, and has been applied in a wide variety of settings [37.56–60]. The model domain is broken up into a set of rigid blocks or microplates, bounded by active faults. The velocity of a GPS site is the sum of the rotation of the block it lies on and the elastic deformation caused by the slip deficit on all faults in the model. The elastic deformation is computed from three-dimensional (3-D) dislocation theory (*Okada* [37.55], for an elastic half-space) assuming backward slip on the locked part of the fault at the long-term fault slip rate. This is the same superposition described above for the two-dimensional (2-D) strike slip fault. In this approach, the fault slip rates are determined by the relative motions of the blocks on either side of the fault and the orientation of the fault. With the fault geometry specified, the motion of all GNSS sites in the model domain can be computed from a linear equation with the vector components of the block angular velocities as the parameters.

Early applications of block modeling assumed that all faults were completely locked from the surface to a constant locking depth. *McCaffrey* [37.56], with his widely-used DEFNODE software, subdivided the fault into a set of subfaults, and used a coupling coefficient that can vary across the fault so that the rate of slip deficit on each fault segment can vary between 0 and the long-term fault slip rate. This is particularly useful for subduction zones, but can be applied to any fault. *Loveless* and *Meade* [37.61] used a similar approach for modeling deformation in Japan, modeling the subduction zone geometry using a set of triangular dislocations. The inversion problem is linear when either the coupling coefficients or the block angular velocities are fixed; when both are estimated the inversion must be solved by a nonlinear method. Some authors have also included the option of making blocks deform internally rather than being rigid [37.60, 62]. As with the variable coupling, this extension makes the problem nonlinear except when the block angular velocities are fixed.

## 37.5 Seismology

Earthquakes result from abrupt and rapid slip on a fault. This induces permanent deformation in the surrounding medium (Earth), with the magnitude of the displacements scaling with both the amount of slip $s$ and the area $A$ that slipped. The product of these two quantities, or more properly the surface integral $\iint s\mathrm{d}A$ over the fault surface, is called the seismic potency, and when multiplied by the elastic shear modulus of the surrounding material it becomes the seismic moment $M_0$. For a point source (or small enough area $A$), the surface displacements everywhere are proportional to the seismic moment. Most large earthquakes involve slip over a large fault area, and for finite fault sources the displacements depend on the spatial distribution of slip on the fault.

Most people, including the general public, are familiar with the *Richter scale* of magnitudes for earthquakes. Richter's magnitude scale is technically called a *local magnitude* or $M_\mathrm{L}$, because he defined the scale in terms of the amplitude of seismic waves for earthquakes in southern California, as recorded on a particular instrument (and corrected for the distance between the earthquake and seismometer). All subsequent earthquake magnitude scales have been calibrated to be consistent with Richter's original definition. Because magnitude is a logarithmic scale, an increase in magnitude by 1 represents a roughly thirtyfold increase in seismic moment. Earthquake magnitudes based on the seismic moment are called moment magnitudes, and are abbreviated as $M_\mathrm{W}$, and moment magnitudes are always used for the largest earthquakes. The moment magnitude is related to the log of $M_0$. For $M_0$ in Newton meters

$$M_\mathrm{W} = \frac{2}{3}\log_{10}(M_0) - 6.0\,. \tag{37.4}$$

Earthquakes are observed to follow several empirical scaling laws. One of these shows that the average slip in an earthquake increases with increasing fault size, so that the seismic moment and thus the magnitude of displacements scale roughly with the cube of the rupture length–width. This means that large earthquakes produce much larger displacements than smaller earthquakes. These scaling relationships can change slightly for very large earthquakes because the shape of the area that slips is constrained by the physical properties of the fault. In particular, fast seismic rupture only occurs (for the most part) at relatively shallow depths, which means that rupture areas for large earthquake are usually much longer than they are wide.

The process of slip on the fault, including its acceleration and deceleration, causes the radiation of oscillatory seismic waves away from the fault surface in addition to the permanent displacements. The field of seismology focuses mainly on the observation of and interpretation/modeling of the seismic waves, which can propagate globally for earthquakes of substantial size. A wide variety of seismic waves with various propagation paths and velocities are generated by fault slip. Within the scope of this handbook, it is sufficient to divide the main types of seismic waves into body waves, which travel through the Earth, and surface waves, which travel along Earth's surface. Body waves can further be subdivided into compressional waves (P waves) and shear waves (S waves). P waves travel at a higher speed and thus arrive first, followed by S waves. Surface waves travel yet more slowly, sometimes over a longer path, and arrive even later. The Earth is mostly elastic at the timescale of seismic wave propagation, but the amplitude of the waves decreases with distance due to geometric spreading of the wavefronts and to anelastic attenuation. However, seismic waves can retain large displacements at great distances away from the rupture. Surface waves in particular can propagate long distances with large amplitudes due to their long wavelengths and 2-D geometric spreading. Unlike the seismic waves, the permanent displacements are much more localized around the region of slip.

Geodesists should view earthquakes primarily from a geometric perspective, in which motion on a surface within the Earth creates stresses that cause the surrounding medium to change its shape. In general, the pattern of static earthquake displacements can be visualized intuitively be imagining motion on a fault surface and thinking about whether the surrounding medium would be sheared, compressed, or extended by that slip. The spatial pattern of displacements from the simple case of uniform strike-slip motion on a linear fault is shown in Fig. 37.10c. Away from the ends of the fault, the displacements are parallel to the fault (which is also the direction of slip), and decrease from a maximum near the fault to zero in the far field. Near the ends of the fault, the displacements are directed toward or away from the fault, and display an antisymmetric pattern. A rough approximation of the displacements for other fault orientations can be visualized by rotating this pattern to other fault orientations; this is only approximate because the free surface (ground surface) has an impact on the displacements due to the stress-free boundary condition there.

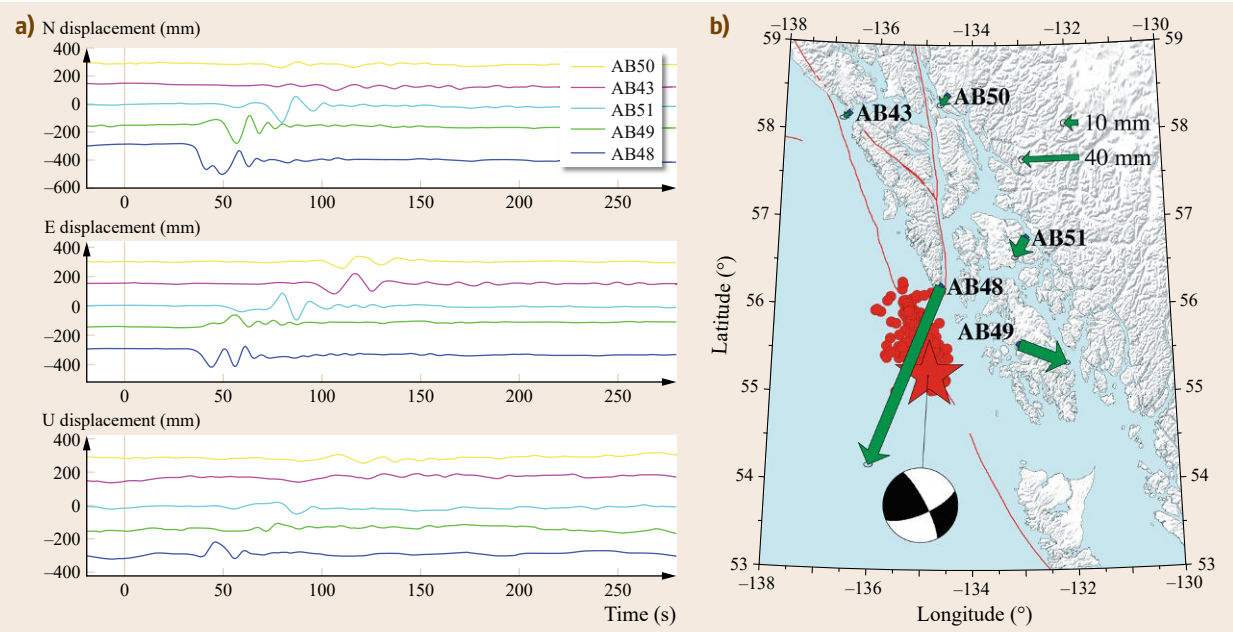

**Fig. 37.11** **(a)** Kinematic displacement record (from 08 : 58 : 00 to 09 : 03 : 00 on 5-Jan-2013) from five plate boundary observatory sites, due to the January 5, 2013 M7.5 earthquake offshore Craig, Alaska. Displacements are shown for east, north, and vertical with each site having a different line style. The *vertical brown line* is the origin time of the earthquake. The first displacements above the noise level are seen with the arrival of the seismic S waves. **(b)** Map showing the site locations and the static offsets. The *thin red lines* are the main active faults and the cluster of aftershocks outline the earthquake rupture. The mainshock focal mechanism is also shown

### 37.5.1 Static Displacements

Static displacements refer to the final permanent displacements caused by fault slip in the earthquake. These displacements are not instantaneous at the time of the earthquake, but rather occur with the arrival of the seismic S waves at the site. Thus at rapid timescales (seconds) even the static displacements appear as an outward-propagating disturbance in the elastic medium of the Earth. They are recognizable as the displacement that remains once the seismic waves have propagated onward past a given site (Fig. 37.11).

Static displacements are estimated from daily or subdaily time series of GNSS positions. Averaging over several days before and after the earthquake can reduce measurement noise, but the positions after the earthquake may be changing due to postseismic deformation (Sect. 37.5.5). When displacements are small or data are limited (e.g., when only a few days of data are available), then the typical practice is to ignore the postseismic deformation and use the average position and the scatter of the daily positions to determine the offset and uncertainty. A better approach is to fit an offset for the earthquake and a time-dependent model for the postseismic deformation to the position time series (Fig. 37.12). As discussed in Sect. 37.1.3, a time-correlated noise model should be used in this fit in order

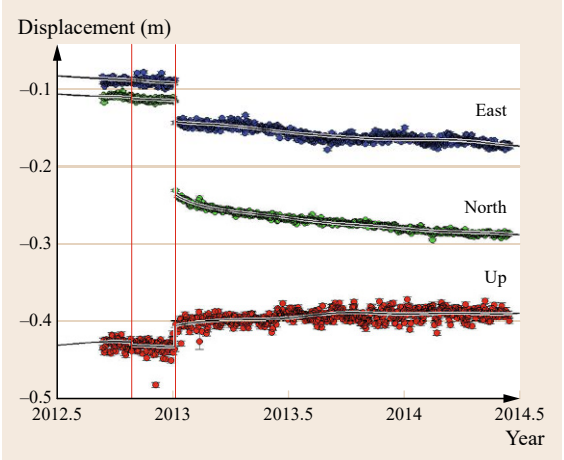

**Fig. 37.12** Time series showing coseismic offset and 1.5 years of postseismic deformation for the January 5, 2013 $M_W$7.5 earthquake offshore Craig, Alaska. The model curve shown includes seasonal terms (estimated from the full pre-earthquake time series) and a logarithmic relaxation (Sect. 37.5.5) with a time constant of 24 d

to get an accurate estimate of the uncertainties of the coseismic displacement.

The pattern of static displacements is most easily visualized for the case of a long, straight strike-slip fault, that is, a vertical fault in which the two sides slip horizontally and parallel to the fault (Fig. 37.10). Direct observation of fault displacement using GNSS confirms that if the total slip on the fault is $s$, each face of the fault moves a distance $s/2$ (in opposite directions). For faults that break the surface, the maximum displacement usually will be observed adjacent to the fault, with the displacements decaying toward zero at greater distances. This pattern can change somewhat depending on the fault geometry and the pattern of slip; for example, if the slip at depth is much greater than the slip at the surface then the maximum displacement may be located away from the surface trace of the rupture.

Displacements as large as several meters have been observed with GNSS for several earthquakes. As most of the largest earthquakes (and thus largest slip and largest displacements) occur in subduction zones, the largest surface displacements from such events are typically offshore. However, repeat triangulation data from the great 1964 Alaska $M_W$9.3 earthquake, still the second largest earthquake ever recorded, measured surface displacements as large as 20–25 m [37.63, 64]. For the 2011 $M_W$9.0 Tohoku-oki earthquake, GNSS/Acoustic sites on the seafloor measured surface displacements offshore on the order of 25–30 m, which resulted from slip of as much as 50 m [37.65, 66]. GNSS/Acoustic measurements combine kinematic GNSS positioning of a ship or buoy on the sea surface with acoustic ranging to transponders on the seafloor to estimate positions of points on the seafloor.

Because the Earth behaves as an elastic body over short timescales, geodetic surface displacements from earthquakes are modeled using the elastic dislocation theory, assuming that the geometry of the fault and the distribution of slip are known. Most studies use the analytical solution for planar rectangular dislocations in a uniform elastic half-space given by *Okada* [37.55]. The Earth is not a uniform half-space, however, so this computation is only an approximation. Better approximations, depending on the spatial scale of the problem, can include elastic spaces with several elastic layers [37.67], or layered spherical models [37.68]. In reality, the exact distribution of slip on the fault and the fault geometry are never perfectly known. The true elastic structure of Earth is also known only approximately. Thus, it should be kept in mind that GNSS measurement accuracy for displacements exceeds the accuracy of the model calculations that link fault slip to displacements.

Displacements measured by GNSS are often used in the inverse problem, to estimate the location and geometry of the fault and the magnitude of slip based on the measured displacements. This inverse problem comes in two general forms. If the geometry of the fault (location and orientation) needs to be estimated, then there is a nonlinear relationship between the model parameters and the displacements, and a nonlinear optimization approach is required. However, if the geometry is kept fixed but the distribution of slip on the fault surface is estimated, then there is a linear relationship between the model parameters (slip values) and displacements. This problem is, in general, a mixed-determined problem that can be solved with damped least squares or another generalized inverse method [37.69, 70]. It is very common to add smoothing constraints, usually the Laplacian (second derivative) of the slip distribution, into the inversion with some weight relative to the data. Positivity or other inequality constraints also act to stabilize the inversion and select against oscillatory solutions for the slip distribution. Some authors have also varied the model geometry in specific ways, and estimated a slip distribution for each model fault geometry; the best overall model is then chosen [37.28].

Figure 37.13 shows an example of coseismic displacements and a slip model, from the 2002 $M_W$7.9 Denali fault earthquake in Alaska [37.27]. The inversion used 224 GPS displacement vectors plus surface offsets measured along the fault by geologists. The fault geometry was based on the mapped surface rupture, with the fault dip angle optimized where a dense GPS profile crossed the fault. The displacements at that location showed that the fault was vertical. The slip distribution was estimated using a bounded variable least squares algorithm [37.71], including smoothing via a Laplacian operator on the slip distribution. The weight given to model smoothness, relative to data misfit, is a hyper-parameter that must be chosen by the analyst. *Hreinsdóttir* et al. [37.27] used a combination of the model misfit/roughness *L-curve* [37.70] and a weighted cross-validation sum of squares, which tests how well a model can predict a data point that was left out in the inversion to determine the model [37.72]. Although the cross-validation approach is philosophically appealing, the displacements of sites close to the fault are so large that these sites completely dominate the cross-validation assessment. Balancing these two measures gave a range of reasonable smoothing weights. The midpoint of the range was chosen as the optimal model, but interpretations of the slip distribution were based on inspection of the entire family of models within the range of reasonable smoothing values.

Although the static displacements are localized around the area of slip, the largest earthquakes still have a very long reach given their extreme size. Six of the 13 largest earthquakes ever recorded occurred during

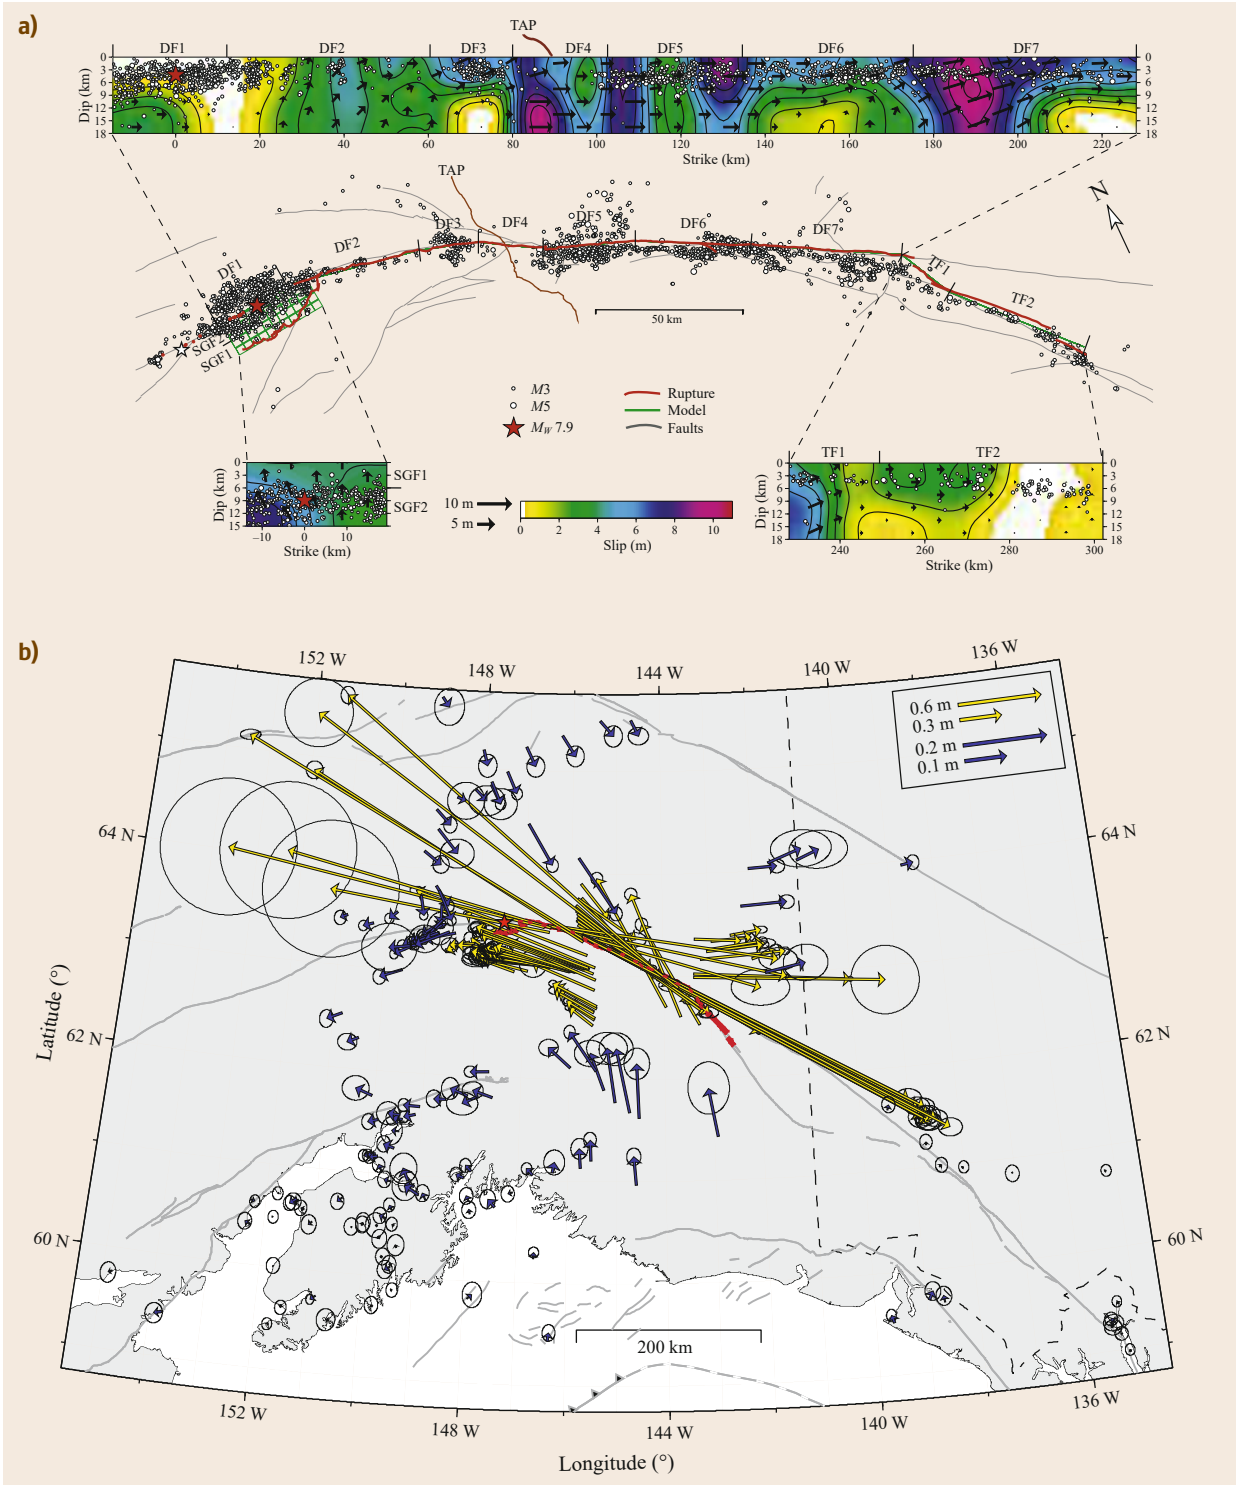

**Fig. 37.13a,b** Slip model and coseismic displacements for the 2002 Denali fault earthquake. The hypocentral location, the point of rupture initiation, is shown by the *red star* and the surface rupture shown by a *thick red line*. **(a)** The fault slip model with the estimated total displacement on each patch of the fault indicated by the *color scale*. Aftershocks are shown in map view and on the cross-section. **(b)** Map of observed horizontal displacement vectors, with two different scales used because of the ≈ 2 orders of magnitude range of displacements (after [37.27], courtesy of John Wiley and Sons)

the 8 year period 2004–2012, giving us many examples of the far-field impacts of the largest earthquakes. *Banerjee* et al. [37.73] demonstrated that the 2004 $M_W$9.2 Sumatra–Andaman earthquake caused measurable static displacements (several millimeters) at least 4000 km away, in Korea. The 2010 $M_W$8.8 Maule earthquake offshore of Chile caused ≈ 10 mm displacements at the Atlantic coast of Argentina, about 1000 km away. And displacements from the 2011 $M_W$9.0 Tohoku-oki earthquake offshore of northeastern Japan could be measured across all of north China and as far away as Mongolia [37.74]. These studies show only how far away displacements can be clearly separated from the noise in the GNSS time series. The slip models for these earthquakes predict that millimeter-level displacements should extend much further away. *Tregoning* et al. [37.75] suggested that the cumulative distortion of the geodetic reference frame from the sum of these earthquakes was at nearly the millimeter level or larger worldwide.

### 37.5.2 Dynamic Displacements from Kinematic GNSS

Dynamic displacements refer to the seismic waves that propagate outward from the rupture. Seismic waves can be recorded globally by seismometers. The study by *Nikolaidis* et al. [37.76] was one of the first studies to demonstrate the capability of GNSS to measure seismic waves. They processed a linked set of baselines on an epoch-by-epoch basis, and showed good agreement with long-period seismic waves. Long-period waves (such as surface waves) can have large amplitudes at great distances from the source, although shorter period body waves spread and attenuate faster. Thus, the largest dynamic displacements seen at great distances from an earthquake will most likely be surface waves. *Larson* et al. [37.77] measured the propagation of surface waves across North America from the 2002 $M_W$7.9 Denali fault earthquake in Alaska, and demonstrated that GNSS records remained accurate and on-scale even when modern digital broadband seismometers went offscale because of the large ground motions.

Most GNSS studies of seismic waves have used data sampled at a rate of 1 Hz. In general, this sampling rate is sufficient for estimation of earthquake source models such as finite fault rupture models. These models require accurate simulation of seismic waveforms, which are generally limited to frequencies of 1 Hz and lower by the spatial resolution of the seismic velocity structure used for the computations. However, for the 2011 L'Aquila earthquake in Italy, *Avallone* et al. [37.78] demonstrated that sampling at 5 Hz or 10 Hz was needed to provide unaliased measurements of the displacements for sites close to the earthquake source. Important characteristics of the seismic source and the propagation medium can be determined from the waveforms directly, so for these purposes higher time resolution GNSS data would be desirable. It is not clear whether GNSS data recorded at even higher time resolution would provide important new information. GNSS positions at 5 Hz were analyzed for the 2010 $M_W$7.2 El Mayor-Cucapah earthquake in Mexico, but the energy at frequencies higher than 1 Hz was only a minor contribution to the total signal [37.79]. The precision of high rate GNSS positions and the potential benefits of recording at a very high rate (e.g., 50–100 Hz) and filtering or averaging the resulting positions will be addressed later in this section.

Figure 37.11 shows dynamic and static displacements observed at the PBO station AB48 from a $M_W$7.5 earthquake that occurred offshore of Craig, Alaska on January 6, 2013 [37.80]. Approximately 40 s passes from the start of the earthquake to the arrival of the first observable seismic waves at the site, located ≈ 75 km from the closest part of the rupture surface. The station position oscillates for approximately 20–25 s after the arrival of the first major displacement, eventually settling at the final static displacement. In this case, the largest static displacement is in the north component, being ≈ 10 cm to the south.

Earthquake displacement records such as this are computed through standard kinematic positioning techniques (Chap. 25). Kinematic precise point positioning (PPP) solutions are particularly straightforward for this purpose, although these solutions assume that the reference stations used for the orbit/clock solution are far enough away from the earthquake that the earthquake does not displace these stations. Otherwise, the clock and possibly orbit estimates may be biased. Kinematic baseline solutions (Chap. 26) can also provide good results, although care must be taken with baseline solutions, because these will show displacements when the seismic waves reach the *base* station in addition to the displacements of the *rover* station.

The noise spectrum of kinematic positioning is complex, and not yet fully described. Over very short times, for example, several seconds to tens of seconds, the satellite constellation geometry does not change much and propagation delays like atmospheric delays are approximately constant. Over such short timescales, the error in changes in position of a GNSS antenna is quite small, dominated mainly by the noise of the phase measurement and to a lesser extent by multipath variations. In effect, errors caused by path delays or orbit mismodeling cause systematic errors in the position but contribute only slightly to the estimate of position change. The impact of other errors depends on

the solution type; for example, interpolation of clock estimates can contribute to errors in kinematic PPP solutions. Thus, kinematic time series such as that shown in Fig. 37.11 display a variety of errors that are longer in period than the seismic waves of interest, and can be removed by filtering. *Genrich* and *Bock* [37.81] found that the noise spectrum of very high rate GNSS positions was nearly white for frequencies above 0.5 Hz, which means that averaging positions determined from much higher rate sampling can achieve significant noise reduction.

Because the change in position is the quantity we wish to measure to study dynamic displacements from seismic waves, the effective noise of GNSS position records is quite low and GNSS records are observed to agree extremely well with co-located seismometers, provided the seismometers remain on scale [37.77, 82, 83]. *Elósegui* et al. [37.84] tested a GPS antenna on a shake table with known motion and found that the root mean square (RMS) error of the kinematic GPS solution was quite small over 15–25 min windows. Using data from a time period in which no displacements were expected, *Genrich* and *Bock* [37.81] estimated that horizontal positions with a precision of 0.5 mm could be recovered by averaging positions determined at 20 Hz sampling down to a rate of 2 Hz. However, in a comparison of 5 Hz GPS records to doubly integrated accelerometer records for the 2010 $M_W$7.2 El Mayor-Cucapah earthquake, *Zheng* et al. [37.79] estimated the error in the GPS displacements to be 4–5 mm. The precision of very high rate GNSS positions depends on the bandwidth of the phase lock loop (PLL) used within the receiver [37.85]. That study examined displacements recorded at 100 Hz sampling with PLL bandwidths of 25–100 Hz. The standard deviation of positions with a PLL bandwidth of 100 Hz was about twice as large as that for 25 Hz, and the autocorrelations of the position time series increased as the PLL bandwidth decreased. This indicates that there is minimal benefit to recording positions at a sampling rate with frequency higher than the PLL bandwidth.

*Crowell* et al. [37.83] proposed a method for integrating GNSS displacement records with co-located strong-motion (acceleration) seismometers. The accelerometer records must be integrated twice to get displacement, and must be corrected for any instrumental tilt caused by the earthquake displacements (static or dynamic) in addition to assuring that the integration constants are chosen properly to match the static displacements. They devised a method to combine the two data streams using a Kalman filter, and demonstrated that they could recover broadband ground motions with high fidelity. A number of continuous GNSS stations in California are now outfitted with co-located accelerometers to provide enhanced data for rapid determination of earthquake magnitude and potentially earthquake early warning. *Tu* et al. [37.86] applied a similar method using a low-cost single frequency GNSS receiver and obtained ≈ 20 mm accuracy for the displacement estimates.

GNSS displacement records are now commonly used in earthquake source inversions along with seismic data. These inversions are like those described for the static displacements above, but attempt to reconstruct the time history of slip at each point on the fault and not just the total. *Miyazaki* et al. [37.82] demonstrated that such models could be derived entirely from GNSS displacement records, for the 2003 $M_W$8.3 Tokachi-oki earthquake offshore of Hokkaido, Japan. Several more recent studies include those of the 2011 $M_W$9.0 Tohoku-oki earthquake [37.80], the 2012 $M_W$8.6 Wharton Basin earthquake [37.87], and the 2013 $M_W$7.5 Craig, Alaska earthquake [37.80].

### 37.5.3 Real-Time Application to Earthquake Warning and Tsunami Warning

The displacements from earthquakes large enough to be damaging or deadly can be very large near the source. In particular, the displacements from large subduction zone earthquakes, which are capable of generating devastating tsunamis, can be as large as several meters in the near field. Even far-field displacements from such earthquakes can be very large compared to the precision and accuracy of real-time kinematic GNSS solutions. This motivates efforts to use real-time GNSS for earthquake early warning or tsunami warning [37.88], and systems to implement this are under development.

Real-time GNSS displacements can provide estimates of the earthquake magnitude and rupture dimensions that are highly complementary to the information available in real time from seismology. Some commonly used seismic methods to measure earthquake magnitude saturate because the seismic observations used are limited in frequency band. As a result, earthquakes much larger than $M_W$8 can be initially reported as $M_W$8. However, the displacements observed by GNSS do not suffer from this limitation, and the displacements from an $M_W$9 earthquake are immediately recognizable as being much larger than those of a $M_W$8 earthquake (Fig. 37.14). Figure 37.14 also illustrates some other properties of the earthquake source that are easily constrained by GNSS displacements. The length of the $M_W$9 earthquake rupture is easily derived from the displacements, simply by noting where the seaward motions fall off toward zero. An experienced analyst could draw a reasonable approximation of the rupture

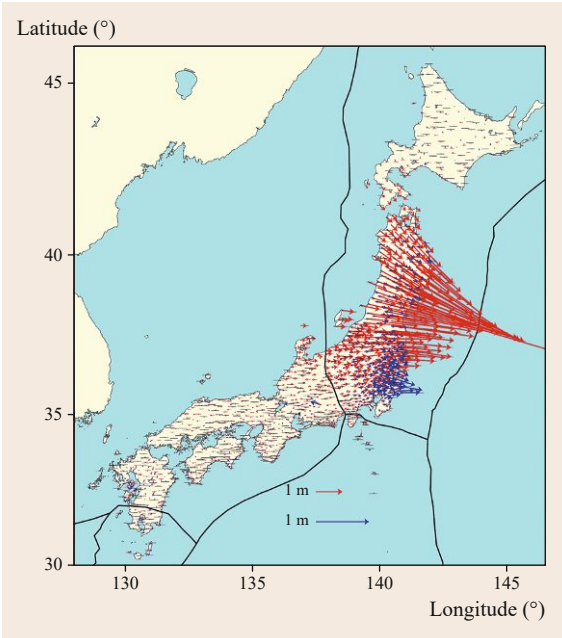

**Fig. 37.14** Comparison of displacements from the March 11, 2011 $M_W$9.0 Tohoku earthquake (*red*), and it's $M_W$7.9 aftershock (*blue*), based on GEONET data. Displacements computed by the Caltech/Jet Propulsion Laboratory (JPL) ARIA project (after [37.89]). This illustrates the vast difference in size between earthquakes 1 magnitude unit apart, and also shows how easily the rupture length can be inferred from the displacement data. *Black lines* show a simplified view of the major plate boundaries (Japan is a region of complex deformation)

plane from these displacements alone, and an inversion for a finite fault rupture can be done immediately once these displacements are available. The finite fault model gives information that could not be obtained from seismology until a few hours after the event.

There are several potential limitations for the application of real-time GNSS to earthquake early warning or tsunami warning. Timing and magnitude of the deformation signal are intrinsic limitations of the method, while precision of the GNSS orbit and clock products and quality control are limitations that can be addressed by improved techniques. As can be seen in Fig. 37.11, displacements of a GNSS site will be observed when the seismic body waves reach the site, not at the time the earthquake begins. This means that only GNSS sites very close to the fault rupture can contribute to earthquake early warning, which is aimed at warning of the ground shaking before it arrives. This is less of a problem for tsunami warning, as the tsunami waves travel much more slowly than the seismic waves. In addition, sites must be close enough to the earthquake source to record significant displacements given the noise level.

Improvements in techniques will result in better orbit and clock products being available in real time. IGS ultra-rapid orbit products are already very good, because orbits can be predicted ahead by integrating the equations of motion. Clock estimates cannot be predicted ahead far in time, so real-time PPP processing is dependent on the quality of real-time estimates of satellite clock error. Current real-time clock estimates have an accuracy of $\approx 0.1$ ns in the best case [37.90], which can provide positioning accuracy of 20 mm for horizontal positions and 40 mm for vertical positions [37.91]. For comparison, the IGS final clock solutions have a standard deviation half as large, while forward prediction of clock errors has an accuracy 10–20 times worse. The desired goal is to have real time clock estimates that are as accurate as the IGS final clock estimates. Probably the biggest challenge for this application is in quality control, mainly the detection of cycle slips or other data anomalies in real-time streams. In some approaches, such as that originally used by *Nikolaidis* et al. [37.76], ambiguities are resolved independently for each epoch, because the phase is not assumed to be continuous in time (this means there is no need to detect cycle slips). Refer to Chaps. 23, 25, and 26 for more information about the technical details of ambiguity resolution, kinematic, and differential positioning.

Use of GNSS real-time position time series for warning requires automated methods for detection and measurement of earthquake displacements, and for inversions of these data for earthquake source parameters. The details of these methods depend on whether or not it is assumed that information from seismology will be available. Rapid detection of earthquakes using seismic networks is more straightforward than using geodesy, and the tools to do it already exist. However, there have been several approaches taken to the detection problem using GNSS data alone. *Ohta* et al. [37.92] used a short-term average versus long-term average root-mean-square (RMS) comparison to detect both the occurrence of a displacement event and to detect when the ground motions have stabilized at the post-event positions. Even if the event detection is primarily based on seismology, it is still necessary to detect when the dynamic ground motions have finished so that the static displacements can be estimated as quickly as possible.

Real-time inversion procedures have been outlined by several authors [37.83, 92–94]. *Melgar* et al. [37.93] proposed using displacement time series to estimate a point source approximation for the earthquake, a CMT or centroid moment tensor solution. *Crowell*

et al. [37.83], *Ohta* et al. [37.92], and *Minson* et al. [37.94] outlined methods for real-time finite fault inversions. There are three basic approaches used by these authors. One approach uses a catalog of predefined faults or fault segments, which results in a linear inversion for slip on the faults. This approach may fail if the earthquake is on an unexpected fault, or involves a complex multifault rupture. Another approach uses a point source CMT solution or a set of point sources in time to define the approximate location and orientation of the fault plane, and then a nonlinear inversion or inversions for the slip distribution. The third approach uses a Bayesian inversion framework to estimate properties of the rupture plane and slip distribution. The best approach to solve this problem in general remains under investigation, but all of these authors report that reliable solutions can be obtained within a few minutes, given an accurate set of static displacements.

Two recent papers suggest that earthquake magnitude can be determined directly from the displacement waveforms, with no need for inversion. *Fang* et al. [37.95] showed that *Gutenberg*'s relation between peak displacement and magnitude [37.96] holds up to nearly $M_W$9.0. This suggests that peak amplitudes can be read directly from the displacement waveforms and used in a magnitude calculation, just as is done routinely from seismology for smaller events. *Crowell* et al. [37.97] identified amplitudes of P waves from combined seismo-geodetic stations, and developed scaling relationships for these as well as the peak ground displacement. These amplitudes showed a clear scaling with earthquake magnitude. These new results suggest that an initial estimation of magnitude can be made even while the ground shaking still continues.

### 37.5.4 Transient Slip

In addition to earthquakes, some faults also slip in a slow or transient manner. These slip events are called slow slip events, and they have been documented at most subduction zones that have adequate instrumentation. Slow slip is often accompanied by seismic tremor, and the occurrence of these together on a highly repeatable basis in the Cascadia subduction zone led to these events being termed as episodic tremor and slip (ETS) events [37.98]. Slow slip events occur in a wide range of sizes. *Schwartz* and *Rokosky* [37.99] and *Ide* et al. [37.100] summarized the seismic and geodetic evidence for these events; GNSS data are the critical geodetic data in most cases. Earthquakes can also trigger slow slip or creep on nearby faults [37.101, 102].

These slow and transient events challenge some of the assumptions commonly made in geodesy, such as the use of linear models to describe motion with time. Although deviations from a linear trend may be due to noise, some variations reflect real nonlinear motion. Spatial correlation of deviations from linear motion provides the key to the separation of nonlinear signal from noise. Given the quality of today's GNSS orbit and other products, position errors resulting from orbit mismodeling are small and usually will be strongly correlated over very long distances. Time-dependent deformation, on the other hand, will be correlated over much shorter distances, and will vary in space in characteristic ways that can be predicted if the likely slip region on the source fault can be identified. Modeling of slow slip events is very similar to the problem of modeling static displacements from earthquakes, apart from the different timescales involved.

### 37.5.5 Postseismic Deformation

Postseismic deformation refers to transient deformation following earthquakes. Large stress changes caused by large earthquakes induce changes in the pattern and rate of strain around the fault. The time evolution of strain depends on the rheology of the crust and upper mantle [37.103] and the fault geometry and coseismic slip distribution of the earthquake. Rheology refers to the mechanical properties of materials, which describe how they deform and flow. Earth materials under different temperature, pressure, and stress conditions (and different timescales) can behave as elastic, plastic/ductile, viscoelastic, or viscous materials. Postseismic deformation provides an important opportunity to estimate these properties and study the forces that drive tectonic deformation. It is thought to result from a superposition of three main physical mechanisms, which cause deformation on different spatial and temporal scales:

- Viscoelastic relaxation of the mantle and possibly lower crust
- Afterslip on the very shallow or deep parts of the fault zone
- Poroelastic relaxation.

This section focuses on the observable geodetic effects of postseismic deformation rather than the details of the mechanisms themselves. Postseismic deformation can be large and long lasting, although there is great variation from earthquake to earthquake. Postseismic displacements are always nonlinear in time. After a large earthquake, one can expect that GNSS sites over a large area surrounding it will move in a tran-

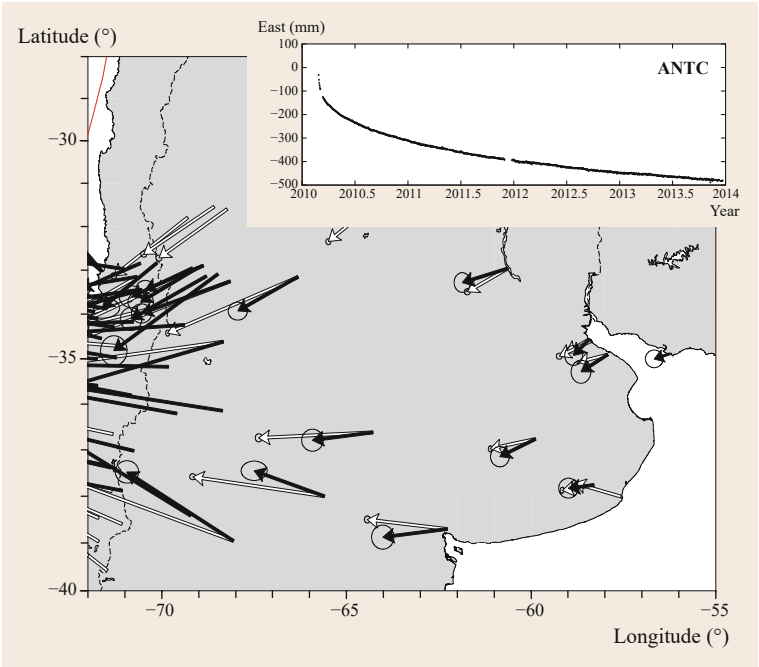

**Fig. 37.15** Comparison of far-field coseismic and postseismic displacements for the 2010 Maule, Chile earthquake ($M_W$8.8). *White vectors* are coseismic displacements (after [37.104, 105]), and *black vectors* are postseismic displacements over the first 15 months after the earthquake (after [37.105]). The *inset* shows the postseismic east component time series for the site ANTC, which is located in Chile at the western edge of the map

sient fashion due to both afterslip on the fault zone and viscoelastic relaxation of the lower crust and/or upper mantle. This means that postseismic GNSS time series may exhibit complex time dependence. Poroelastic relaxation, which is deformation driven by fluid flow in porous media that relieves pressure differences caused by the earthquake, is generally considered to be important only very close to the fault and near geometric complexities such as fault stepovers and bends.

### Afterslip

Fault friction laws and empirical models suggest that slip $s$ on a particular spot on the fault from afterslip should follow a roughly logarithmic decay with time [37.47, 106]

$$s = S \log\left(1 + \frac{t}{\tau}\right), \tag{37.5}$$

where $t$ is the time after the earthquake, $S$ is a multiplicative constant, and $\tau$ is a relaxation time that depends on the frictional properties. Empirical estimates usually find a relaxation time on the order of 0.05–0.1 yr. Because the surface displacements resulting from fault slip are linearly proportional to the slip on the fault, the contribution of afterslip to GNSS time series also will follow a logarithmic decay if the spatial pattern of afterslip is time-invariant. Afterslip can occur both at shallower and deeper parts of the fault zone, compared to the slip in the earthquake. Thus, the spatial pattern of displacements will generally be different from that of the earthquake. Afterslip has been identified or proposed following many earthquakes [37.32, 101, 107–111]. Theoretically, afterslip could be predicted from the coseismic slip if the fault frictional properties were known, but there appear to be spatial variations in these properties. As a result, afterslip models usually are estimated from observed displacements through an inversion similar to that for coseismic slip.

### Viscoelastic Relaxation

For the simplest case of a one-dimensional material with a constant linear (Maxwell) viscosity, the displacements $d$ from viscoelastic relaxation would follow an exponential decay with time

$$d = A\left[1 - \exp\left(-\frac{t}{\tau}\right)\right], \tag{37.6}$$

where $t$ is the time after the earthquake, and $\tau$ is a relaxation time that depends on the ratio of the shear modulus and viscosity of the viscoelastic material. In the real Earth, viscosity varies with space (certainly with depth) and a power law rather than linear model may be expected; both of these factors will result in the exponential decay of displacements with time being an approximation only. Viscoelastic layers lie deeper within the Earth than most earthquakes, so the spatial pattern of postseismic displacements has a longer spatial wavelength than the coseismic displacements.

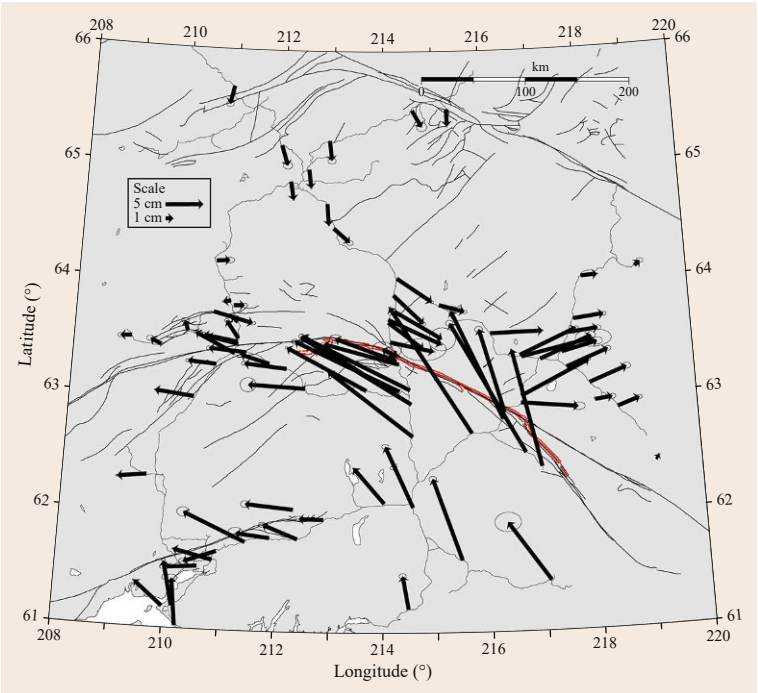

**Fig. 37.16** Total postseismic displacements over a 6 year period after the 2002 Denali Fault earthquake, starting 8 months after the earthquake. The postseismic displacements were computed after removing the pre-earthquake trend from the time series, and represent the transient component of the displacement, and exceed 20 cm in places. Postseismic displacements are small close to the fault and reach a maximum at a distance of ≈ 50 km from the fault, indicating that they come from a deep source. *Black lines* are active faults, and the *thick red line* shows the extent of the 2002 surface rupture

There is considerable debate about the viscosity of materials within the Earth, but many postseismic deformation models find evidence for upper mantle (asthenosphere) viscosities in the range of $10^{18}$–$10^{19}$ Pa s, which correspond to relaxation times of 2–20 yr, respectively [37.112]. It is important to note here that the mantle viscosity beneath tectonically active areas is lower than that below old, stable continental areas by orders of magnitude.

### Examples and Implications

Adjacent to the fault, postseismic displacements are usually significantly smaller than coseismic displacements, reflecting the smaller amount of slip involved and the generally deeper deformation source. For a vertical fault, the maximum postseismic deformation is generally found 30–50 km from the fault. However, the longer spatial wavelength of the postseismic signal that results from its deeper or spatially distributed source means that far-field postseismic displacements can be a significant fraction of, comparable to, and sometimes larger than the coseismic displacements. This has been the case for several recent large earthquakes, including several in Sumatra and the 2010 Maule earthquake offshore Chile (Fig. 37.15).

Because neither the viscosity structure of the Earth nor fault frictional properties are known in detail, studies of postseismic deformation attempt to estimate them by inversion of GNSS observed surface displacement time series. Afterslip and viscoelastic relaxation can produce similar surface deformation patterns, especially in the horizontal components, when there are enough adjustable parameters in the inversion model. This is especially true when a limited time span of data is considered, and as a result controversy over the proper postseismic deformation models can linger for years, even for well-studied earthquakes. Vertical displacements and the evolution of the transient deformation over a long time can distinguish between these physical mechanisms.

Empirical time series models are often used to describe the postseismic time evolution of GNSS coordinates. In the ITRF reference frame solutions (up through ITRF2008), only piecewise linear models are used to provide a model for coordinates, a station trajectory model, in the terminology of [37.113]. However, these models provide a poor fit to the data and/or require a very large number of parameters in cases of large postseismic displacements, such as those shown for the site ANTC in Fig. 37.15. A simple model involving one or two relaxation functions usually provides an accurate representation of the postseismic displacements over a period of several years, usually one with a short relaxation time (≈ 1 month) and one with a longer relaxation time (a few years). A complete model for the time series for one component of the position, including relaxation

terms like (37.5) and (37.6) is

$$x(t) = x_0 + v(t-t_0) + H(t-t_{eq}) \times \left[ C + L \log \left[ \frac{1+(t-t_{eq})}{\tau_l} \right] + E \times \left( 1 - \exp \left[ -\frac{(t-t_{eq})}{\tau_e} \right] \right) \right], \quad (37.7)$$

where $x(t)$ represents the time series of some component (east, north, and up), $t$ is time, $t_0$ is the reference time for the position, $t_{eq}$ is the time of the earthquake, $\tau_l$ and $\tau_e$ are logarithmic and exponential relaxation times, respectively, and $H(t)$ is the Heaviside (step) function. The capital letters are constants to be estimated based on the time series:

- $C$ for the coseismic displacement
- $L$ for the logarithmic relaxation
- $E$ for the exponential relaxation.

*Bevis* and *Brown* [37.113] showed that postseismic time series can also be usually fit well by a single logarithmic relaxation with a relaxation time of $\approx 1$ yr, if data from the first few months after the earthquake are neglected. Because of tradeoffs between parameters in curve fitting to the GNSS time series, multiple models can fit the time series well enough. This means that the time constants empirically estimated from the GNSS time series might not accurately reflect the underlying physical parameters.

The 2002 $M_W$7.9 Denali fault earthquake provides a useful example. Ten continuous GPS sites were set up within a few weeks of the earthquake and nearly 100 sites were surveyed repeatedly over the next several years, providing a rich data set in space and time (Fig. 37.16). All sites show an initially rapid rate of deformation that decayed over time. In general, site velocities averaged over the first 2 years were $\approx 20$ times faster than the pre-earthquake rates. Even several years after the earthquake, average velocities remained several times higher than the pre-earthquake rates at many sites. The time series reflects the superposition of multiple relaxation processes. No single relaxation function of time, such as an exponential or logarithmic relaxation, can explain the temporal variations of the time series to within the scatter in the measurements [37.114]. However, a combination of relaxation functions such as (37.7) can explain the temporal decay of the displacements quite well.

## 37.6 Volcano Deformation

Active volcanism also causes ground deformation, so surface displacements can provide critical information about the volcanic source. Injection or removal of magma in the subsurface causes changes in pressure and volume that result in surface deformation. Many deforming volcanoes have been studied using GNSS, interferometric synthetic aperture radar (InSAR), or a combination of the two. InSAR has the advantage that it can be used any time repeat satellite passes are available, and does not require access to the volcano on the ground. Remote volcanoes are thus more often studied using InSAR. However, InSAR provides only one component of displacement, which combines horizontally and vertically, so a few point displacements measured with GNSS provide an excellent complement for InSAR, and can be easier to interpret and model.

Physical sources of volcanic deformation include expansion or contraction of dikes or sills (roughly planar cracks, oriented roughly vertically or horizontally, respectively), or inflation or deflation of volumetric sources, often assumed to be spherical or ellipsoidal. Pressure changes of volumetric sources result in horizontal displacements that are oriented radially away from or toward the source (Fig. 37.17) and substantial vertical displacements.

The simplest volcanic source model is the *Mogi* model (Fig. 37.18), a spherical point pressure source [37.115]. This very simple model has provided a good fit to observed displacements in many cases. It describes the deformation at the surface caused by a pressure change within a small spherical body at depth in an elastic half-space; the point source approximation actually holds even for relatively large bodies. Although other, more complex, volcanic source models exist, the Mogi source remains by far the most widely used. The success of the Mogi source is an indication that it is difficult to constrain the shape or size of a volumetric source at depth using surface observations.

The Mogi source predicts displacements that are radially symmetric about the source (Fig. 37.18). For a pressure change $\Delta P$ in a small spherical cavity of radius $a$

$$\Delta r = \frac{3a^3 \Delta P r}{4\mu (r^2 + d^2)^{\frac{3}{2}}}, \quad (37.8a)$$

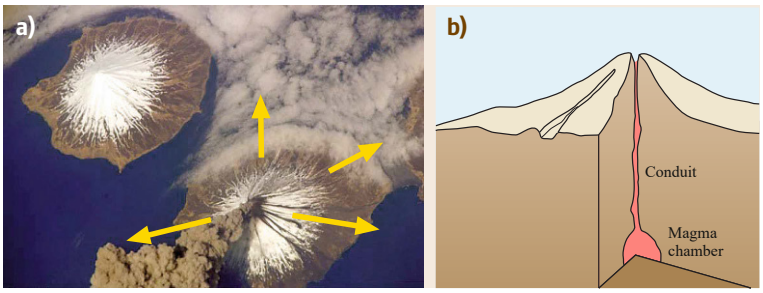

**Fig. 37.17** **(a)** Photo of Cleveland volcano erupting in 2006, taken from the International Space Station. Horizontal displacements from volcanic sources often have radial symmetry about the volcanic vent. **(b)** Cutaway view of a volcano, showing a magma chamber (the most common deformation source) connected to the surface by a conduit. The base image in panel **(a)** is from astronaut photograph ISS013-E-24184 (courtesy of the Earth Science and Remote Sensing Unit, National Aeronautics and Space Administration (NASA) Johnson Space Center)

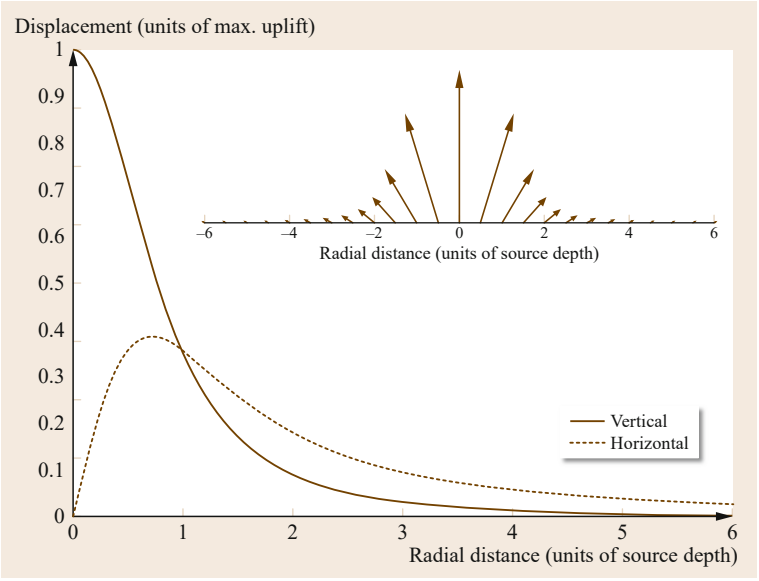

**Fig. 37.18** Mogi model displacements. The *blue* and *red curves* show the vertical and horizontal displacements, respectively. The $x$-axis is scaled in units of source depth, while the $y$-axis is scaled in units of the maximum vertical displacement, which is equal to the product of the source strength and the depth of the source. The *inset* shows the displacement vectors along a radial cross-section

$$\Delta h = \frac{3a^3 \Delta P d}{4\mu (r^2 + d^2)^{\frac{3}{2}}} , \tag{37.8b}$$

where $\Delta r$ and $\Delta h$ are radial and vertical displacements, respectively, $d$ is the depth of the source and $r$ is the radial distance in the horizontal plane from the source to the observation point. The constant $C = 3a^3 \Delta P / 4\mu$ is called the *source strength*, and it is related to the change in cavity volume $\Delta V$

$$\Delta V = \frac{4\pi C}{3} = \frac{\pi a^3 \Delta P}{\mu} . \tag{37.9}$$

The surface displacements in the Mogi model are linearly proportional to the volume change of the subsurface reservoir (combining (37.8a)–(37.9)). If the magma is incompressible, which should be true if it does not contain exsolved gas bubbles, then the volume change of the subsurface reservoir is equal to the volume of magma intruded into it. However, some magmas contain exsolved gas bubbles, and this gives the magma a significant compressibility. In the presence of bubbles, the mass of the intruded magma cannot be determined from the surface deformation without assumptions about the magma compressibility. Compressible magma can accumulate in the subsurface without causing significant surface deformation, although this would still cause changes in gravity.

Many past studies have documented both inflation prior to eruption and deflation during eruption. There are a few cases of simultaneous deflation at depth and inflation close to the surface, such as the 2000 eruption of Usu volcano in Japan, for which deformation and gravity change data were fit best by a model with a de-

flation source at ≈ 4 km depth, connected to the surface by an intruded fissure [37.116, 117].

A simple *eruption cycle* model does not seem to apply to volcanoes. Unlike tectonic loading, magma supply is not uniform in time [37.118–120], and successive eruptions at the same volcano can be quite different in volume and style. It is likely that multiple bodies of crystal mush or partially solidified magma reside underneath very active volcanoes [37.121], and an eruption can be triggered when a relatively small amount of new magma rises into and remobilizes one of these bodies [37.122].

GNSS, and especially continuous GNSS (Fig. 37.19), is a powerful tool for measuring and monitoring volcanic deformation. Volcanic deformation can be quite large, involving displacements as large as meters in the case of some eruptions. Volcanoes are highly dynamic, and deformation can occur over a variety of timescales from seconds to years, such that continuous GNSS measurements are the ideal method to study them. *Fournier* et al. [37.120] provide an example of using a GNSS time series to study the long-term inflation of a volcano over several years as it was slowly built toward eruption. They used an unscented Kalman filter, a type of nonlinear Kalman filter, to estimate the volume changes over time at Okmok Volcano, revealing pulses of inflation as new magma was intruded beneath the volcano. But significant signals, especially during eruptions, can occur on very short timescales. *Larson* et al. [37.123] discussed how to optimize GNSS processing and filtering to recover deformation signals for volcano monitoring with high resolution in time. They recommended using a kinematic solution strategy that includes a degree of temporal smoothing in the GNSS solution itself, such as estimating the position using a random walk noise model with a Kalman filter. Doing so suppresses noise but still allows for accurate detection of abrupt changes in the time series (Fig. 37.20).

**Fig. 37.19** Photo of a continuous GNSS station for volcano monitoring, at Okmok volcano, Aleutian Islands, Alaska. The GPS antenna is mounted on a braced structure anchored in rock, with a separate hut for the receiver and batteries (*behind*). Solar panels run the instrument and its co-located seismometer. The ash deposits here are from a 2008 eruption emanating from the cone in the background (courtesy of Jeff Freymueller)

GNSS signals also have been used to detect volcanic ash clouds in the atmosphere. The presence of dense ash clouds can have two possible impacts on the GNSS signals and positions. First, there can be a signal path delay through the ash cloud that is large enough to bias kinematic positions, and which can

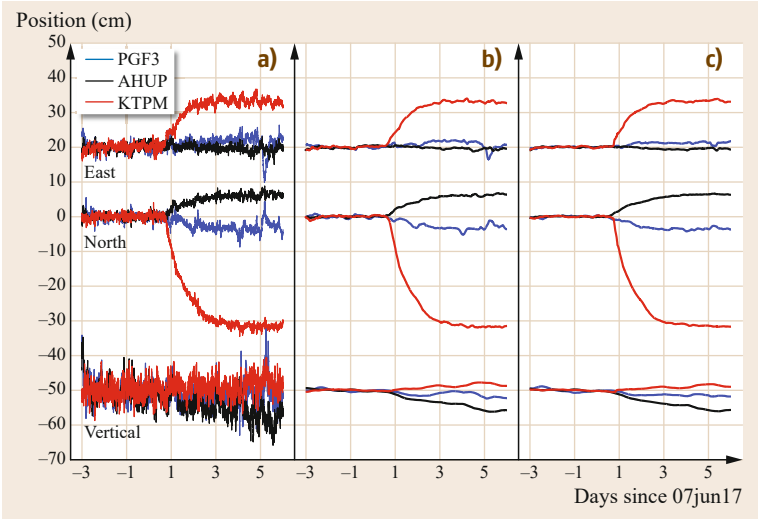

**Fig. 37.20a–c** Kinematic GPS position records for three stations (PGF3, AHUP, KTPM) from an intrusion of magma that preceded an eruption of Kilauea volcano, Hawaii, using three different kinematic estimation strategies (for a Kalman filter-based analysis). AHUP and PGF3 are relatively far-field stations north and south of the intrusion, while KTPM is located close to the intrusion. **(a)** Shows the positions estimated with a white noise model (independent positions each epoch), while **(b)** shows the same data but a random walk process noise model applied to the positions. **(c)** Is the same as the center panel but with gradients in the tropospheric delay also estimated (after [37.123], courtesy of John Wiley and Sons)

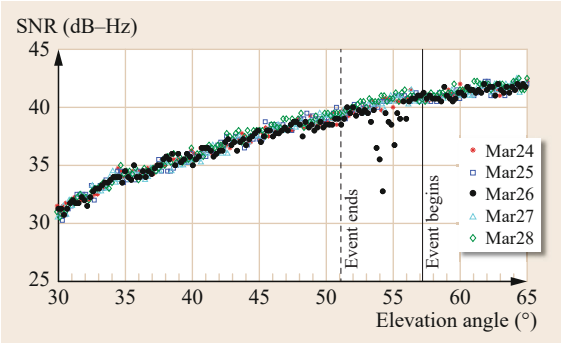

**Fig. 37.21** Detection of volcanic ash through signal to noise ratio (SNR) variations. The *colored dots* show SNR values for the same part of the sky on several days, each shown with a different color. The eruption occurred on March 26 (*black dots*), and while the eruption plume is in place there is a period of time for which the SNR is substantially lower than normal as the signal is attenuated by passage through the plume (after [37.124], courtesy of John Wiley and Sons) ►

be detected through its impact on tropospheric path delay estimates [37.125]. The path delay most likely occurs because ash clouds can contain large amounts of water vapor. Signal paths that travel through the plume thus show substantial propagation delays relative to paths that do not. Second, the ash in the plume scatters and attenuates the GNSS signal, and can be detected through its impact on the SNR [37.124]. *Larson* [37.124] examined eruptions of Okmok and Redoubt volcanoes in Alaska, and showed that the effect of the plume could be seen through a temporary drop in SNR reported by the receiver (Fig. 37.21). One advantage of this approach is that no positioning solution is needed; the plume detection can be made based on the SNR variations reported by the receiver, which means it could be done in real time if data are available.

## 37.7 Surface Loading Deformation

This section discusses loading deformation at periods greater than daily, although the methods of computing loading deformation due to the ocean tides are identical to those used for other elastic loads. Although this section focuses on timescales longer than daily, it is essential that subdaily loading variations be correctly modeled in the GNSS processing (Sects. 2.3.5 and 25.2.3 of this handbook). Errors in modeling subdaily loading will be aliased into longer time periods, and can produce systematic periodic biases in displacements at fortnightly, semiannual, and annual periods, which might be erroneously interpreted as due to loading variations at those periods [37.126, 127].

Surface loads, such as surface water, ice, or snow, exert forces on the surface of the Earth, which cause the Earth to deform. The response of the Earth depends on the timescale for changes in loading, being elastic at short periods and viscoelastic over long periods of time. Which response is most important depends on both the spatial scale of the load and its temporal behavior. Spatially large loads cause stress changes deep within the Earth, and thus cause viscous flow more readily than spatially small loads. However, regardless of spatial scale, an elastic response is expected if the characteristic timescale of the loading variations is short compared to the viscoelastic relaxation time of the viscoelastic material. In practice, this means that loading variations at seasonal or shorter timescales can be safely treated as an elastic problem, while load changes over years to decades might result in either an elastic or viscoelastic response, depending on the local viscosity structure. Load changes over hundreds of years or millennia, such as the load changes due to deglaciation, always require a viscoelastic model.

### 37.7.1 Computing Loading Displacements

Loading displacements can be computed in two general ways. For a point load or a load of a given shape and size, for example, a disk of a given radius, a Green's function can be computed to describe the surface displacements everywhere due to a load of unit size. The Green's function depends on the elastic or viscoelastic structure of the Earth and the spatial dimension of the load. More complex loads can be computed by superposition of multiple Green's functions. This approach is simplest when the load can be described by a small number of simple shapes, or if the load is given in the form of a gridded data set.

If the load is instead given as a sum of spherical harmonic basis functions, for example, a surface load model derived from GRACE spherical harmonic solutions, then the loading response can be computed easily using Love's loading theory [37.128]. Gravity changes, surface load changes, and surface displacements are all related via potential theory and elastic loading theory. The relationship between gravity and surface loads is derived from the principle of Green's

equivalent layer [37.129]. The gravity field (measured externally) can be represented mathematically as being caused by a thin layer of varying surface density at the surface of the Earth. In the case of surface loading, the surface layer refers to the time variations in the gravity field, and these are naturally visualized as arising from a thin surface layer of *load* that represents the variations in the mass of the hydrosphere and atmosphere. The same spherical harmonic coefficients (Stokes coefficients) describe the mass of the load, its contribution to the gravity field, and the surface displacements caused by the load. The spherical harmonic coefficients for surface loads derived from GRACE observations or from hydrological and atmospheric models [37.130] are thus directly related to the loading displacements.

Displacement in height can be expressed in terms of spherical harmonic coefficients for the changes in the surface load and the load Love numbers [37.128]

$$\Delta h = \frac{3R\rho_\mathrm{w}}{\rho_\mathrm{e}} \sum_{l,m} \frac{1}{2l+1} h'_l P_{lm}(\cos\theta) \times (\Delta C_{lm} \cos m\phi + \Delta S_{lm} \sin m\phi) \,, \qquad (37.10)$$

where $R$ is the average Earth radius, $\rho_\mathrm{w}$ and $\rho_\mathrm{e}$ are the density of seawater ($1025\,\mathrm{kg/m^3}$) and the average density of Earth ($5517\,\mathrm{kg/m^3}$), respectively, $P_{lm}$ are fully normalized associated Legendre functions for degree $l$ and order $m$; $\Delta C_{lm}$ and $\Delta S_{lm}$ are spherical harmonic coefficients of the variations in the surface load, and $h'_l$ is the load Love number for degree $l$, and $(\theta, \phi)$ are colatitude and longitude. In this case, fully normalized means that the spherical harmonic functions, including the cosine and sine terms, are fully normalized for integration over the sphere. The key element of this equation is that, for a load that has the spatial form of a spherical harmonic basis function, the displacement is proportional to the load, with the load Love number giving the constant of proportionality. Load Love numbers depend only on the elastic structure of the Earth and are provided by *Farrell* [37.131] and other authors for various Earth models. Similar equations are used for the horizontal displacements [37.132].

A more complete description of the mathematical theory for elastic and viscoelastic loading computations can be found in other sources, for example, [37.133]. The solution for the viscoelastic problem can be derived from the solution for the elastic problem using the correspondence principle. When the load is represented in spherical harmonic basis functions, the viscoelastic problem has a similar form to (37.10), except that the Love numbers are a function of time. In detail, there are a variety of computational methods used to solve viscoelastic loading problems for GIA, using different approaches to compute the deformation rapidly and accurately. A recent benchmarking study that illustrates the variety of software developed for the problem, and assesses their computational accuracy, is given in [37.134].

### 37.7.2 Examples of Loading Displacements in GNSS Studies

The elastic structure of the Earth is known very well independent of geodesy, so loading models and GNSS displacements should agree with each other well. However, systematic errors in the GNSS position time series or in the loading models will result in misfit, and loading effects can bias reference frame realization, as loading deformation can be aliased into frame transformation parameters [37.28, 135, 136]. *Heki* [37.137, 138] demonstrated that seasonal deformation in Japan could be explained primarily in terms of snow loading. *Dong* et al. [37.139] assessed seasonal deformation globally and found that about 40% of the variations could be explained in terms of loading variations. *Blewitt* et al. [37.140] used the IGS network to detect global degree-1 deformation associated with seasonal inter-hemispheric mass transport.

Before about 2009, more detailed comparisons between loading model predictions and GNSS coordinate variations did not agree very well. *Van Dam* et al. [37.130] did such a comparison for Europe, and found poor agreement between observed and predicted displacements outside of a few areas with very large loading signals. They suggested that the discrepancies were mainly caused by systematic errors in the GNSS time series. GNSS time series based on systematically reprocessed data show much better consistency with the predictions of loading models, so it is now clear that these systematic errors have been reduced. Recent work in several areas of large magnitude surface loads has shown very good agreement (Fig. 37.22) between seasonal load models or GRACE observations and GNSS coordinate variations [37.132, 141–144].

Loading displacements can be extremely large. Seasonal vertical displacements in the Amazon basin have an amplitude of as much as 40 mm, $\approx 80$ mm peak to peak, and are described well by loading models based on GRACE [37.145]. Even horizontal GNSS displacements there are coherent and in agreement with the loading model predictions [37.132]. Seasonal displacements in West Africa [37.142], the Himalaya [37.143], and Alaska [37.144] have amplitudes of 10–20 mm, while displacement due to river loads in Bangladesh can approach 30 mm amplitude [37.146].

Care must be taken in comparing GNSS displacements to a loading model, depending on what components are removed in the processing of the data.

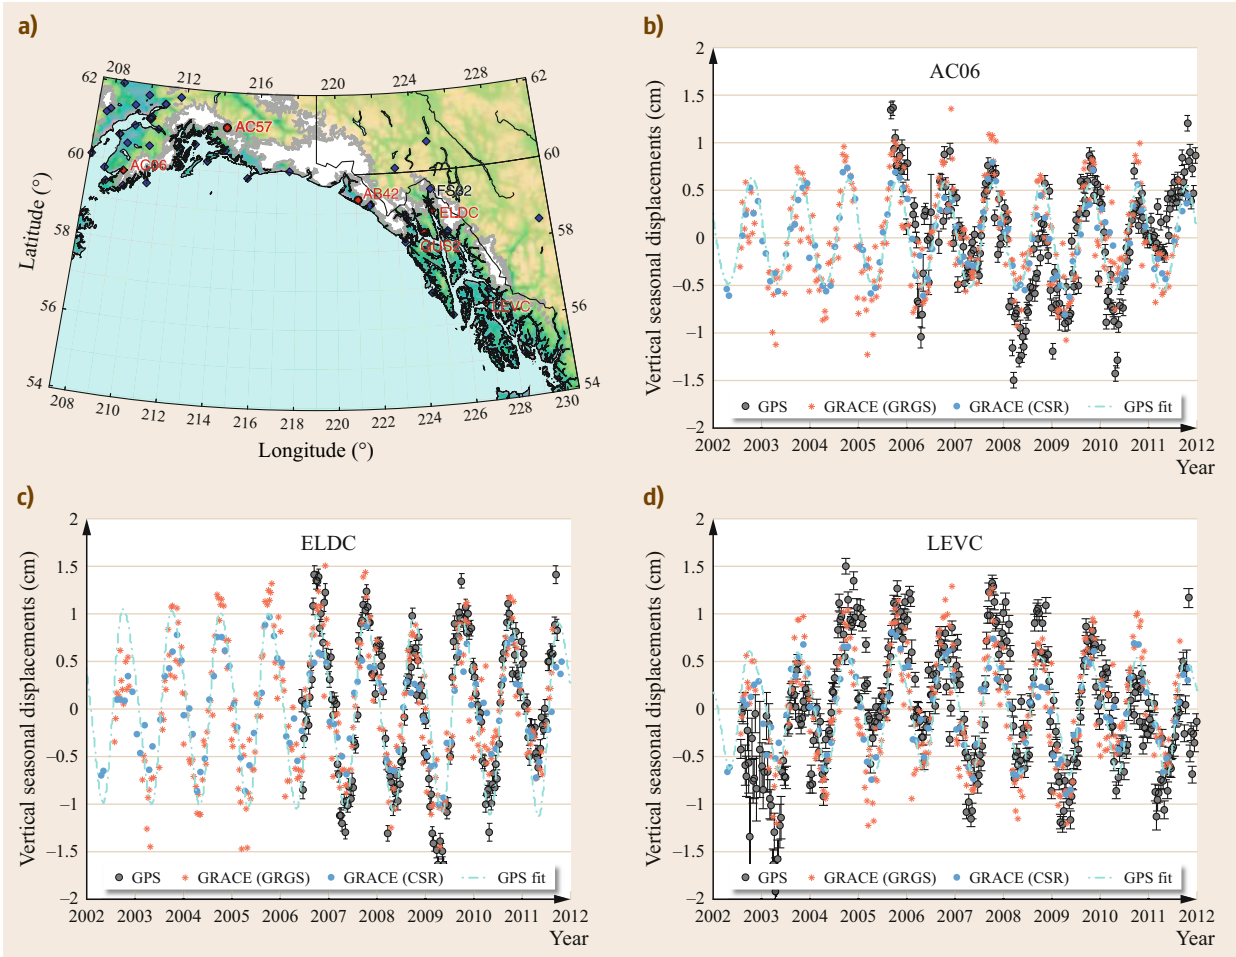

**Fig. 37.22a–d** Comparison of GPS observed and GRACE predicted seasonal displacements for three sites in Alaska (after [37.144]). Sites are labeled on the map in **(a)**. **(b–d)** *Black dots* are 10-day averaged GPS height estimates, *red dots* are the predictions of a GRACE model based on the GRGS analysis center, and *blue dots* based on the CSR/University of Texas analysis center. All time series have been detrended. Different GRACE solutions show only minor differences in predicted displacements, and agree with GPS in amplitude and phase of the seasonal signal, and also in interannual variations. The AOD1B antialiasing model has been added back to the GRACE solutions, so all time series show loading due to the sum of continental hydrology, atmospheric pressure and nontidal ocean variations (after [37.144], courtesy of John Wiley and Sons)

For example, many GRACE loading models represent continental hydrology only, as atmosphere and ocean loading effects have been removed in the GRACE processing. In order to compare these models to GNSS time series, either atmospheric and ocean loading effects must be removed from the GNSS positions, or they must be added back into the GRACE model by adding the AOD1B antialiasing model. See [37.147] or [37.144] for a full discussion and examples. Removing atmospheric and ocean loading deformation from the GNSS positions is the logical approach when the goal is to use the displacements to study continental hydrology. Adding the AOD1B antialiasing model back to the GRACE gravity fields is the logical approach when the goal is to compare the total loading displacements between the two geodetic measurement systems.

### 37.7.3 Loads and Load Models

The following subsections briefly describe the models available for different loading components. Time series of load models and predicted displacements for many loading sources can be found at the Global Geophysical Fluid Center (GGFC) [37.148].

#### Nontidal Ocean Loading

Nontidal ocean loading refers to the loading due to nontidal oceanic mass redistribution, such as seasonal changes in freshwater runoff, sea surface height, salinity, or variations in oceanic dynamic topography due to changes in currents, winds, and so on. For sites near the coasts, this can be a significant cause of deformation. Nontidal ocean loading models are based on global ocean bottom pressure models such as the ECCO model [37.149].

#### Atmospheric Loading

Atmospheric pressure loading is due to spatial variations in atmospheric pressure acting on the surface of the Earth. Pressure variations can occur rapidly, changing substantially over a matter of hours, but can also be relatively stable over much longer time periods (several days) in some places. *Bevis* et al. [37.147] demonstrated in the case of Greenland that the average seasonal variation in atmospheric pressure is large enough that it contributes nearly as much to the seasonal position variations as the seasonal mass variations of the Greenland ice sheet. However, outside of the polar latitudes, atmospheric pressure loading is dominated by short-term load variations. Data for the atmospheric pressure variations usually come from operational or reanalysis products such as the NCEP reanalysis product, or equivalent from the European Centre for Medium Range Weather Forecasting (ECMWF). A method for computing the deformation from atmospheric pressure loading was proposed by *van Dam* and *Wahr* [37.150]. They accounted for pressure variations within $\approx 1000\,\mathrm{km}$ of the station, and assumed an inverted barometer response of the oceans to atmospheric pressure.

Some researchers have proposed that atmospheric pressure loading should be removed from GNSS and other geodetic time series on a routine basis because global atmospheric pressure variations are well known from global atmospheric models. Doing so will remove some short-term noise in the time series, and some of the seasonal variation in parts of the world that have a strong seasonal cycle in average atmospheric pressure. However, removing atmospheric pressure loading alone may leave large loading variations still in the position time series, because atmospheric loading usually is not the dominant component of the load model.

#### Continental Hydrology Loading

A variety of models for continental hydrology are now available. Development and validation of such models are an active area of research, especially given the critical new constraints on long-wavelength movements of continental surface water that come from the GRACE mission. Some of the available models for continental water storage include the GLDAS model [37.151], WGHM (WaterGAP Global Hydrologic Model) from the University of Kassel and University of Frankfurt, and MERRA-Land from NASA Goddard [37.152]. Geodesists are actively using and evaluating all of these models. *Li* et al. [37.153] found that MERRA produced better agreement with GPS seasonal variations than GLDAS (they did not evaluate WGHM).

### 37.7.4 Impacts of Loading Variations on Reference Frame

Seasonal variations are not included in the ITRF, although they are present in GNSS time series. Unmodeled seasonal variations at sites used for reference frame alignment are aliased into the reference frame parameters and can bias all coordinates in the transformed solution. As a result, real seasonal variations at sites used for reference frame alignment affect coordinate time series at a seasonal timescale. Ignoring true seasonal variations will bias both the reference frame parameters and the coordinates of all sites. *Collilieux* et al. [37.135] investigated this problem extensively, using a suite of forward models and studies on synthetic data sets, mainly from the point of view of methods to mitigate the aliasing of seasonal variations into global terrestrial reference frame (TRF) parameters. They concluded that the impacts of loading variations are significant, and the reference frame aliasing effect can exceed the millimeter level in coordinates and larger than that in frame parameters.

Future reference frame models might include standard conventional models to approximate the displacement due to loading on a seasonal or other basis. If so, it is not yet clear what models would be chosen to represent these displacements. *Zou* et al. [37.22] showed that a seasonal augmentation to the ITRF is needed in order to make an accurate comparison of GPS time series and loading models, and that use of ITRF2008 without seasonal terms causes the amplitude of seasonal variations in the coordinate time series to be damped down relative to the true loading deformation. Furthermore, *Zou* et al. [37.22] compared a loading model based on GRACE to the suite of forward models used by *Collilieux* et al. [37.136]. The model based on GRACE performed substantially better, although performance over most of North America was similar to the forward models. It is likely that deficiencies in the continental hydrology models in areas of limited terrestrial data are responsible for this difference.

### 37.7.5 Glacial Isostatic Adjustment (GIA)

Great ice sheets covered much of the northern parts of North America and Scandinavia until the LGM, about 23 000 years ago. At that point, the ice sheets began to disintegrate due to a warming climate, and were largely gone by 8000–10 000 yr ago [37.154, 155]; the Greenland and Antarctic ice sheets remain but also have lost mass since LGM. The mass of the ice sheets depressed the surface and induced stresses that caused the mantle to flow way from the loads, even at great depths. Upon retreat of the ice sheets, the process was reversed and the mantle is still responding to the load changes caused by deglaciation, resulting in a significant GIA deformation signal. Note that the load changes include both the loss of ice in glaciers and ice sheets, and the increase of water in the oceans. In Scandinavia and the Hudson's Bay region, present-day uplift rates are on the order of 10–12 mm/yr [37.30, 41, 156]. GNSS has become an essential tool for studying the response to these past ice changes, and for quantifying present-day ice mass changes globally.

The most rapid GIA uplift rates today arise not from the areas formerly covered by the great ice sheets, but from areas with regional ice masses (glaciers and ice fields) that have been losing mass recently. Ice mass loss in Alaska and surrounding parts of Canada in North America and in Patagonia in South America has been large enough since the end of the little ice age (LIA) $\approx 200$ years ago to account for 10–20% of twentieth century global sea level rise over that time [37.159–162]. In both of these regions, measured uplift rates exceed 30 mm/yr at their peak, and significant uplift has been observed in a broad area surrounding the regional ice fields. In Alaska, the observed uplift depends significantly on both the ongoing regional ice mass loss and the nineteenth century deglaciation of Glacier Bay [37.163]. The former source has important elastic and viscoelastic components, while the latter is purely a viscoelastic response, because the main ice loss in Glacier Bay occurred more than a century ago.

#### GIA from Last Glacial Maximum

The BIFROST project [37.31, 156, 157] began continuous GPS measurements in Sweden and Norway in 1993 to study GIA, tectonics, and sea level change across the former extent of the LGM Fennoscandian ice sheet. The network later expanded to cover Finland and other countries around the Baltic Sea, and the sites eventually became part of the national networks for positioning and mapping.

*Lidberg* et al. [37.31] summarized the results based on 13 years of continuous GPS data, beginning with data from mid-1996 (Fig. 37.23a). Their velocity solution had an internal consistency as good as 0.2 mm/yr for horizontal velocities. Their preferred *realistic uncertainty* estimate (based on a feature of the GAMIT software) was, typically, a factor of 2–3 larger than an estimate based on a white noise assumption, and horizontal uncertainties were commonly $< 0.1$ mm/yr with vertical uncertainties commonly $< 0.3$ mm/yr. Independent analyses of the data using GAMIT and GIPSY agreed at the 0.1–0.2 mm/yr level. They found that the data (Fig. 37.23a) could be explained by a GIA model (Fig. 37.23b) with a misfit at the level of (0.2, 0.3, 0.3 mm/yr) for the (east, north, and vertical) components, respectively, once a 0.9 mm/yr vertical bias between the observations and the model was removed (the GPS vertical velocities were larger than the model). This estimated frame bias is within the range of the values estimated later for the frame origin bias in ITRF, discussed in Sect. 37.1.3. Their optimal GIA loading model featured a 120 km thick elastic lithosphere and a two-layer viscoelastic mantle. The viscosities of the mantle layers were $5 \cdot 10^{20}$ Pa s for the upper mantle and $5 \cdot 10^{21}$ Pa s for the lower mantle, which is very similar to the VM2 and VM5a models [37.164, 165] shown in Fig. 37.24.

Compared to Scandinavia, a smaller GNSS data set is available for study of the Laurentide ice sheet in North America, at least in terms of stations located above the main loading center in northern Canada. However, there are many sites located near the southern edge of the LGM ice sheet in the United States. *Sella* et al. [37.41] produced a velocity field of 362 GPS sites, of which 123 were campaign sites of the Canadian Base Network with several occupations over an 11 year span, and the remainder continuous sites. Vertical velocities due to GIA in Eastern North America are, roughly speaking, uplift in Canada over the former LGM ice sheet, and subsidence in the United States over the formerly uplifted forebulge.

Although the GIA signal is much larger in the vertical component than in the horizontal (Fig. 37.23), in North America the region with significant horizontal deformation due to GIA is quite substantial. *Sella* et al. [37.41] used their vertical velocity field to mask out sites likely to have significant horizontal motion due to GIA so that they could estimate the angular velocity of the North American plate without bias due to the GIA horizontal deformation. Horizontal displacements from different mantle viscosity structures are quite different, but horizontal displacements are also very sensitive to lateral variations in the Earth structure [37.166]. In addition, the long length scale of the deformation can make it difficult to isolate the relatively small horizontal GIA signal from plate motions. These factors have

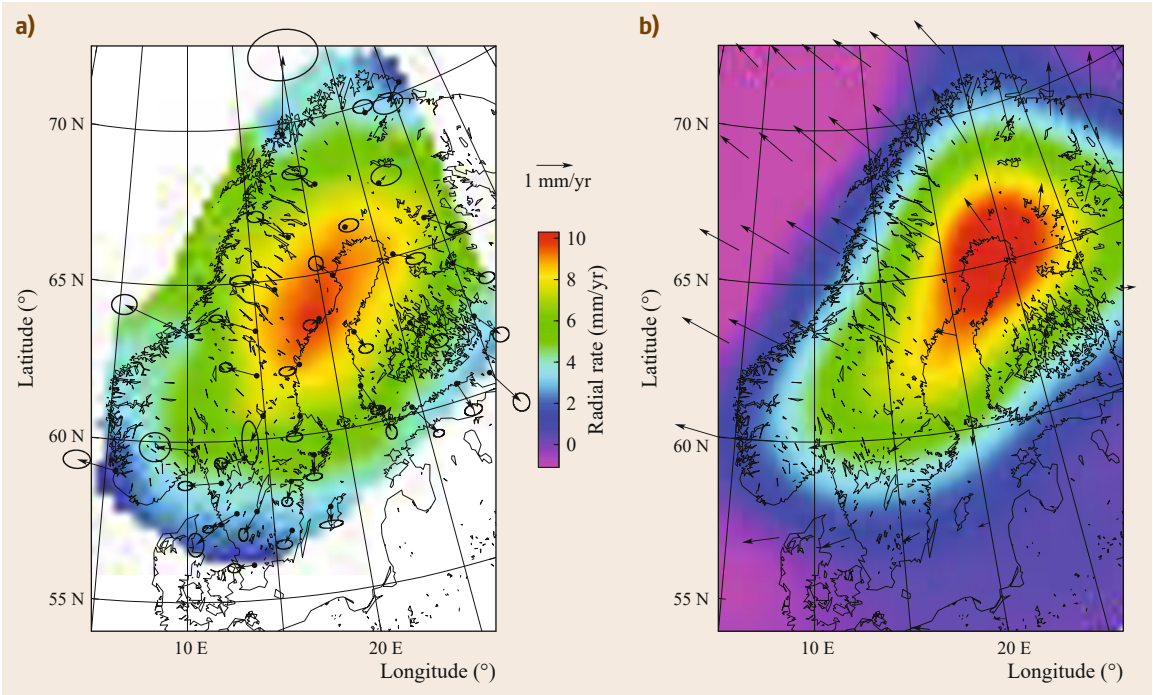

**Fig. 37.23a,b** Observations and model predictions for GIA for Scandinaivia, using the BIFROST solution of (after [37.157]). **(a)** Horizontal velocities relative to the Eurasian plate (*arrows*, with 95% confidence *ellipses*), and vertical velocities (*background color*). **(b)** Model predictions based on the ICE-3G ice model (after [37.158]), with lithosphere thickness 120 km, upper mantle viscosity $5 \cdot 10^{20}$ Pa s, and lower mantle $8 \cdot 10^{21}$ Pa s (after [37.40])

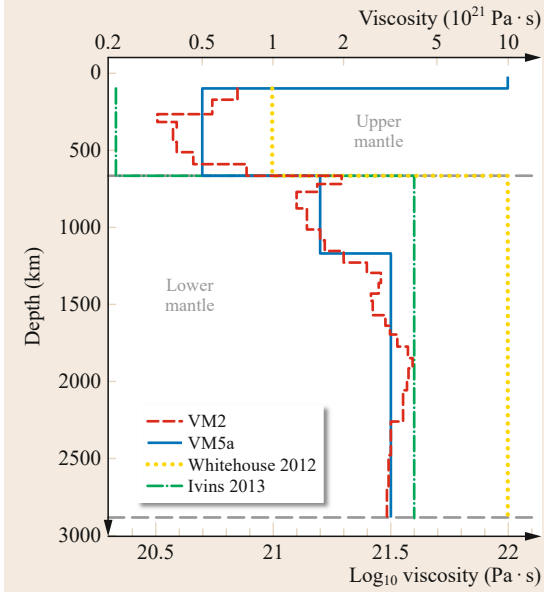
**Fig. 37.24** Viscosity structure for several mantle viscosity models. Models for low viscosity regions like Alaska, Patagonia and the Antarctic peninsula are similar at depths greater than 300 km, but require a thin (50–60 km) elastic lithosphere and an asthenospheric viscosity 1–2 orders of magnitude lower than models shown here (after [37.165], courtesy of Oxford University Press) ►



made the comparison of horizontal GIA observations and models challenging and subject to vigorous debate.

### Post-Little Ice Age (LIA) GIA in Alaska and Patagonia

Glaciers in the coastal mountains of Alaska (USA) and British Columbia (Canada) began losing enormous amounts of ice approximately 200 years ago, after the end of the little ice age (LIA). The uplift and ice unloading history there are constrained by observations of glacial moraines and trimlines, raised geomorphic shorelines, tide gauge, and GPS observations [37.163]. Of particular note is the deglaciation of Glacier Bay in southeast Alaska; this one glacial system lost 3030 $km^3$ of ice, mostly during the nineteenth century [37.163]. Ice loss across the entire region in the twentieth century remained rapid, and *Berthier* et al. [37.162] estimated that Alaskan glaciers lost $1800 \pm 360$ $km^3$ of ice over 1962–2006, based on differencing of digital elevation models. That rate was probably sustained over the first

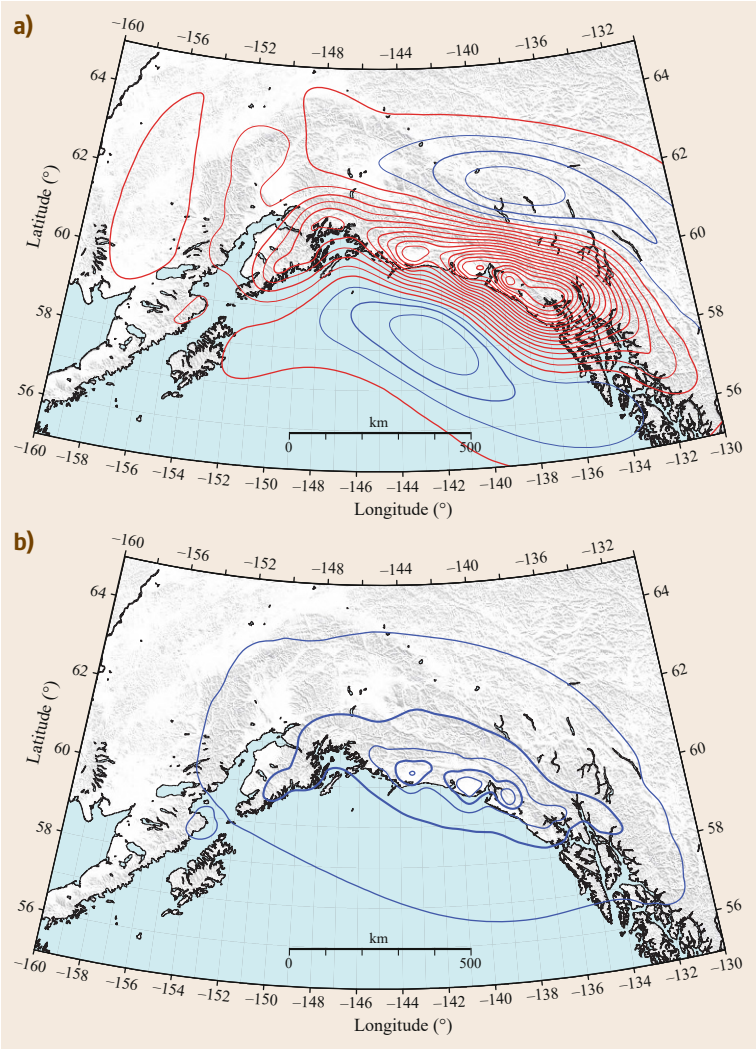


**Fig. 37.25a,b** Alaska GIA model uplift rates and geoid rates (after [37.58]). **(a)** Uplift and subsidence rates. Contour interval is 2 mm/yr, with *red contours* indicating uplifting regions and *blue contours* representing subsiding regions. **(b)** Geoid change rates, neglecting the redistribution of seawater. Contour intervals are 2 mm/yr, with the same color scheme as the vertical motion rates

half of the twentieth century as well, and accelerated over the last two decades [37.163].

These large ice losses cause extremely rapid uplift rates, which have been observed by repeated GPS measurement since the late 1990s. Because the ice loading model and the Earth response are both known, these data can be used to estimate the viscosity structure of the Earth. While the Laurentide and Fennoscandian ice sheets were emplaced on very old, cold, and rigid continental shields, the Earth structure beneath coastal Alaska is very different. This region was a subduction zone for a long time, until ≈ 30–50 million years ago, and is characterized by a thin elastic lithosphere (≈ 50 km) and a low viscosity upper mantle, 110 km thick and $3.7 \cdot 10^{18}$ Pa s [37.58], about two orders of magnitude less than the viscosity inferred at that depth from the large continental ice sheets (Fig. 37.24). The low viscosity is probably due mainly to hydration of the mantle caused by the long period of subduction. The low viscosity means that the mantle flow occurs much more rapidly than for a higher mantle viscosity, producing faster uplift rates for a shorter length of time. Due to the length scale of the regional Alaska load, the present-day response is very sensitive to the relaxation of this shallow, low viscosity mantle layer, and provides little information about the deeper mantle. *Larsen* et al. [37.163] fit the GPS velocities to such an Earth model, and demonstrated that the model could fit both the total uplift over the last two centuries and the present-day uplift rates.

*Elliott* et al. [37.58] provided an updated version of this model (computed to spherical harmonic degree and order 2048), and the predicted model uplift rates and geoid change rates are shown in Fig. 37.25. Uplift rates

exceed 30 mm/yr in several places, and geoid change rates exceed 5 mm/yr. These calculations do not take into account the impact of redistribution of seawater due to the changing gravity field, which given the scale of the load has only a small impact on the vertical velocities. However, it may have a larger effect on the geoid change rate, so the values shown in Fig. 37.25b are lower bounds on the magnitude of the geoid change rate.

The Patagonian icefield in South America also experiences rapid rates of ice loss, although with less overall mass change than coastal Alaska [37.167]. Accordingly, uplift rates there are also extremely rapid, and the peak uplift rate observed in Patagonia even exceeds the most rapid rate reported for Alaska [37.169]. The tectonic setting and Earth structure for Patagonia is similar to that of Alaska, and the estimated viscosity structure is comparable as well [37.170, 171].

### Networks for the Study of the Present Ice Sheets

Over the last several years under the auspices of the POLENET (polar Earth observing network) project, extensive networks of continuous GNSS sites have been established to measure changes in the polar ice sheets in Antarctica and Greenland (Fig. 37.26). A few stations had been installed in Greenland and Antarctica by the mid-1990s, but a major expansion began around 2007, at the time of the international polar year. All of these networks represent broad international collaborations.

The Greenland GPS network (GNET) in Greenland (Fig. 37.26a) was installed mostly in 2007–2008, and has documented rapid uplift and variations in uplift rate that correlates with large-scale melting events on the Greenland ice sheet [37.147, 172]. The longest-running sites in Greenland also document clear evidence for a significant change in uplift rates in the early 2000s, which is related to a significant increase in overall mass wastage from the Greenland ice sheet [37.147, 173].

Rapid uplift rates from the Antarctic peninsula were reported by *Dietrich* et al. [37.174], although they were unsure of the significance of that result at the time, mostly because of concern about large vertical velocity uncertainties. *Thomas* et al. [37.175] analyzed GPS data from more than 50 stations across Antarctica, and estimated a more complete and precise vertical velocity field. On the Antarctic Peninsula, they found evidence for a significant increase in uplift rates after 2002–2003, which corresponded to the time of the breakup of the Larsen B ice shelf. The breakup of the ice shelf triggered acceleration and thinning of the tributary glaciers that feed into it [37.176, 177], which in turn resulted in

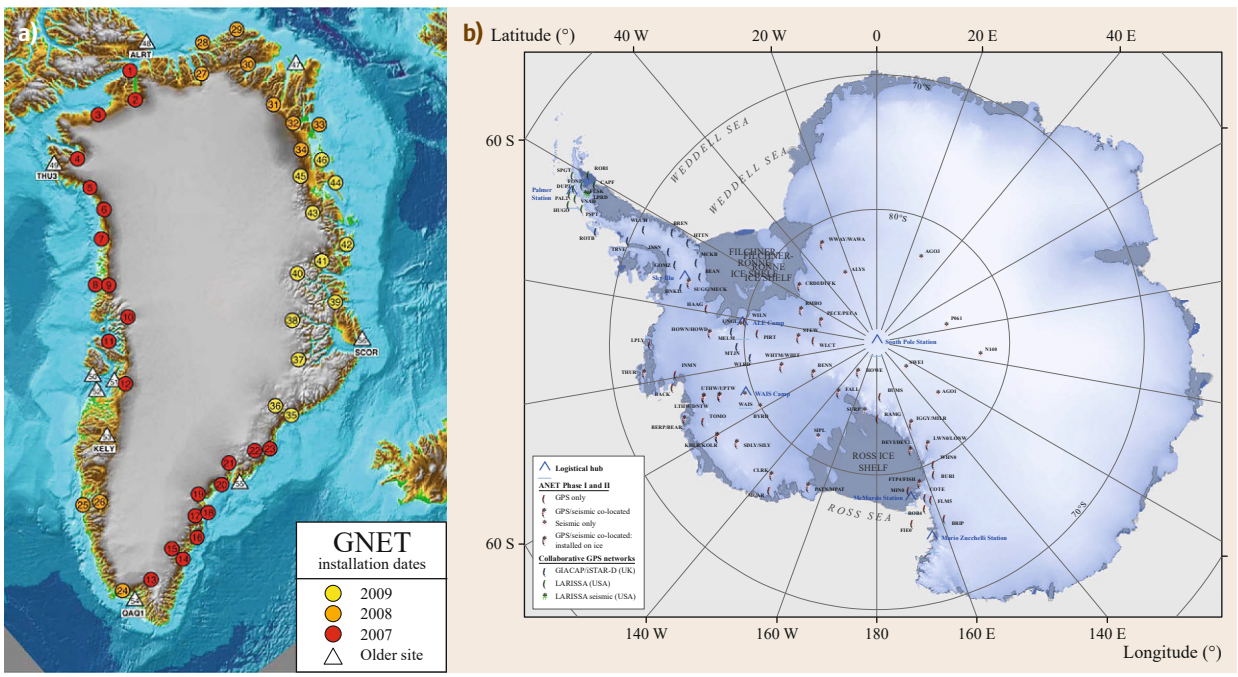

**Fig. 37.26a,b** Maps of recently installed continuous GNSS networks to study changes in the polar ice sheets. **(a)** GNET in Greenland, with sites color coded based on their installation date. **(b)** A-NET in Antarctica, with symbols indicating subnetworks from different contributing organizations. A-NET includes seismic installations as well (after [37.168], courtesy of the POLENET project)

more rapid uplift [37.178]. *Nield* et al. [37.178] added data from six additional continuous GNSS stations to the data set from [37.175] and developed a GIA model to explain the observed uplift rates. They found that the upper mantle viscosity was in the range of $6 \cdot 10^{17}$–$2 \cdot 10^{18}$ Pa s, making the Antarctic peninsula another example of a low viscosity region.

Several GIA and viscosity models exist for the main body of Antarctica, and some of the viscosity models are shown in Fig. 37.24 [37.165, 179–181]. These models differ considerably (Fig. 37.24), because constraints on the loading history are quite limited, which means that both the viscosity structure and loading history must be determined mainly from the present-day uplift rates. This leaves the problem poorly constrained, with differences in load changes since LGM differs by as much as 70%. Models that have higher viscosities also have larger ice load changes, to produce comparable present-day deformation. However, in general we can conclude that the main body of Antarctica has a viscosity structure similar to the mid-continental structure found for the Laurentide and Fennoscandian ice sheets. Uncertainties in the magnitude of the GIA signal due to post-LGM deglaciation are of critical importance in the correction of GRACE gravity change data to measure present-day ice mass balance.

## 37.8 The Multi-GNSS Future

The examples shown in this chapter have all come from a single GNSS system, GPS. Thus far, with the demanding levels of precision and accuracy required for geodynamic applications, GPS+GLONASS solutions have not been demonstrated to be superior to GPS-only solutions. However, this may change with improved Russian Global Navigation Satellite System (GLONASS) modeling, and with the upcoming GLONASS-K2 constellation, which will broadcast code division multiple access (CDMA) signals, more like GPS. Soon, other GNSS systems such as Galileo and Beidou will be equally mature. Details of the various GNSS constellations are given in Chaps. 7–11 of this handbook.

In the near future, multiple full satellite constellations will be available along with a global multi-GNSS tracking network and multi-GNSS orbit and clock products. What impacts can be expected on geodynamic studies? Three areas of impact seem likely:

1. Improvement of precision and accuracy through the addition of independent data.
2. Identification and reduction of systematic errors in GPS through comparison of multi-GNSS solutions.
3. A significant enhancement of kinematic and subdaily positioning capabilities resulting from the improved satellite geometry (more satellites in the sky, and in different parts of the sky).

The first benefit of additional mature multi-GNSS constellations will be the improvement of precision and accuracy through the addition of independent data. A solution using $N$ GNSS constellations with equal precision and accuracy should have its uncertainties reduced by a factor of $N^{1/2}$ relative to a solution using a single constellation. Improvements in combined multi-GNSS solutions could be larger than that, because estimates of parameters like the troposphere delay that are common to all constellations will be improved, and the greater number of simultaneous satellites in view will also help separate the tropospheric delay and vertical coordinate parameters.

It is likely that systematic errors due to mismodeling of various effects will impact solutions differently for different GNSS constellations. Thus, a careful comparison of independent GNSS solutions or a multi-GNSS combination solution will aid in the identification and reduction of these errors. For example, progress has been made in identifying the cause of the draconitic periodic errors in GPS solutions that were discussed in Sect. 37.1.3. However, even the most recent study of [37.18] did not eliminate these errors, which means that further modeling improvements are needed. Multi-GNSS solutions may reveal incompatibilities and errors in models that can then be addressed. Site-specific errors such as multipath may be different for different constellations, potentially allowing enhanced calibration and removal of such errors.

The improvement in kinematic and subdaily solutions using multiple GNSS constellations may be greater than the improvement in daily solutions. The primary reason for this is the enhanced observing geometry that results from having more satellites in view simultaneously. In general, multi-GNSS observations will provide data from satellites in different parts of the sky, so that multi-GNSS observations will have more uniform sky coverage at all times than a single constellation can provide. In addition to improved precision, the greater geometric strength and more uniform sky coverage will allow for enhanced estimation of tropospheric delays, which often must be modeled in a fairly simple fashion in kinematic solutions. Although the ultimate accuracy of future multi-GNSS kinematic positioning is not easy to predict, it is likely to be signif-

icantly better than kinematic positioning with a single GNSS constellation.

Considering all of the above factors, multi-GNSS solutions eventually should reduce the uncertainty of a daily GNSS position estimate to well below the 1 mm level for the horizontal, and to close to 1 mm for the vertical. This will aid in the detection and modeling of very small motions, and in distinguishing between models that make similar predictions. The improved precision will aid in the study of loading deformation and vertical motion relevant to sea level rise, which both involve small signals. It is likely that the improved precision and accuracy of future multi-GNSS systems will improve our ability to measure deformation processes and distinguish between competing geodynamic models, and it is possible that previously unrecognized motions and deformations of the Earth will be identified.

*Acknowledgments.* The author thanks Kimberly DeGrandpre and Shanshan Li for providing comments on an early draft from a student's perspective. Many figures in this chapter were created using the Generic Mapping Tools (GMT) developed and maintained by Paul Wessel, Walter H. F. Smith, Remko Scharroo, Joaquim Luis, and Florian Wobbe.

# 38. Monitoring of the Neutral Atmosphere

Gunnar Elgered, Jens Wickert

Global navigation satellite system (GNSS)-based atmosphere sounding techniques have become a widely recognized and operationally used remote sensing tool. A major milestone of this development was the beginning of the continuous use of GNSS data for improving regional and global forecasts in 2006. The principle behind these techniques is the utilization of atmospheric propagation effects on the GNSS signals on their way from the navigation satellites to receivers on the ground or aboard satellites. The atmosphere delays the time of arrival and introduces a curvature of the signal path. These effects can be accurately estimated and be used for the monitoring of the atmospheric variability. There are two different observation geometries. Therefore, we focus in the first part of this chapter on ground-based networks which are used to estimate the amount of water vapor above each receiver site. The second part deals with the use of radio occultation measurements from GNSS receivers aboard low Earth orbit satellites for global atmosphere sounding. We introduce and describe both techniques which provide observations suitable for the short-term weather forecasting and the long-term time series for climate research and monitoring.

This chapter deals with two distinctly different geometries: observations using ground-based global navigation satellite system (GNSS) networks and occultation observations from low Earth orbit (LEO) satellites. These are illustrated by the sketches in Fig. 38.1. In both geometries, the refractivity along the propagating path is determined by the atmospheric properties mainly in terms of pressure, temperature, and humidity.

The main application of the ground-based geometry is to infer the water vapor content above each receiver site on the ground. In principle, all the water vapor can be found within the troposphere, ranging from the ground up to 8–15 km. With a reasonable view of the sky, there will always be a sufficient number of satellites visible in order to have continuous time series of the estimated water vapor content.

The radio occultation (RO) geometry is more dynamic, since here both the transmitting GNSS satellites and the receiving LEO satellites are in continuous motion with respect to the atmosphere. When occultations occur, height profiles of the refractive index in both the troposphere and the stratosphere are retrieved.

Because of very different geometries, these two methods use different processing techniques and different algorithms in the data analyses. They also produce completely different data products. Therefore, we first

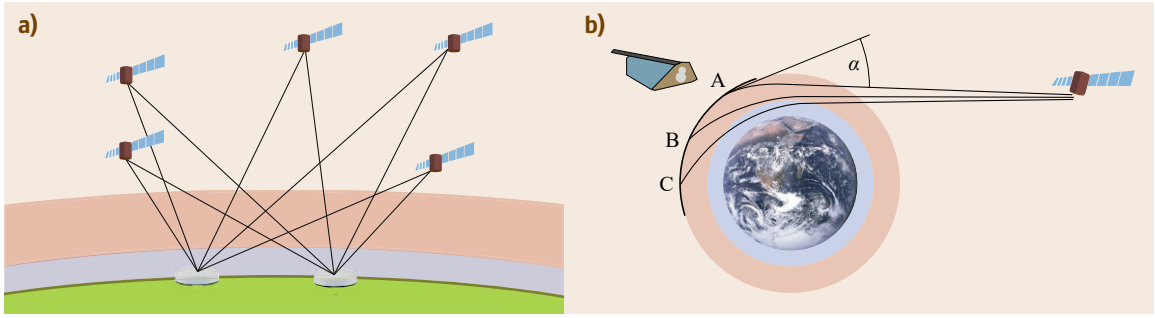

**Fig. 38.1a,b** Example geometries for ground-based observations (a) and ROs (b) of signals from GNSS satellites in a typical medium Earth orbit (MEO). The neutral atmosphere and the ionosphere are indicated by the *blue* and the *red* layers, respectively

discuss them separately. Applications of the remote sensing of the neutral atmosphere based on observations with ground-based networks are discussed in Sect. 38.1, while applications of GNSS receivers in LEO satellites are addressed in Sect. 38.2. The two geometries are of complementary nature, and their strengths for applications in forecasting and research related to atmospheric processes over different timescales, from turbulence phenomena to climate issues, are finally summarized in Sect. 38.3.

## 38.1 Ground-Based Monitoring of the Neutral Atmosphere

As described in Chap. 6, a GNSS signal from a satellite is delayed in the atmosphere compared to propagation in vacuum. The effect, often described as an excess propagation path, is estimated in the GNSS data processing. This means that using a receiver on the ground, it is possible to infer the integrated amount of water vapor (IWV) in the atmosphere.

Figure 38.2 summarize the possible use of GNSS data in three different types of applications. First, the GNSS data can be used as a standalone product, for example, for monitoring the IWV at a specific site over long time. Second, the GNSS data can be used to assess, or verify, the results from numerical weather models used in forecasting or climate research. Third, the GNSS data be combined with other data in order to increase the quality, for example, when assimilated into a numerical weather model in near-real-time weather forecasting.

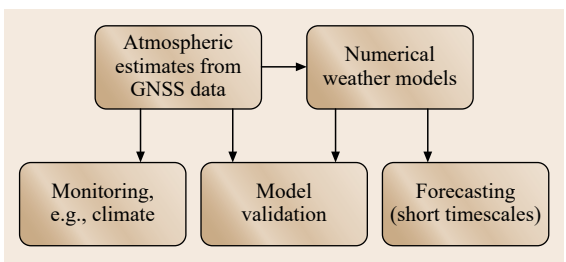

**Fig. 38.2** Block diagram illustrating possible applications of atmospheric estimates from GNSS data in meteorology and atmospheric research

In some applications, it can be a strength to estimate and to work with an integrated quantity, but, of course, for many other applications, profile information is necessary. For the ground-based geometry, the advantage is the accurate estimates of the IWV. This section focuses on this application, although attempts to retrieve profile information using tomographic methods is also discussed.

The radio-based space geodetic techniques of very long baseline interferometry (VLBI) and GNSS are affected by the atmosphere in terms of variations in the refractivity in the atmosphere which delays the time of arrival, the fundamental observable. It was shown in [38.1] and [38.2] that the estimated propagation delays from global positioning system (GPS) data, together with ground pressure observations, resulted in time series of the delays induced by the atmospheric water vapor, and they were in agreement with independent ground-based measurements from microwave radiometry.

The necessary background material needed in order to describe the estimation of propagation delays affecting signals, penetrating the atmosphere on their way to a receiver on the ground, is presented in Chap. 6. Let us here just repeat the basic definitions. The elevation dependence of the propagation delays is modeled by mapping functions, one for the hydrostatic delay and

one for the wet delay in the geodetic GNSS data processing. The end result is the equivalent zenith total delay (ZTD). The ZTD

$$Z_t = Z_h + Z_w \tag{38.1}$$

is hence the sum of the zenith hydrostatic delay (ZHD)

$$Z_h = 10^{-6} \int_{h_0}^{h_\infty} N_h(z)\, dz \tag{38.2}$$

and the zenith wet delay (ZWD)

$$Z_w = 10^{-6} \int_{h_0}^{h_\infty} N_w(z)\, dz\,, \tag{38.3}$$

which are obtained from the integration of the hydrostatic ($N_h$) and wet ($N_w$) refractivities along the vertical propagation path from the height $h_0$ of the receiver to a point $h_\infty$ outside the atmosphere.

With a sufficient number of observations in different directions during a defined time period, a refinement of just estimating an equivalent zenith propagation delay is possible. By defining linear horizontal gradients in the hydrostatic and wet refractivity profiles, an integrated parameter, normally referred to as the horizontal gradient, can be inferred. It was shown in [38.3] that by estimating horizontal gradients in the processing of GNSS data, the geodetic result improves significantly. It is today a common practice to estimate these gradients, although the use in meteorological applications has so far not been extensive. This potential will be further discussed later.

Another concept that occurs in the modeling of the neutral atmosphere is that of slant path delays. A simple method is to add the equivalent zenith delay and the estimated linear horizontal gradient and thereby model a specific delay in any given direction. The idea of adding, in addition, the residual delay toward each satellite from the GNSS data processing has also been proposed but shown to be wrong in the sense that systematic errors are introduced [38.4]. Instead, additional atmospheric parameters have to be estimated simultaneously, for example, by introducing tomographic methods.

### 38.1.1 Accuracy of Propagation Delays

Before describing the different applications of ground-based GNSS meteorology, we will review the error sources that determine the quality of the input data, that is, the estimated ZTD as described in Chap. 6. The uncertainty of these excess propagation delays depends on several effects. Here, we review the relative importance of the type of mapping function used, mismodeling of ionospheric effects (Chaps. 6 and 39), and effects caused by antennas and signal multipath.

#### Mapping Functions

The mapping functions define the elevation dependence of the hydrostatic and the wet delays, and are, therefore, an important parameter when estimating the atmospheric effect in the data processing. The development of more and more accurate mapping functions is described in Sect. 6.2.4. Many qualitative comparisons of mapping functions have been carried out over the years. Most mapping functions perform very well at high elevation angles, so when analyzing the accuracy of mapping functions, it is most interesting to focus on the results that are obtained at the lowest elevation angles, where the accuracy of the functions is decreasing. This means that, for each application, there is an optimum elevation cutoff angle. Low-elevation observations improve the geometry and reduce the formal error of the ZTD, but, at the same time, they introduce larger mapping function errors.

The *Niell* mapping function (NMF, [38.5]) has often been used due to its simplicity. It does not require any additional meteorological data; it only requires the location of the site and the time of the year. The size of uncertainties involved can be assessed by comparing the estimated ZTD using different mapping functions. As an example, a mean reduction of the ZTD of −2.6 mm was observed for 12 sites in Antarctica when changing from the NMF to the Vienna mapping function (VMF1) using elevation angles down to 7° [38.6].

Depending on the application, the need to include observations at low-elevation angles will vary. This is discussed later and now we just note that the choice of the mapping function is more or less irrelevant for GNSS meteorology if it is going to be used with observations acquired at elevation angles above say 15–20°.

#### Mismodeling of Ionospheric Effects

The accuracy of the ionospheric model used in the GNSS data processing affects the accuracy of the ZTD. Errors in the modeling of the signal delays caused by the ionosphere are more or less absorbed into the delays estimated for the neutral atmosphere, that is, the ZTD. To the authors' knowledge, no study has been directly focused on the accuracy of the estimated ZTD for different methods to correct for the ionospheric influence. However, there have been studies addressing the accuracy of the estimated position for different methods of handling the ionosphere. There is a strong correlation between the estimated vertical coordinate and

the estimated ZTD. A relative error in the ZTD is approximately three times smaller than the error in the estimated vertical position. The factor depends on the geometry, in terms of the elevation cutoff angle used for the observations [38.7]. Therefore, studies on the influence of the ionospheric model on the estimated site position indirectly provide information on the accuracy in the estimated ZTD.

The inclusion of higher order terms in the ionospheric model showed a systematic effect at the level of several millimeters in the station positions [38.8]. Later a more accurate model of the International Geomagnetic Reference Field (IGRF) was used [38.9]. Different models for the geomagnetic field have also been studied in [38.10], resulting in the recommendation that corrections for higher order ionospheric effects shall be included, particularly in equatorial regions and over periods of solar maximum when the ionosphere is more active. Given the 11-year-long solar cycle, it is reasonable to assume that the recommendations from such studies will depend on the timescale of the application.

#### Antenna Phase-Center Variations

Antenna phase-center variations exist both at the satellite antenna and at the receiving antenna on the ground. It has been shown that phase center variations (PCVs) (Chap. 17) have a significant influence on the estimated delay in the neutral atmosphere [38.11], and hence also on the IWV. The variation depends on the nadir angle from the satellite to the ground or, equivalently, the elevation angle of the satellite seen from the ground. The main effect is a bias-type of error but will, of course, change with changing geometries. Recommendations for modeling antenna PCVs exist (Chaps. 19 and 25) and shall be used in order to reduce their influence. Proper modeling of PCVs is especially relevant for climate-related applications investigating (small) long-term trends in the IWV. An assessment of the effect caused by the introduction of new GPS satellite types with different antenna phase patterns revealed an artificial trend of up to roughly $0.15\,\mathrm{kg/(m^2\,year)}$ for the estimated IWV over a five-year period [38.12].

#### Signal Multipath

Signal multipath (Chap. 15) degrades the precision of the arrival time of the signal from the satellite. The effect will have a more or less strong dependence on the elevation angle of the direct signal, depending on the local electromagnetic environment at the receiving antenna. It is difficult to model since the environment is changing. For example, the reflective properties of the ground change when it is covered by (rain) water, snow, and soil moisture, if soil is present. It has been shown that the effect of signal multipath can be reduced by mounting a plate with a microwave-absorption material just below the GNSS antenna [38.13].

### 38.1.2 From Delays to Water Vapor Content

The primary estimate from the data processing for the atmospheric influence is the ZTD. For some meteorological applications, the ZTD can be used directly, whereas other applications require the time series of the IWV, for example, when validating results from other instruments where the IWV is the primary output.

The overall data flow is illustrated in Fig. 38.3. The main operation is first to subtract the ZHD from the ZTD in order to obtain the ZWD. Thereafter the IWV is calculated from the ZWD. It shall be pointed out that the use of numerical weather models is not necessary. It is, however, common that information from such models is used to derive and optimize mapping functions,

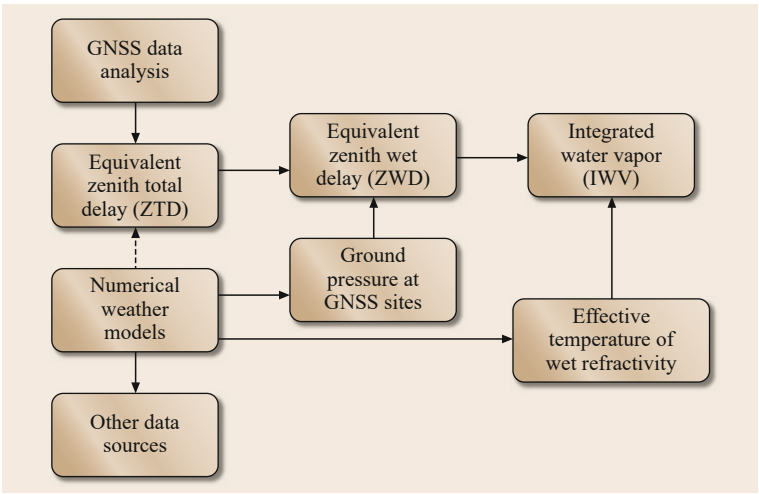

**Fig. 38.3** The data flow for different applications in ground-based GNSS meteorology. Depending on the application the timescales of the data flow between the different operations can vary from seconds to years

and they may also provide a priori information about the atmosphere to the GNSS data analysis. Since the mapping functions for the hydrostatic and the wet delays are different such a priori information has been shown to increase the accuracy of the estimated ZTD [38.6]. As will be discussed below, there are also alternatives to numerical weather models for the estimation of the ground pressure and the effective temperature of the wet refractivity.

Before discussing these further, we note that both steps will require some knowledge of the state of the atmosphere, mainly the profiles of pressure and temperature. For applications such as weather forecasting, up-to-date knowledge already exists in the numerical weather models, and, in such cases, there is no need to compromise by using less accurate relations. Instead, the normal procedure is then to assimilate the ZTD directly into the numerical weather model.

### From ZTD to ZWD

The first step is to subtract the ZHD from the ZTD. Hence, the uncertainty in the ZHD is directly transferred to the ZWD via (38.1) and (6.50). The only observable needed for the calculation of the ZHD is the ground pressure, assuming that the latitude and the height of the station are approximately known. This assumption is indisputable for ground-based GNSS networks used for meteorological applications. There are basically two possibilities to obtain the ground pressure: either to use a barometer at the site or to use the analysis from a numerical weather model which has input observations of the ground pressure of a sufficient accuracy from the surrounding area.

Commercially available pressure sensors provide accuracies much better than 0.5 hPa. Figure 38.4 depicts the observed differences between three barometers at the Onsala VLBI site. Comparison with a barometer from the Swedish Meteorological and Hydrological Institute (SMHI) shows that the present sensor has an absolute accuracy at the level of better than 0.2 hPa. Over the time period of interest, the SMHI barometer has been calibrated approximately every second year, and it is traceable to the SI unit within 0.1 hPa.

Several studies assessing the accuracy of deriving the ground pressure at the site from numerical weather models have been performed. The uncertainty of the ground pressure derived from the European Centre for Medium-Range Weather Forecasts (ECMWF) has been evaluated [38.16]. They compared the interpolated ground pressure from the ECMWF analysis to the local ground measurements at more than 60 globally distributed GPS sites using one year of data. The results revealed an agreement with an overall mean bias and a standard deviation of 0.0 hPa and 0.9 hPa, respectively. A similar test, using more than 10 years of data for the GPS site at the Onsala Space Observatory, resulted in a mean bias and a standard deviation of 0.1 hPa and 0.6 hPa, respectively [38.17]. Pressure sensors of the World Meteorological Organization (WMO) were compared to nearby ($< 50$ km) locally installed sensors and biases of less than 1 hPa for more than 90% of the stations were found [38.18]. Similar results were obtained in [38.19] using independent data sets and models.

These uncertainties together with other parameters in (6.50) are summarized in Table 38.1. Assuming uncorrelated errors, these four add up to a relative uncertainty equal to $2.2 \cdot 10^{-4}$. To this uncertainty shall also be added the uncertainty in the ground pressure. This is illustrated in Fig. 38.5, where the ground pressure uncertainties of 0.2 hPa and 1.0 hPa are assumed to be relevant for the observations and models, respectively. We conclude that the major contribution to the total ZHD uncertainty is from model uncertainties of 1.0 hPa, equivalent to a relative error of $1 \cdot 10^{-3}$, which corresponds to $\approx 2$ mm in the ZHD. If actual high-quality pressure observations are used instead, the

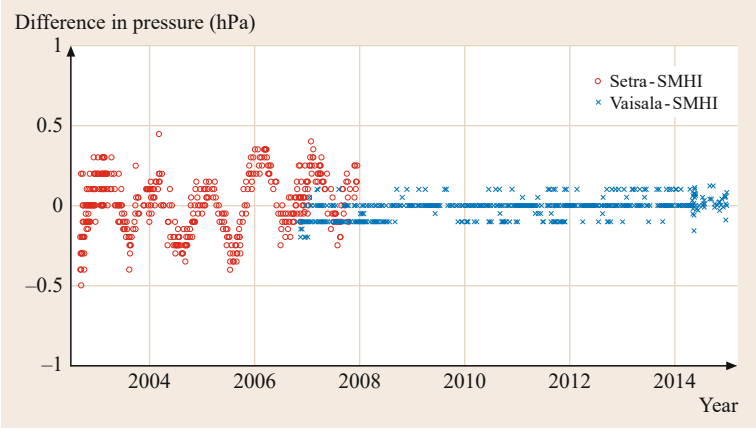

**Fig. 38.4** Differences in the observed pressure by three different barometers. The Setra barometer was the standard unit at geodetic VLBI stations when the Mark III system was introduced. The small annual variations are likely caused by a sensor sensitivity to temperature. These are completely removed when the new barometer from Vaisala was connected to the VLBI system

**Table 38.1** Parameters used to calculate the ZHD, their uncertainties, and the resulting uncertainties in the ZHD ($Z_h$)

| Parameter | Value | Uncertainty | Unit | Relative uncertainty | Reference |
|---|---|---|---|---|---|
| $k_1$ | 77.6890 | 0.015 | K/hPa | $1.9 \cdot 10^{-4}$ | Table 6.2 |
| $R$ | 8.3144621 | 0.0000075 | J mol$^{-1}$ K$^{-1}$ | $9.0 \cdot 10^{-7}$ | [38.14] |
| $M_d$ | 28.9644 | 0.0014 | kg kmol$^{-1}$ | $4.8 \cdot 10^{-5}$ | [38.15] |
| $g_{eff}$ | $\approx 9.784$ | 0.001 | m s$^{-2}$ | $1.0 \cdot 10^{-4}$ | (6.51), [38.15] |
| $p_0$, case 1 | $\approx 1000$ | 0.2 | hPa | $0.2 \cdot 10^{-3}$ | Typical observation, see the text |
| $p_0$, case 2 | $\approx 1000$ | 1.0 | hPa | $1.0 \cdot 10^{-3}$ | Typical model, see the text |
| $Z_h$, case 1 | $\approx 2.28$ | $0.7 \cdot 10^{-3}$ | m | $0.3 \cdot 10^{-3}$ | Typical observation, see the text |
| $Z_h$, case 2 | $\approx 2.28$ | $2.3 \cdot 10^{-3}$ | m | $1.0 \cdot 10^{-3}$ | Typical model, see the text |

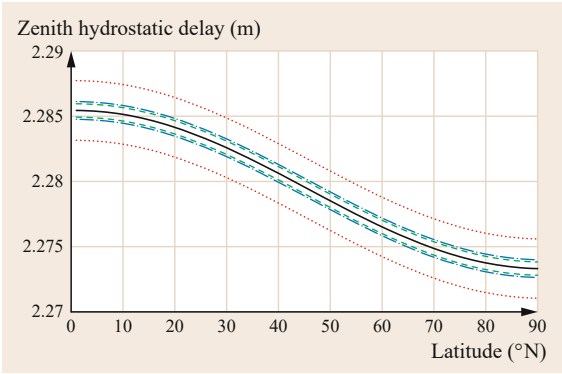

**Fig. 38.5** The expected ZHD when a ground pressure of 1000 hPa is observed from the sea level (*solid black line*). The uncertainty in the ZHD caused by the uncertainties in the constants used in the conversion is indicated by the *green dashed lines*. The total uncertainty, when errors in the pressure observations of 0.2 hPa and 1.0 hPa are taken into account, is shown by the *blue dash-dotted* and the *red dotted lines*, respectively. All errors are assumed to be uncorrelated and added as root-sum-squared

uncertainty from the value of $k_1$ becomes equally important, resulting in a relative uncertainty of $0.3 \cdot 10^{-3}$. This means an uncertainty in the ZHD of less than 1 mm.

Finally, before leaving the subject of calculating the ZHD, it shall be noted that one additional uncertainty exists: the approximation of hydrostatic equilibrium. This approximation is good to one part in $10^4$ [38.20]. The effect has been studied at two specific laser-ranging sites in mountainous areas. It was concluded that deviations from hydrostatic equilibrium may cause errors in excess of 1 cm, corresponding to 3 mm in the zenith direction, although it is an unlikely event [38.21].

### From ZWD to IWV

The water vapor content, $V$, is defined as

$$V = \int_0^\infty \rho_v \, dh \,, \tag{38.4}$$

where $\rho_v$ is the absolute humidity in g/m$^3$ and $h$ is the height in m. An alternative parameter often used to describe the water vapor content of the atmosphere is the precipitable water (PW). This is a measure of the equivalent height of the column formed if all the water vapor is condensed and collected at the ground surface, that is, a PW value of 1 mm is equivalent to an IWV value of 1 kg/m$^2$.

Using the ideal gas law, we can instead use the partial pressure of water vapor $e$ and the temperature $T$ and obtain

$$V = \frac{1}{\rho_w R_w} \int_0^\infty \frac{e(h)}{T(h)} \, dh \,, \tag{38.5}$$

where $\rho_w$ is the density of liquid water and $R_w$ is the specific gas constant of water vapor.

We note that the expression for the ZWD is similar to

$$Z_w = 10^{-6} \left( k_2' \int_0^\infty \frac{e(h)}{T(h)} \, dh + k_3 \int_0^\infty \frac{e(h)}{T(h)^2} \, dh \right) \,, \tag{38.6}$$

where $k_2'$ and $k_3$ are the constants determined from laboratory experiments of the refractivity. The values are given in Table 6.2 and (6.34) of Chap. 6.

We can combine (38.5) and (38.6) and express the IWV in the ZWD as

$$V = \frac{Z_w}{Q} \tag{38.7}$$

where

$$Q = 10^{-6} \rho_w R_w \left( \frac{k_3}{T_m} + k_2' \right) \,. \tag{38.8}$$

The parameter $T_m$ can be estimated from the vertical profiles of the atmospheric temperature and the partial

pressure of water vapor

$$T_m = \frac{\int_0^\infty T(h)\frac{e(h)}{T(h)^2}\,dh}{\int_0^\infty \frac{e(h)}{T(h)^2}\,dh}\,. \tag{38.9}$$

It can be seen as a mean atmospheric temperature weighted by $(e/T^2)$. Now, let us study the uncertainties introduced when calculating the IWV using the ZWD as an input. The relation between these two parameters is defined by (38.7), involving the density of wet air, the specific gas constant for wet air, $k_2'$, $k_3$, and $T_m$. We note that $T_m$ is the only one of these which will vary spatially and temporally.

In order to obtain $T_m$ for a specific GNSS site, an obvious and accurate method is to use the vertical profiles of atmospheric temperature and humidity. Such profiles may be obtained from the reanalysis based on a numerical weather model. If such tools are not available, one may use a more simple relation. A linear relation was derived in [38.22]

$$T_m = 70.2 + 0.72\,T_s\,, \tag{38.10}$$

where $T_s$ is the surface temperature in K.

A global study, using six years of data, of the uncertainty in $T_m$ calculated from the surface temperature used results from numerical weather models and radiosonde observations [38.23]. It showed that the root mean square (rms) error was dominated by a mean bias. For example, the bias found when using (38.10) varied in the interval $\pm 3.5\%$. When the bias is removed, the remaining error was less than 0.5% over most of the globe.

We can also calculate values of $Q$ using a model optimized for a specific region based on the annual variability in $Q$ due to seasonal temperature variations. For Europe, such a model

$$Q = a_0 + a_1\theta + a_2 \sin\left(2\pi\frac{t_D}{365}\right) + a_3 \cos\left(2\pi\frac{t_D}{365}\right) \tag{38.11}$$

was derived from radiosonde data [38.24]. Here, $\theta$ is the site latitude in degrees and $t_D$ is the decimal day of the year. Values for the coefficients $a_0$, $a_1$, $a_2$, and $a_3$ are given in [38.25] based on radiosonde data from 38 sites in Europe and spanning a period from 1989 to 1997. The resulting rms error in the IWV is of the order of 1.5%.

To conclude the discussion on how to estimate $T_m$, there can be calculations of statistical averages for sites, regions, or the whole globe. For a specific region or for a specific site, it is possible to develop a model including yearly variability which is often based on observational data, for example, from radiosondes. A more accurate method is to use an analysis based on a numerical weather model. There are several similarities to the technique of how to optimize the mapping function for a given site/region. The issue will be further discussed in the section on climate applications.

We can now assess the relative importance of the different contributions to the total uncertainty in the IWV. Summarizing the discussions above, we have:

- An uncertainty of 2–5 mm in the ZTD from the processing of GNSS data.
- An uncertainty in the ZHD, which is determined by the uncertainties of the parameters in Table 38.1 and illustrated in Fig. 38.5.
- The uncertainties introduced by the conversion from ZWD to IWV. These include uncertainties in $k_2'$, $k_3$, the specific gas constant for water vapor $R_w$, and the mean temperature $T_m$. The temperature dependence of the density of liquid water is sufficiently small over the range of atmospheric temperature so that it can be neglected [38.26].

In order to compare the relative importance of all these contributions, a number of different assumptions about these uncertainties are made in Fig. 38.6. These plots show the uncertainties for a dry and cold, a temperate, and a hot and humid troposphere. We note that in a dry and cold troposphere, the IWV uncertainty is mainly caused by the assumed accuracy of 3 mm in the ZTD plus the assumed accuracy in the ground pressure observations. As the troposphere becomes warmer and more humid, the relative importance of the uncertainty in the conversion factor $Q$ increases.

### 38.1.3 Applications to Weather Forecasting

Water vapor is an important parameter determining the state of the atmosphere. A general understanding can be obtained by studying the water cycle in the atmosphere. In short, it can be described as follows:

Water on the ground – in the oceans, lakes, streams, and vegetation – evaporates and transpirates into the atmosphere. It carries energy, which is released when the water vapor condenses into clouds. These clouds may form precipitation more or less immediately, or at a later stage when the atmospheric conditions cause the liquid drops formed to be large enough to fall back to the surface of the Earth.

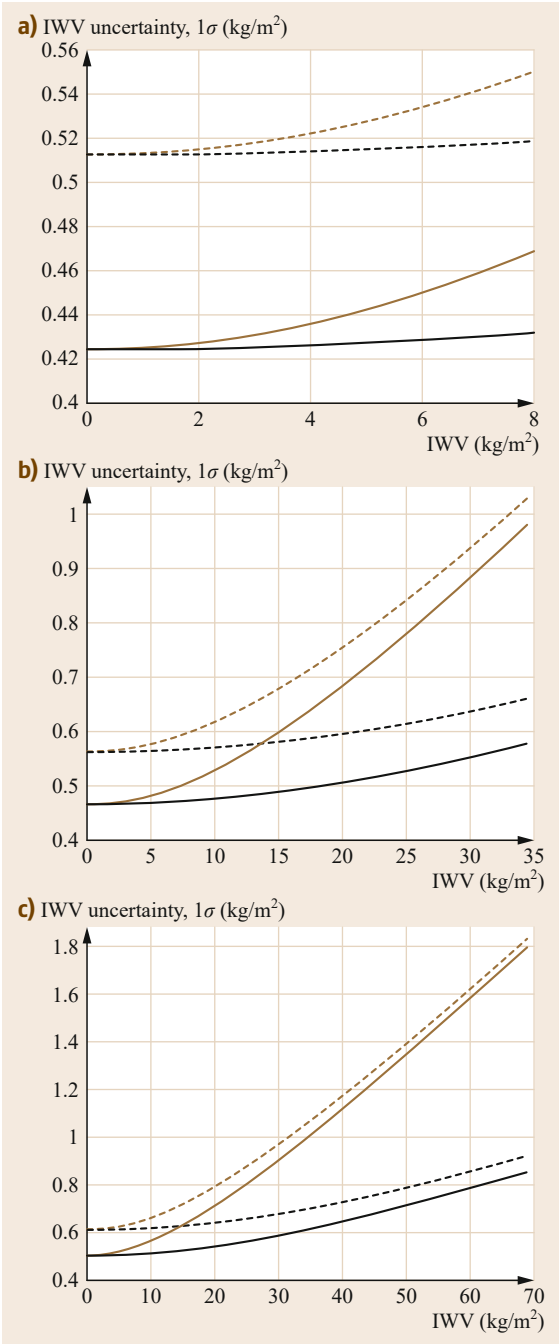

**Fig. 38.6a–c** The expected uncertainty in terms of one standard deviation in the IWV. Three different weather conditions are presented: cold ($T_m = 250\,K$, $Q = 7.26$, **(a)**), medium ($T_m = 275\,K$, $Q = 6.63$, **(b)**), and hot ($T_m = 300\,K$, $Q = 6.10$, **(c)**). Since the temperatures are strongly correlated with the absolute humidity in the atmosphere the chosen ranges for the IWV are different for different cases. In all cases we assume an uncertainty in the ZTD of 3 mm. We add an uncertainty due to the hydrostatic delay for two different uncertainties in the ground pressure: either 0.2 hPa (*solid lines*) or 1.0 hPa (*dotted lines*) and finally the uncertainty from the conversion from ZWD to IWV for two different uncertainties in the parameter $Q$: either 1.0% (*black lines*) or 2.5% (*light brown lines*). All errors are assumed to be one standard deviation, uncorrelated, and are added as root-sum-squared ◀

Knowledge about the amount of water vapor in the atmosphere is mainly important for short-term forecasts or nowcasting. The IWV is highly variable in space and time. For example, it may change by a factor of 2 in just a couple of hours due to moving mesoscale weather systems carrying different types of air masses in terms of temperatures and humidities. In order to be useful in weather forecasting, the IWV results must be available within a couple of hours, but the sooner the better.

Because warm and cold air masses often correlate strongly with the IWV, large-scale motions of mesoscale systems are easily tracked by ground-based networks. Distinct cold or warm fronts can be the cause of significant spatial and temporal gradients in the IWV above a GNSS site. Combining time series from many sites makes it possible to track such weather systems [38.27]. Such a spatiotemporal structure was assessed by an Empirical Orthogonal Function (EOF) analysis, where over 90% of the water vapor variability is explained using the first temporal eigenvector only [38.28]. For very dense networks and weather situations that are accurately described by a *frozen flow*, it has been shown that estimates of wind speed and wind direction can be made [38.29]. It shall, of course, be noted that this is an indirect method, and when the frozen flow hypothesis is not valid, the method will break down.

Large investments have been made in continuously operating reference networks for surveying and real-time kinematic (RTK) applications. Such networks are typically established on a national scale by government bodies, but also commercial networks exist. This means that not all data are openly available in real time which in practice means some restrictions on how data can be distributed for close to real time processing. An example is the EUMETNET GNSS Water Vapour Programme (E-GVAP). A snapshot of the status at a specific time is shown in Fig. 38.7. (EUMETNET is a group of European National Meteorological Services that provides a framework for co-operative programmes in the various fields of basic meteorological activities.)

In Germany, where many stations participate in the E-GVAP network, the receivers are distributed with

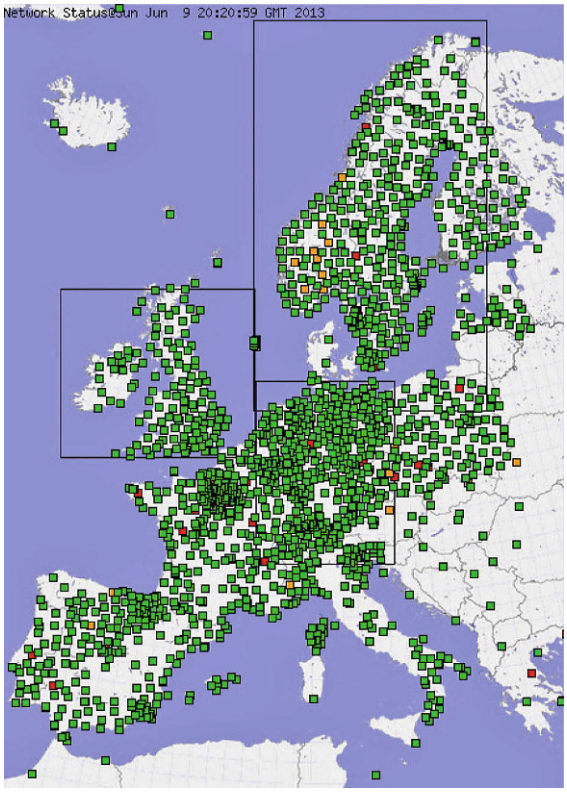

**Fig. 38.7** The E-GVAP project is an example of a network of GNSS receivers consisting of several subnetworks where data processing is distributed to several centers. This example is from 2013 and the number of stations continues to increase (after [38.30])

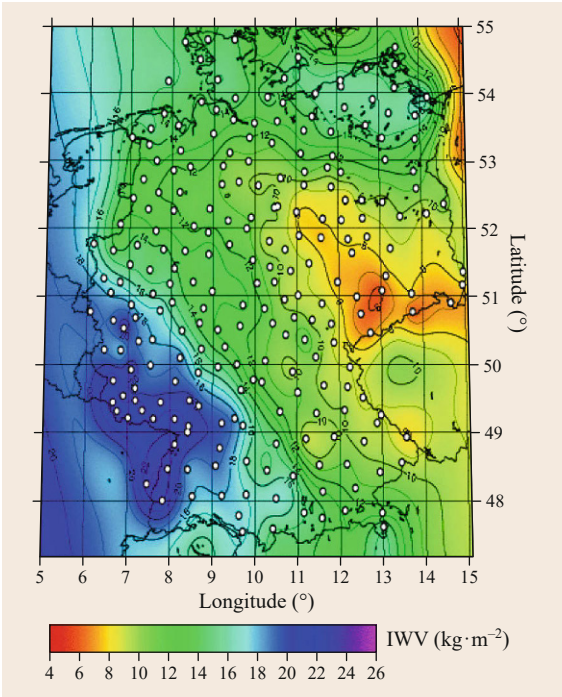

**Fig. 38.8** The IWV over Germany on Feb. 28, 2010, 00:07 coordinated universal time (UTC), derived from ground-based GNSS stations. The white circles denote the locations of GNSS receiver sites (courtesy of G. Dick, GFZ)

a rather high spatial resolution and baseline lengths of the order of 40 km. An example of GNSS-based results of the IWV is shown in Fig. 38.8.

Assimilation of the estimated IWV was first considered when using GNSS data for weather forecasting. However, it was almost immediately realized that because the necessary information, in terms of pressure and temperature fields, is already available in the numerical weather model it is an advantage to instead assimilate the ZTD.

The method of three-dimensional variational data assimilation (3D-Var) is often used with a typical update period of 3 h. However, the four-dimensional variational data assimilation (4D-Var) method offers to benefit from the much higher temporal resolution of the GNSS results. The timing of the passage of weather systems and different dry and wet air masses is crucial for short-term weather forecasts [38.31].

There have been many assessments of the impact on the quality of weather forecasts when using GNSS data. Assimilation of ZTDs has, for example, shown improvements in precipitation and cloud cover forecasts (see [38.32] and [38.33], respectively).

A further refinement may be to assimilate slant delays [38.34]. These delays may be estimated by combining the ZTD with estimated linear gradients. An alternative in order to study small-scale variations in the atmospheric water vapor (without assimilation) is to apply tomographic methods to very dense ground-based networks. Having all GNSS receiving antennas on the ground will, however, imply a weak geometry for the inversion algorithms used in tomography. This can to some extent be compensated for by introducing constraints on the variability in the water vapor density between the different volume pixels defined and used in the estimation method [38.35, 36]. The geometry is, of course, improved if the receivers are located in a landscape where the height differences are large as this will directly yield differential IWV values for different atmospheric layers. Such studies have, for example, been performed on Hawaii [38.37].

In the future, one can imagine that the raw GNSS observations are assimilated, effectively meaning that the entire GNSS data processing is executed in the numerical weather model.

### 38.1.4 Applications to Climate Research

Water vapor in the atmosphere is of great relevance also for climate research because it is a very important parameter in the water cycle as well as an efficient greenhouse gas. An increase of 20% of the IWV in the tropics has a larger impact than a doubling of the carbon dioxide concentration [38.38].

One key question is to quantify the positive feedback due to an increase in the IWV. A study of both the short-term and the long-term feedback concluded that the time series of observed water vapor need to be longer than 25 years in order to accurately determine the effect [38.39]. The GNSS ground-based networks established in the mid-1990s will, hence, have the potential to be useful for such applications in the 2020s.

Within the Global Climate Observing System (GCOS), there is a specific international reference observing network called the GCOS Reference Upper Air Network (GRUAN). One component in GRUAN is ground-based GNSS observations in order to provide IWV time series at selected reference sites where several independent observing techniques are available [38.40].

We first present some examples of GNSS results focusing on different timescales: trends over decades, annual components, and diurnal components. These may be used for climate monitoring and for evaluating of climate models which concludes this first part of GNSS meteorology using ground-based networks.

#### Long-Term Trends

There is a demand for long and stable time series for monitoring and therefore there is a need to assess the uncertainty at an absolute level, or at least as a stability measure, over decades. Since errors in the empirically determined constants $k_1$, $k_2$, and $k_3$ will not influence the uncertainties in the observed trends, for this application, it is more appropriate to refer to requirements on the long-term stability than on the absolute accuracy.

The difficulty to estimate trends that are of the order of a few percent over decades is illustrated in Fig. 38.9. The variability is huge – not only on a day-to-day basis but also over the seasons and from one year to another. Therefore, it is important to note that estimates of linear trends by no means shall be expected to be identical for adjacent periods of several years.

In addition to the large variability in weather, an additional issue is change (controlled or uncontrolled) in the electromagnetic environment of the receiving antenna. Examples of such changes are installations of different types of antennas and radomes, as well as their orientation. For the case of estimating a trend in the vertical coordinate, when there are reasons to believe that the trend is constant over the length of the time series, one may choose to estimate an additional offset at the time of the intervention (see Fig. 38.10 and [38.41] for more details).

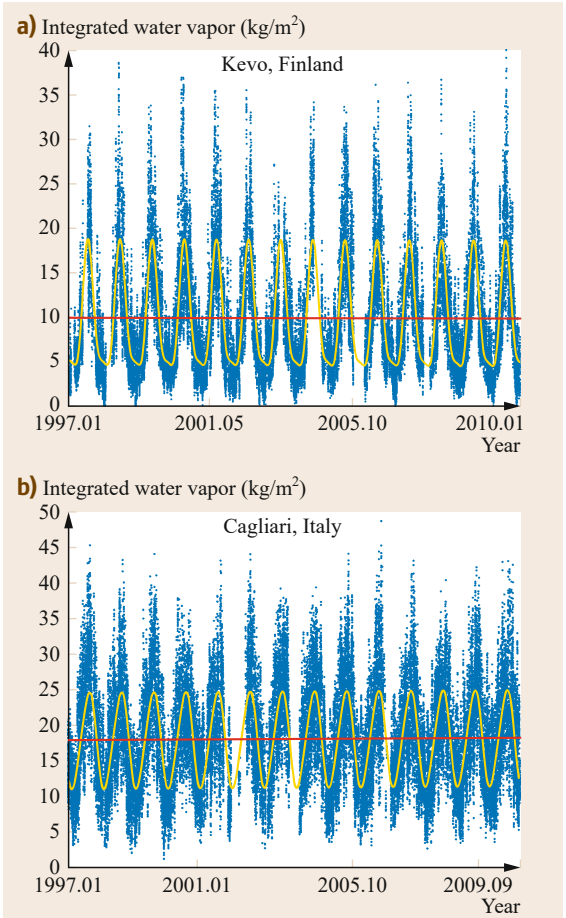

**Fig. 38.9a,b** Time series of the water vapor content at Kevo, Finland **(a)** and Cagliari, Italy **(b)**. A model including a mean value plus a linear trend (*red line*) and a seasonal component (*yellow line*) is fitted to the hourly estimates (*blue dots*)

As already mentioned, it is not reasonable to assume that a true trend in the IWV should remain constant over many years, in spite of the fact that an estimated linear trend is an obvious parameter to estimate as an indicator of a change in the climate.

A similar method was assessed in [38.42], where an effort was made to model the impact of a change of radome at Onsala, Sweden, on February 1, 1999. It was more reliable in this case to study the mean difference of the wet delay between the GNSS and the VLBI techniques and to apply the observed change in offset

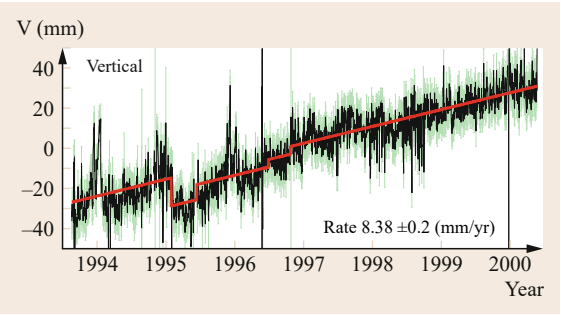

**Fig. 38.10** Estimates of the vertical coordinate using GPS data from the station Sveg, Sweden (courtesy of Scherneck & Haas)

as a constraint when estimating a trend from the full time series, thereby indirectly using the VLBI technique as an independent data source to calibrate the absolute scale of the IWV from the GNSS data.

A possibility of handling false jumps in the IWV time series when no independent results are available could be to make use of the correlation between estimates of station coordinates and the propagation delay. This idea requires further studies.

### Annual Components in the IWV

Annual components in the IWV show large differences over the globe caused by different weather patterns related to the seasons. Through continuously operating ground-based networks and a homogeneous processing, GNSS is a tool to continue such systematic studies. For example, 13 years of data from 155 globally distributed GNSS sites were studied in order to conclude that the large seasonal amplitudes occurred at mid latitudes [38.43].

Also, more local studies, with a higher spatial resolution, have been carried out. For example, a 10 year long period was studied using GNSS data from the Iberian peninsula in [38.44] and [38.45] revealed a systematic deviation in the southwest of Spain during the summers.

### Diurnal Components in the IWV

The diurnal variability in the IWV is driven by the incoming solar radiation. Hence, it is more dominant in the equatorial region, and as we go away from the equator, the amplitude decreases and vanishes in the areas close to the poles. For the same reason, and because the absolute humidity typically increases with the temperature, it is also expected to be larger during the summer compared to the winter. The knowledge of its amplitude and phase can be a useful tool in order to assess the accuracy of numerical weather models used both for forecasting and in climate research.

In a global study using 1 year of data from 151 International GNSS Service (IGS) sites, diurnal amplitudes between 0.2 mm and 10.9 mm in the ZTD were observed [38.46]. This corresponds to approximately from less than 0.1 up to 1.7 $kg/m^2$. A similar study also using a US network [38.47] obtained similar results and also assessed the accuracy of three different reanalysis products.

In a study using 14 IGS sites in the equatorial region, diurnal amplitudes up to 3 $kg/m^2$ were observed [38.48]. The amplitudes were larger for sites that are not close to the sea, which is expected, in general, because of the lower diurnal variability of the temperature close to the sea compared to more inland areas.

It may be worth noting that the diurnal components at mid to high latitudes is hidden by the much larger moving mesoscale weather systems. This together with the fact that the diurnal variation of the solar radiation has a much smaller amplitude means that typically many years of GNSS data must be averaged in order just to detect the diurnal component [38.49].

### Evaluation of Climate Models

We have already touched upon the application of using the GNSS data in order to evaluate numerical climate models for the trends, annual, and diurnal components in IWV time series.

An additional study that focused both on the validation of seasonal and interannual variations in the IWV was presented in [38.50]. The authors of this study found, in general, an agreement at the submillimeter level for the precipitable water in Europe and North America between GNSS and a numerical weather prediction model from National Centers for Environmental Prediction (NCEP). On the other hand, the model was found to underestimate the seasonal signal by up to 40% and 25% for the equatorial region and Antarctica, respectively.

In [38.51], a regional climate model was evaluated in terms of the IWV differences between GNSS observations and the climate model. It was found that a couple of GNSS sites showed large differences, which in turn were attributed to a cold temperature bias and an underestimate of the diurnal temperature range for the model in that area. It was also noted that the model produced a positive bias in the IWV at sites close to the sea (the surface tile of the model gridpoint has a water coverage $> 60\%$), possibly due to the fact that evaporation in the model has a too high influence on the IWV mean value for the gridpoint.

As mentioned several times already, climate studies require long-term averages. It therefore seems appro-

priate to note that so far the potential of ground-based GNSS has been demonstrated, but there is a limitation today on the studies that are meaningful due to the length of available time series. This situation will however improve over the years to come.

The next section will deal with the occultation geometry in GNSS meteorology. Thereafter, we will conclude the chapter by summarizing the GNSS applications for the remote sensing of the neutral atmosphere.

## 38.2 GNSS Radio Occultation Measurements

### 38.2.1 Introduction and History

On July 17, 1995 the U.S. Air Force announced

> *[...] that the Global Positioning System satellite constellation has met all requirements for Full Operational Capability.*

Already before this announcement on April 5, 1995 the LEO MicroLab-1 satellite was launched and recorded for the first time at all signals from setting GPS satellites, which tangentially traversed the Earth's atmosphere. The main purpose of these observations was atmosphere sounding using the innovative GPS RO technique within the GPS/MET(GPS/METeorology)-Experiment [38.52, 53].

GPS/MET was a real story of success. For the first time, globally distributed vertical profiles of atmospheric temperature, water vapor, and electron density were successfully derived from spaceborne GPS data. The GPS (or, more generally, GNSS) RO technique became reality as a new and innovative remote-sensing method. The properties of this calibration-free atmospheric limb-sounding technique (e.g., all-weather-capability, high accuracy, high vertical resolution, low-cost realization) promised to have a great potential for atmospheric and ionospheric research, numerical weather forecasts, space weather monitoring, and climate change detection [38.54].

Around 20 years later, it can be stated, that GNSS RO kept this promise and is widely recognized as an established atmospheric remote-sensing technique. A major and prominent example for this development is the beginning of the operational use of GNSS RO data to improve global numerical weather forecasts (e.g., [38.55, 56]). Figure 38.11 shows a schematic illustration of the GNSS observation geometry. A GNSS receiver aboard an LEO satellite tracks the signals (carrier-phase and amplitude) of an occulting GNSS satellite, that is, within the period directly before satellite *set* or before satellite *rise*. These are the occultation events and last typically 1–2 min for atmosphere sounding from the Earth's surface up to around 100 km. During these events, the signal goes through different vertical layers of the atmosphere and is modified in a characteristic way. By appropriate inversion of the time series of the signals during the occultation, vertical profiles of atmospheric parameters, as refractive index, temperature, or water vapor can be derived. GNSS RO can also be used to derive vertical electron density profiles, as described in more detail in Chapt. 40 of this book. A key observable is the bending angle $\alpha$ of the signal path from the occulting GNSS to the LEO satellite, which is assigned to the impact parameter $a$ and the point of the closest approach of the signal path to the Earth's surface $r_0$. Additional LEO measurements from a referencing GNSS satellite and GNSS ground station data from the occulting and referencing satellite are used for the calibration of the atmospheric excess phase of the occultation measurements, which is the base for the bending angle derivation. More details are given in Sect. 38.2.2.

### 38.2.2 Basic Principles and Data Analysis

#### Derivation of the Atmospheric Excess Phase

The GNSS RO technique is based on precise dual-frequency (for ionosphere correction) phase measurements of a GNSS receiver in an LEO, which is tracking setting or rising GNSS satellites. Combining these measurements with the satellites' position and velocity information, the phase path increase due to the atmosphere during the occultation event can be derived. This phase path increase is called atmospheric phase delay or atmospheric excess phase, $dA$ and the geodetic key observable of GNSS RO and its derivation here briefly reviewed.

The observed phase $L$ for each frequency of the occultation link (see in Fig. 38.11 between occulting GNSS satellite and LEO) in units of meters can be written as

$$L = \rho + c(dt - dT) - dI + dA + \epsilon \,. \qquad (38.12)$$

Here, $\rho$ denotes the true range between the transmitter and receiver taking into account the signal travel time, $c$ is the velocity of light, $dt$ and $dT$ are the transmitter and receiver clock errors, respectively, $dI$ and $dA$ are the phase delays due to ionosphere and neutral atmosphere

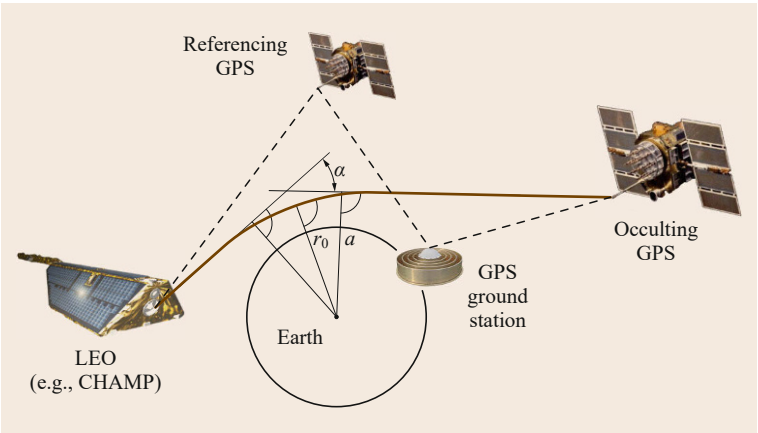

**Fig. 38.11** The principle of GNSS RO measurements aboard a LEO satellite such as CHAMP (CHAllenging Minisatellite Payload). A key observable is the atmospheric bending angle $\alpha$ of the signal path from the occulting GNSS to the LEO satellite. Under assumption of spherical symmetry an impact parameter $a$ can be assigned. LEO measurements from a referencing GNSS satellite and GNSS ground station (*dashed lines*) are used for calibration of the RO measurements.

along the ray path, respectively, and $\epsilon$ is a residual error composed of, for example, measurement noise and uncorrected multipath.

For the analysis of the GPS/MET and the initial CHAllenging Minisatellite Payload (CHAMP) measurements [38.52, 57], a double-difference technique was used to eliminate the GNSS transmitter and LEO receiver satellite clock errors: the signals from the occulting GNSS satellite were differenced with those from a reference GNSS satellite. These satellite measurements were synchronized with simultaneously recorded data provided by a fiducial ground network [38.58]. The corresponding observation geometry is depicted in Fig. 38.11.

The double difference,

$$\Delta\Delta L = (L_{\mathrm{CO}} - L_{\mathrm{CR}}) - (L_{\mathrm{GO}} - L_{\mathrm{GR}}) \,, \tag{38.13}$$

is formed from simultaneous CHAMP and ground station measurements of signals from both the occulting and the referencing GNSS satellite during an occultation (e.g., [38.58]). The subscripts C, O, R, and G denote CHAMP, occulting and referencing GPS satellite, and the ground station, respectively. The corrections of relativistic and light time effects have to be taken into account [38.59]. Equation (38.13) shows that in the double-difference method, both the transmitter clock errors $dt_{\mathrm{O}}$ and receiver clock errors $dt_{\mathrm{R}}$ cancel. While the double-difference method eliminates the satellite clock errors, other errors are introduced by the three auxiliary satellite links involved. These errors are uncalibrated atmospheric and ionospheric contributions and additional noise. Furthermore, for differencing with nonsynchronous receiving times of occultation and reference satellite, the ground receiver clock drifts and also multipath wave propagation at the ground station location have to be taken into account (e.g., [38.60]).

Due to the termination of Selective Availability (SA) on May 2, 2000, which reduced the apparent variations in the GNSS transmitter clocks by various orders of magnitude, and due to the higher stability of presently available LEO satellite clocks, the application of single- and even zero-differencing analysis techniques represents the current state of the art for GNSS RO data analyses [38.61, 62].

For example, the space-based single difference,

$$\Delta L = (L_{\mathrm{CO}} - L_{\mathrm{CR}}) \tag{38.14}$$

is the difference between phase measurements of CHAMP from the occulting GNSS, $L_{\mathrm{CO}}$, and the referencing GNSS, $L_{\mathrm{CR}}$, respectively. In this scheme, the GNSS satellite clock errors remain and need to be corrected for, what is feasible after the termination of SA even with the standard data products of the IGS. For GNSS RO satellites with ultra stable oscillators (USOs), as, for example, GRACE-A or Metop, even the forming of single differences is not required and the phase data of the occultation link $L_{\mathrm{CO}}$ can be directly used for the derivation of $dA$. With single and zero differencing, the level of random noise in $dA$ should be lower and also systematic errors from the calibration links are avoided.

More details of the excess phase calibration are given in several publications, for example, [38.59, 61]. Figure 38.12 shows the atmospheric phase delay and the corresponding amplitude (signal-to-noise ratio, SNR) for a typical TerraSAR-X occultation measurement. Typically, occultation measurements for the neutral atmosphere (0–120 km altitude) last around 1–2 min, and the atmospheric excess phase is around 1 km in the vicinity of the Earth's surface.

### Derivation of Vertical Atmospheric Profiles

The calibration of the atmospheric excess phase can be regarded as a geodetic task and is the basis for the

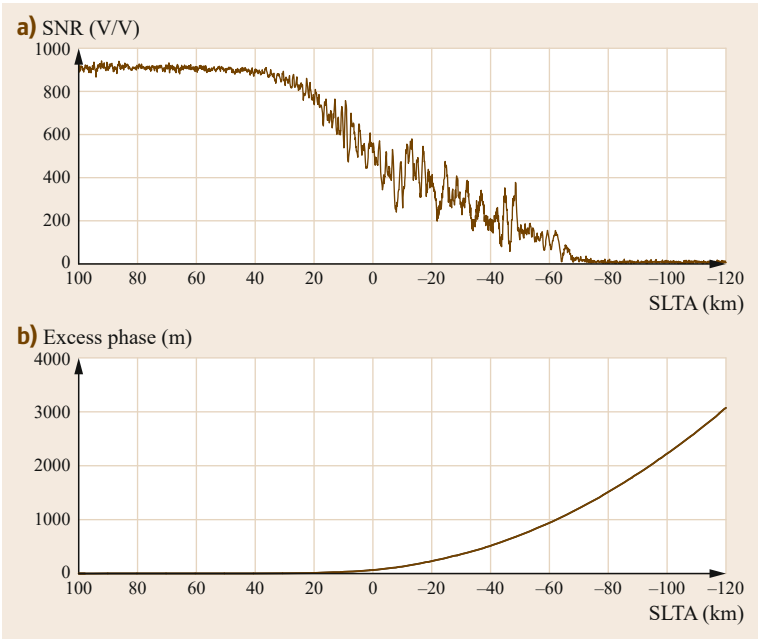

**Fig. 38.12a,b** Variation of the SNR **(a)** and the corresponding atmospheric excess phase **(b)** for a typical occultation event. SLTA indicates the Straight Line Tangent point Altitude. The plots characterize an occultation measurement of the TerraSAR-X satellite on February 18, 2012, 05:46 UTC, 79.6°N and 88.5°W (courtesy of F. Zus, GFZ)

mathematic-physical calculations to retrieve the vertical atmospheric profiles. The first step consists in the derivation of atmospheric bending angles, which are obtained from the time derivative of the atmospheric excess phase using the Doppler shift equation (e.g., [38.63])

$$f_\mathrm{d} = f_\mathrm{c}\left(\frac{c-(\boldsymbol{v}_2\cdot\boldsymbol{m}_2)n_2}{c-(\boldsymbol{v}_1\cdot\boldsymbol{m}_1)n_1}-1\right) . \tag{38.15}$$

In (38.15), $\boldsymbol{v}_{1,2}$ are the velocity vectors of GPS and LEO satellite respectively, $\boldsymbol{m}_{1,2}$ are the unit wave vectors and $n_{1,2}$ are the refractivity at the satellite positions as shown in Fig. 38.13. The Doppler shift $f_\mathrm{d}$ is related to the phase $L$ by

$$f_\mathrm{d} = -\frac{f_\mathrm{c}}{c}\frac{\mathrm{d}L}{\mathrm{d}t} \tag{38.16}$$

with the carrier frequency $f_\mathrm{c}$ and the vacuum light velocity $c$. $L$ can be expressed as

$$L = L_0 + dA_\mathrm{LO} \tag{38.17}$$

Thus, the Doppler shift $f_\mathrm{d}$ is represented by two terms

$$f_\mathrm{d} = f_{\mathrm{d}0} + f_{dA} \tag{38.18}$$

The first term in (38.18), $f_{\mathrm{d}0}$, is equal to the frequency shift in the absence of the atmosphere and depends on $L_0$. It can be calculated using the precise orbit information of the satellites (position and velocity). The second term, $f_{dA}$, depends on the time derivative of the measured atmospheric excess phase $A_\mathrm{LO}$ of the occultation link between GPS and LEO. The bending angle is (Fig. 38.13)

$$\alpha = \phi_1 + \phi_2 + \theta - \pi . \tag{38.19}$$

$\phi_1$ and $\phi_2$ are unknowns; thus, one more equation is needed to calculate both $\phi_1$ and $\phi_2$. Assuming local spherical symmetry of the refractivity $n = n(r)$, Snell's law applies

$$r_1 n(r_1)\sin\phi_1 = r_2 n(r_2)\sin\phi_2 . \tag{38.20}$$

Equations (38.16) and (38.20) are nonlinear and cannot be solved analytically. It can be solved with an iterative method, as, for example, described in [38.63]. Starting with some increment $\Delta\phi_2 = \phi_2 - \phi_{20}$ ($\phi_{20}$ is equal to $\phi_2$ in the absence of the atmosphere and can be calculated with satellite's orbit information) with (38.20) the corresponding $\Delta\phi_1$ can be calculated. Then the vectors $\boldsymbol{m}_1$ and $\boldsymbol{m}_2$ are constructed. Applying (38.15) $\Delta f = f_\mathrm{d} - f_{\mathrm{d}0}$ is calculated and compared with the observed value $f_{dA}$. Depending on the deviation of $\Delta f$ from $f_{dA}$, the increment $\Delta\phi_2$ is modified and the procedure is repeated until $\phi_1$ and $\phi_2$ for each sample and with (38.20) the appropriate $\alpha$ is found.

The ionospheric correction is performed by the linear combination of the bending angle profiles obtained for each individual signal frequency (e.g., GPS L1 and

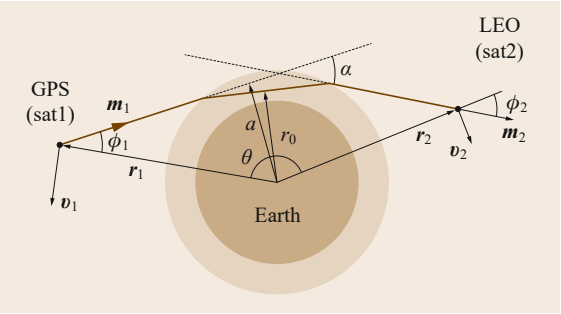

**Fig. 38.13** Derivation of the bending angle $\alpha$ from the Doppler shift ($a$: impact parameter; $r_0$: radius of the point of closest approach). For details, see the text

L2; [38.64]).

$$L_C(t) = \frac{f_1^2}{f_1^2 - f_2^2} L_1(t) - \frac{f_2^2}{f_1^2 - f_2^2} L_2(t) \qquad (38.21)$$

$$\alpha_C(a) = \frac{f_1^2}{f_1^2 - f_2^2} \alpha_1(a) - \frac{f_2^2}{f_1^2 - f_2^2} \alpha_2(a) \,. \qquad (38.22)$$

The ionosphere correction in (38.22) avoids the effect of dispersion ($L_1$ and $L_2$ have separate signal paths), which forms the major error budget of (38.22) because the linear combination of the bending angles (38.22) is formed at the identical impact parameter for both frequencies.

Vertical profiles of the atmospheric refraction index $n$ can then be retrieved from the ionosphere corrected bending angle profiles by the inverse Abel transform

$$n(r_0) = \exp\left(\frac{1}{\pi} \int_a^\infty \frac{\alpha(x)}{\sqrt{x^2 - a^2}} \mathrm{d}x\right) \qquad (38.23)$$

for the given point of the closest approach of the signal path to the Earth's surface $r_0$, bending angle $\alpha$, and impact parameter $a$.

After accounting for ionospheric bending as described above, the atmospheric refractivity ($N = (n-1) \cdot 10^6$) is related to pressure ($p$ in mbar), temperature ($T$ in K), and water vapor pressure ($p_w$ in mbar) via the *Smith–Weintraub* equation [38.65]

$$N = 77.6 \frac{p}{T} + 3.73 \cdot 10^5 \frac{p_w}{T^2} \,. \qquad (38.24)$$

For dry air, the density profiles are obtained from the known relationship between density and refractivity. Pressure and dry temperature

$$T_d = 77.6 \frac{p}{N} \qquad (38.25)$$

are obtained from the hydrostatic equation and the equation of state for an ideal gas. There are numerous publications, describing these retrieval steps in very detail, for example, [38.54, 60, 66].

When water vapor is present, additional information is required to determine the humidity and density from refractivity profiles, due to the joint contribution of the dry and wet term to the refractivity in (38.24). Temperature profiles from operational meteorological analyses (e.g., of the European Centre for Medium-Range Weather Forecasts, ECMWF) are used to derive humidity profiles from the calculated refractivity in an iterative procedure [38.67]. This algorithm suffers from a high sensitivity to even small errors in the analyses temperatures, resulting in large uncertainties of the derived water vapor profiles [38.68]. More elaborate retrieval methods are based on the estimation of both temperature and humidity in parallel including the error characteristics of the measurement and the *background* information, which is usually obtained from meteorological analyses (optimal estimation, for example, [38.69, 70]). These methods show an increased potential for obtaining water vapor profiles with high accuracy.

By way of example, Fig. 38.14 shows vertical profiles of dry temperature and water vapor derived from a TerraSAR-X occultation measurement. The deviation (cold bias) of the dry temperature from the temperature below 10 km altitude is clearly seen and most obvious below 3 km, where the major part of the atmospheric water vapor is present. The magnitude of this deviation can itself be regarded as a measure for the atmospheric water vapor. It is noted that the key observables for the assimilation of RO data into forecast models are the bending angles or refractivities, rather than temperature and water vapor. The separation of these observables into dry and wet contributions, which finally provides the temperature and water vapor, is performed during the model analysis process using additional data from other observing systems. Also, for several climate change-related investigations, bending angle and refractivity data are used (e.g., [38.71]).

A major challenge in the GNSS RO data analysis is the parameter retrieval in the lower troposphere. Sharp refractivity gradients, mainly due to irregular water vapor distribution, complicate the proper signal tracking and the assumption of geometrical optics for analysis cannot be applied in contrast to higher altitudes. The application of the open-loop GNSS signal tracking technique as well as the development and application of advanced occultation data analysis techniques, however, brought significant progress during the last decade [38.72–76]. Another recent challenge is the data analysis in the upper stratosphere, where the occulta-

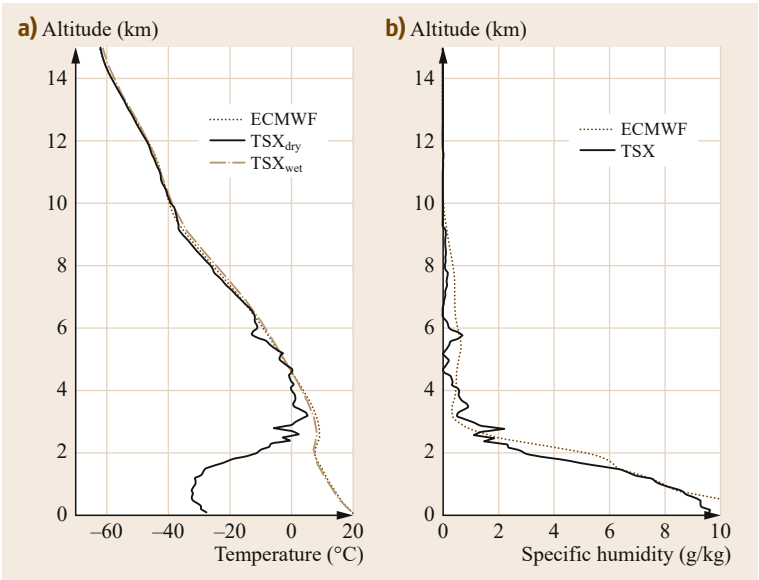

**Fig. 38.14a,b** Typical vertical dry (*black*) and wet (*light brown*) temperature **(a)** and water vapor profiles **(b)** derived from GNSS RO data. The example is from the TerraSAR-X (TSX) mission (July 19, 2010, 02:47 UTC, 31.43°N 145.67°E). Only the troposphere is shown. The RO data are compared with corresponding values from ECMWF analyzes (*brown dotted line*) (courtesy of S. Heise, GFZ)

tion signal is very weak and measurement errors (e.g., ionosphere) start to dominate the neutral atmosphere signal [38.66, 77].

### 38.2.3 Occultation Missions

A nearly complete and recent (as of 2016) list of satellite missions with GNSS RO instruments is given in [38.78]. Here, we give more details on selected missions of most importance for the development of the GNSS RO technique.

Initial GNSS RO data were recorded within the GPS/MET experiment aboard the MicroLab-1 satellite from 1995 to 1997 [38.52, 53]. However, the analysis of these data was primarily focused on the four *prime-times*, that is, periods of 2–3 weeks, when an anti-spoofing (A/S) encryption of the GPS signals was disabled and MicroLab-1 was oriented so that GPS satellites were occulted in the aft or anti-velocity direction toward the Earth's limb.

The German CHAMP satellite, launched on July 15, 2000 provided for the first time continuous and also near-real-time GPS RO data [38.57, 79]. These were especially used for various assimilation studies to investigate the potential improvement of RO data to numerical weather forecasts [38.80, 81]. In addition, CHAMP provided the first long-term set of GPS RO data covering the 2001–2009 period. In view of its high precision, it was used for initial climate-change-related investigations [38.82–84]. Furthermore, it triggered an international comparison of analysis results from different RO processing centers to define the structural uncertainty of GNSS RO data [38.85–87]. The CHAMP RO experiment can therefore be regarded as a big success and as a forerunner for several succeeding missions. However, the daily number of available occultation measurements was limited to about 150.

Gravity Recovery And Climate Experiment (GRACE) is a US/German twin-satellite mission with focus to the detection of climate-relevant long-term variations of the Earth's gravity field determination, which was launched on March 17, 2002. The two spacecraft are equipped with the same *BlackJack* GPS RO flight receiver provided by Jet Propulsion Laboratory (JPL) as CHAMP. Continuous GPS RO measurements were activated on May 22, 2006 aboard the GRACE-A satellite [38.79], which provides around 130 near-real-time occultation profiles until today (as of end 2015). Recently, the GRACE Follow On (GRACE-FO) mission was confirmed, which is foreseen for launch in 2017 and will also include a GNSS-RO instrument according to the current planning.

A breakthrough for the number of daily occultations and for improved data quality in the lower troposphere was the launches of the U.S./Taiwan six-satellite-constellation FormoSAT-3/COSMIC (April 15, 2006; [38.55]) and of the two European Metop satellites (October 19, 2006 [38.88] and September 17, 2012). FormoSAT-3/COSMIC initially provided more than 2000 occultations daily in an open-loop tracking mode for better data quality in the lower troposphere. By 2013, the number of daily RO measurements had dropped to roughly half that value, since the nominal life time of the mission was reached and several satellites exhibit technical problems. Both Metop satellites together provide continuously and with high reliabil-

ity more than 1200 daily occultations. In addition, the German twin-satellite constellation TerraSAR-X (launched June 15, 2007) and TanDEM-X (launch June 21, 2010) provides a unique set of parallel occultation measurements [38.89] to investigate the accuracy potential of the GNSS RO technique in more detail. Data from TerraSAR-X are also provided in near real time for operational use in numerical weather forecasts.

The successor of the FormoSAT-3/COSMIC mission FormoSAT-7/COSMIC-2 is foreseen to be launched in 2016. This 12-satellite constellation will provide multi-GNSS LEO data (GPS, GLONASS, Galileo) from two different orbital inclinations. Six satellites are planned to be launched into low-inclination orbits in early 2016, and another six satellites into high-inclination orbits in 2018. This configuration will improve the global coverage of the GNSS RO data, especially in the Tropics. The GNSS RO payload, named TGRS for TriG (Tri-GNSS) GNSS RO System, is being developed by NASA's JPL and will be capable of tracking up to 12 000 high-quality profiles per day once both constellations are fully deployed. The third satellite of the Metop series will be launched in 2018. The planning for the follow-on system of the current EUMETSAT POLAR SYSTEM (EPS) includes also considerations for GNSS RO measurements. The EPS can be expected in the 2020 time frame.

In addition to these large and operational missions, there are several smaller international missions, which are in more detail overviewed in documents, generated by the International Radio Occultation Working Group (IROWG, [38.90]). The IROWG was established as a permanent Working Group of the Coordination Group for Meteorological Satellites (CGMS) in 2009 as part of the activities of the World Meteorological Organization (WMO). The IROWG serves as a forum for operational and research users of RO data.

Another RO-related activity is CICERO (Community Initiative for Continuous Earth Remote Observation), which acts as a commercial provider of RO data. CICERO plans to launch a demonstration satellite in 2016 followed by an operational six-satellite constellation (CICERO-I) in the same year. Each satellite is foreseen to provide more than 900 GPS occultations per day.

CICERO-2, the planned extension up to 24 satellites by 2019, will offer enhanced performance with GPS/GLONASS/Galileo-enabled receivers. It potentially will provide more than 1600 occultations per day from each satellite.

### 38.2.4 Occultation Number and Global Distribution

Figure 38.15 shows the number of daily occultations from the six-satellite FormoSAT-3/COSMIC and Metop-A/B missions since the beginning of 2009. The maximum number of daily FormoSAT-3/COSMIC measurements was reached in early 2009 with up to 2500 profiles. At that time, the mission had already accomplished the nominal lifetime of three years. Nevertheless, it provided up to 2000 profiles daily even seven years after launch. The decreasing number of daily profiles and its quite large variation is associated with increasing technical problems of the satellites, which are already in orbit more than double of the nominal lifetime. The number of RO measurements, provided by both Metop satellites, is very stable, and around 1400 profiles daily are operationally available in near-real time.

The number of daily vertical profiles available from GRAS is before quality control, while the FormoSAT-

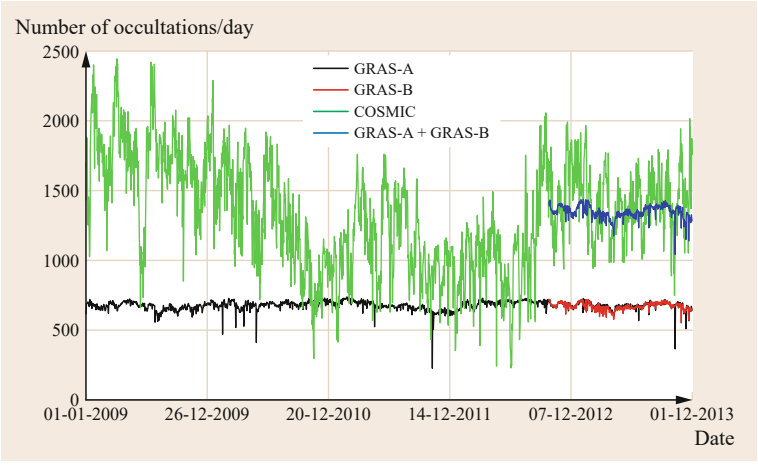

**Fig. 38.15** Daily number of GNSS occultation measurements from GRAS-A (*black*), GRAS-B (*red*) and FormoSAT-3/COSMIC (*green*) between January 1, 2009 and December 1, 2013. The sum of the GRAS-A and -B data is indicated by the *dark blue line* (courtesy of A. von Engeln, EUMETSAT)

3/COSMIC numbers are after quality control. Typically, about 5–10% of the GRAS data are removed in quality control in the assimilation process of the weather services. Each of the GRAS receivers provides an almost constant number of daily occultations of around about 650–700. Some longer term variations are driven by the availability of GPS satellites for occultations, the short spikes are caused by, for example, loss of satellite data downloads or instrument updates.

Currently (as of end 2016), also GRACE-A and TerraSAR-X provide near-real-time RO data, but the daily number of around 150 measurements per satellite is much lower compared to Metop and FormoSAT-3/COSMIC.

A key property of the GNSS RO technique is the global coverage of the measurements, but the distribution is not uniform and depends mainly on the orbital geometry of the GNSS and the LEO satellites. As an example, Fig. 38.16 shows the global distribution of RO measurements from the FormoSAT-3/COSMIC mission (LEO orbit inclination $\approx 70°$). The figure is based on about 4.2 millions RO profiles obtained between 2007 and 2012. The spatial distribution is global and nearly symmetric with respect to the Equator but not equally distributed. Most significant are the variations with latitude from $\approx 800$ occultations per pixel (Equator) or even lower in the Polar regions to $\approx 2500$ at 25 and 50° N/S in the mid-latitudes.

The orbit inclination of the LEO satellite is a key parameter to modify the global distribution of the RO measurements. Low-inclination LEO orbits will result in higher occultation density in the Equator region, which is of major interest for the prediction of severe weather events such as typhoons. Therefore, the first six satellites of the 12 satellite FormoSAT-7/COSMIC-2 constellation (Sect. 38.2.3) will be deployed in a 20° inclination orbit. This will allow a higher equatorial occultation density compared to its predecessor mission. Near-polar orbiting LEO satellites (e.g., CHAMP, GRACE, Metop) exhibit a similar occultation distribution as shown in Fig. 38.16, but with more data available in the Polar regions (not shown here).

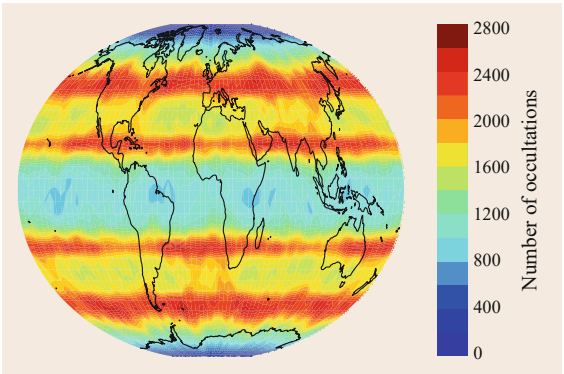

**Fig. 38.16** Global distribution of GNSS RO data from the FormoSAT-3/COSMIC mission. The plot is based on about 4.2 million measurements, obtained between 2007 and 2012. The colors indicate the number of occultations per $5 \times 5°$ lat/lon grid cell (courtesy of C. Arras, GFZ)

## 38.2.5 Measurement Accuracy

Numerous validation studies were performed throughout the last years to evaluate the quality of the various occultation missions (e.g., [38.52, 55, 79, 88, 89, 91]). The vertical profiles of refractivity, temperature, and water vapor were validated with data from different meteorological analyzes and radiosondes. In addition, co-located RO profiles, observed from two different satellite platforms, were compared [38.89, 92]. The results indicate that especially temperatures in the upper troposphere lower stratosphere (UTLS) region agree well with the analyses and sonde data.

Between approximately 8 and 25 km altitude, that is, in the UTLS region, mean temperature deviations are $\leq 1$ K, and rms errors fall within the 1–2 K range. Also, only very small biases of about $\pm 0.1\%$ and rms uncertainties of $\leq 0.5\%$ are observed for the refractivity (see, for example, Fig. 38.17 for TerraSAR-X). The deviations at these heights could be either due to analysis/sonde data or the RO retrievals.

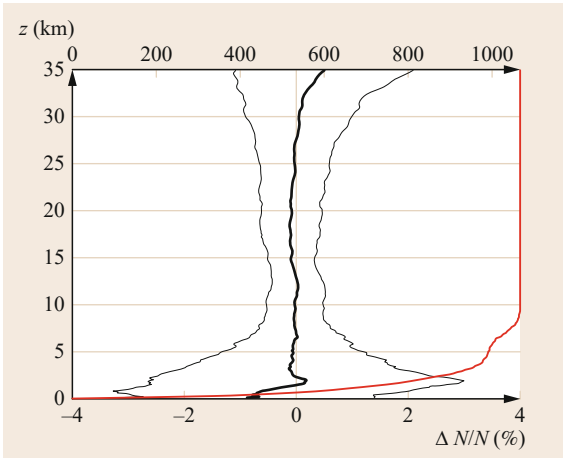

**Fig. 38.17** Statistical comparison of refractivity profiles from TerraSAR-X with corresponding ECMWF data between November 26 and December 2, 2011. *Thick* and *thin black line* indicate bias and rms $(1-\sigma)$, the *red line* shows the number of compared data versus altitude (courtesy of F. Zus, GFZ)

A negative refractivity bias and significant loss of observations in the lower troposphere, especially at low latitudes, are observed in the RO retrievals and were in focus of numerous scientific studies, for example, [38.72–76]. One reason for this was found to be the application of the so-called phase lock loop (PLL) tracking mode of the occultation receivers of the early RO missions, such as GPS/MET or CHAMP. In the PLL mode, the phase of the RO signals is modeled (projected ahead) by extrapolating the previously extracted phase. This technique works well for standard GNSS observations (single-tone signals with sufficient SNR), but often fails for the occultation-geometry-like observations in the moist lower troposphere. Here, multipath propagation causes strong phase and amplitude fluctuations, which results in significant errors of the extrapolation-based phase model, a loss of SNR and finally loss of lock of the occultation signal. For this reason, the PLL mode does not allow in many cases a penetration of the occultation signals deep into the troposphere and is also the reason for systematic tracking errors. PLL mode receivers are also limited to the tracking of setting occultations only. An alternative tracking technique, open-loop (OL), that is, the raw sampling of the complex signal, was already applied to the data analysis of the planetary occultations and that also allows us to analyze rising occultation events [38.93]. However, a raw sampling of the signal is practically not feasible for routine GNSS RO sounding. Therefore, a model-based OL-tracking technique (e.g., [38.73]) was developed for the application in the moist troposphere for both rising and setting occultations and is used for several recent missions, for example, FormoSAT-3/COSMIC. In addition to these improvements of the occultation signal tracking, also the wave-optics-based retrieval techniques for the data analysis in the lower troposphere were improved during the years (e.g., [38.74–76, 94]).

The increased deviations above $\approx 25$ km are also in the focus of recent investigations by RO and analysis specialists (e.g., [38.77]). On the one hand, GNSS RO retrievals become more difficult at these altitudes due to very small atmospheric excess phases; on the other hand, the analyses and the radiosondes exhibit problems at these altitudes.

The TerraSAR-X and TanDEM-X tandem satellite configuration (mean distance $\approx 20$ km) provided for more than one year continuously vertical profiles at close quarters, recorded from different satellite platforms. This is a unique data set to investigate the accuracy potential of the RO technique and to determine its precision. Figure 38.18 shows a statistical comparison of corresponding refractivity profiles [38.89].

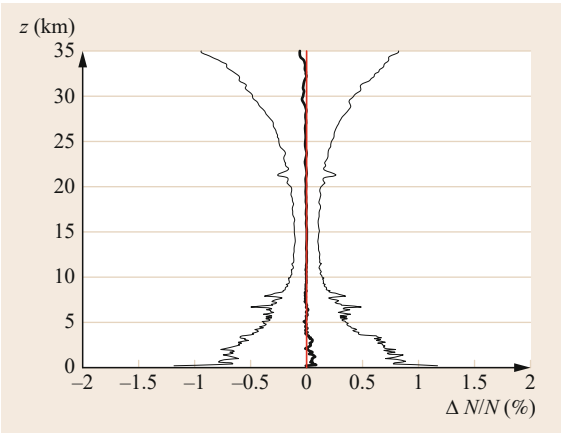

**Fig. 38.18** Statistical comparison of the corresponding refractivity profiles from TerraSAR-X and TanDEM-X between November 26 and December 2, 2011. *Thick* and *thin black lines* indicate bias and rms, the *red line* indicates no deviation (courtesy of F. Zus, GFZ)

Nearly no or only an insignificant bias at the lower troposphere and above $\approx 30$ km can be observed. The standard deviation is $\approx 0.1\%$ in the UTLS, $\approx 0.5\%$ in the lower troposphere, and above $\approx 30$ km. These findings are in very good agreement with those in [38.92] for co-located FormoSAT-3/COSMIC profiles during the deployment phase of this multisatellite mission.

It is only briefly noted here that the high precision of the GNSS RO data is a valuable property to calibrate other satellite data from microwave sensors, which are widely used for global weather forecasts [38.95].

### 38.2.6 Prospects of New Navigation Satellite Systems

Similar to other GNSS applications, the availability of new navigation satellite systems (such as Galileo, BeiDou, and QZSS), along with the impressive renaissance of GLONASS and the modernization of GPS, will also be of great benefit for GNSS RO science and technology. GNSS RO will obviously profit from the significantly increased number of transmitting satellites. Even a single-satellite mission could potentially increase the number of daily occultation observations by a factor of 3 or 4, compared to only GPS. Besides this quantitative aspect, the new GNSS signal structures exhibit various advantages for the data quality of future RO missions. One example is the use of a third carrier frequency for improved ionospheric correction and better RO data quality in the stratosphere (Sect.38.2.5). An initial summary on the prospects of the new GNSS for RO is given in [38.96].

### 38.2.7 Weather Prediction

The highlight of the GNSS RO applications and the breakthrough for its acceptance as an established atmospheric remote-sensing technique was the start of the operational use to improve global weather forecasts. Forerunner for this development was the German CHAMP satellite, which has been providing continuous near-real-time GNSS RO data since 2003. The average delay between the measurement and corresponding provision of globally distributed vertical atmospheric profiles was reduced from 5 h in 2003 to around 2 h in 2006 mainly by the implementation of optimized precise orbit determination procedures for CHAMP. These near-real-time data from GFZ were used by the leading forecast centers to develop appropriate assimilation techniques and to investigate and quantify the impact of the RO data on the forecasts [38.81]. Currently, the RO data are routinely used by the world-leading weather centers to improve their global numerical forecasts.

Several NWP (Numerical Weather Prediction) centers have reported a positive forecast impact with GNSS RO data (e.g., [38.80, 97–99]), despite the fact that the RO data numbers are low when compared with those of satellite radiances (major part of satellite data used) that are assimilated. For example, ECMWF assimilates around 10 million of conventional and satellite observations per 12 h period, of which 90% are satellite radiance measurements, and only around 2% are GNSS RO-bending angles. The main GNSS RO impact is seen for upper-tropospheric and stratospheric temperatures. The GNSS RO measurements are beneficial because they provide complementary information to the satellite radiance measurements. Compared with satellite nadir sounders, the GNSS RO measurements have excellent vertical resolution and do not require bias correction, so they *anchor* the bias correction applied to satellite radiances and help identify NWP model biases [38.100].

Figure 38.19 shows the historical begin of the assimilation of GNSS RO data from FormoSAT-3/COSMIC, CHAMP, and GRACE-A on December 12, 2006. The major information is the reduction/elimination of the ECMWF bias in the background and analysis temperature ($\approx 0.2$ K and $\approx 0.4$ K) and geopotential height (5–10 m) of the 100 hPa pressure level compared to radiosonde data, which can be regarded as truth at these altitudes.

### 38.2.8 Climate Monitoring

RO observations are well suited for establishing a stable, long-term record required for climate monitoring (e.g., [38.82, 101, 102]). Key properties for this application are: global coverage, high accuracy, high vertical resolution, and independence from weather. Most important, however, is that the fundamental RO obser-

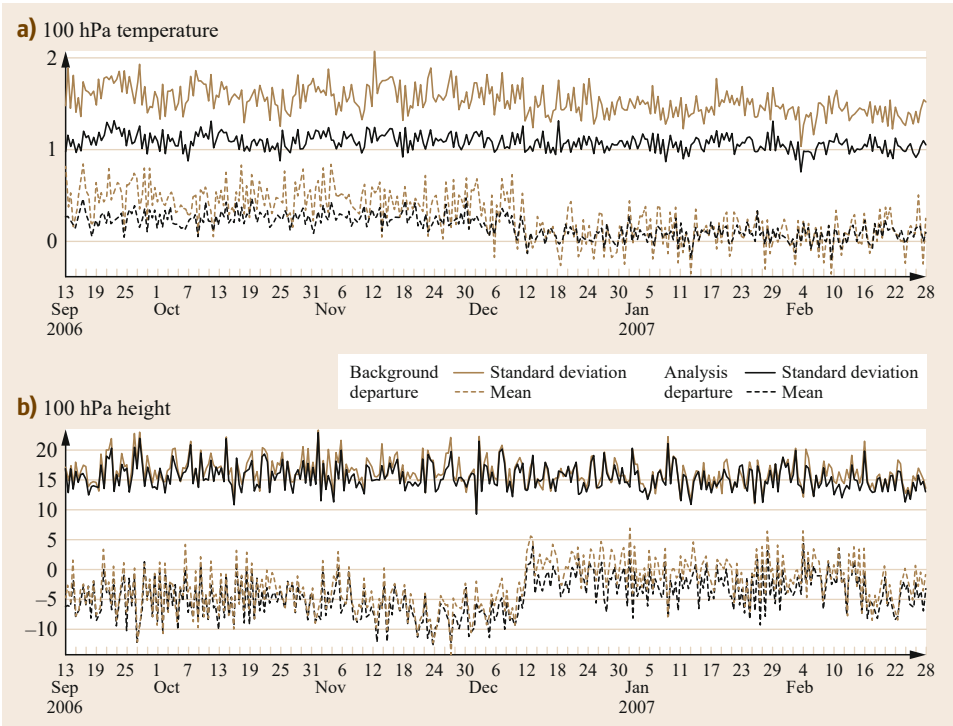

**Fig. 38.19a,b** Time series of the mean and standard deviation of the ECMWF operational background departures and analysis departures for **(a)** temperature and **(b)** geopotential height radiosonde measurements at 100 hPa in the southern hemisphere. GNSS-RO was introduced on December 12, 2006 (courtesy of S. Healy, ECMWF)

vation is a measurement of time (determination of the signal travel time), which is performed by atomic clocks with unequaled accuracy and stability. During an occultation, the GNSS receiver measures the change in the flight time of the signal transmitted by the occulted GNSS satellite. The clocks aboard the GNSS transmitters remain synchronized to the most stable atomic clocks on the ground. The clock in a GNSS receivers aboard an LEO satellite is synchronized, using the signals from up to 10 nonocculted GNSS transmitters in view and is thus tied to the stable ground-based GNSS time as well. Therefore, an extremely accurate measurement of the signal flight time with long-term stability can be achieved. Because the fundamental observation is a measurement of time, RO is a promising technique for climate monitoring.

The detection of climate trends is enormously important, especially because of their huge social and economical consequences, but there is presently no atmospheric instrument that can meet the stringent climate monitoring requirements of 0.5 K accuracy and 0.04 K decade$^{-1}$ stability [38.102].

### Global Temperature Trends

The upper troposphere and lower stratosphere (UTLS) are the key regions of the atmosphere with important links to the stratosphere–troposphere exchange as well as climate research. The determination of the UTLS temperature and tropopause (TP) height trends is crucial for the monitoring of climate-change processes (Sect. 38.2.8). Global high-resolution temperature observations in the UTLS region are only available from GNSS RO data. Here the CHAMP mission has generated the first long-term RO data set (2001–2008) that is continued with data from other mission (GRACE, FormoSAT-3/COSMIC, MetOp, TerraSAR-X). The UTLS region is also the vertical atmosphere region, where GNSS RO exhibits the highest accuracy (Sect. 38.2.5), another important property for the use in UTLS climate studies.

A global pattern of atmospheric temperature trends between 5 and 25 km is shown in Fig. 38.20. The figure was derived from CHAMP, GRACE-A, and TerraSAR-X GPS RO data between 2001 and 2013. The TP altitude is indicated with a white line. A slight overall warming in the upper troposphere (above 5 km to the TP) can be observed with largest values in the subtropical region of the southern hemisphere (SH). In the lower stratosphere from the TP up to 25 km predominant negative temperature trends (cooling) are detected. The equatorial TP region and the lower SH stratosphere reveal warming [38.82, 83, 103].

The results of these studies indicate the great potential of the very precise GNSS data to monitor even

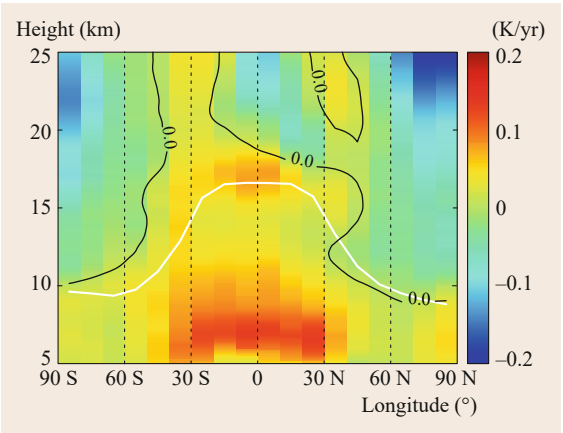

**Fig. 38.20** Global temperature trends in the upper troposphere and lower stratosphere based on CHAMP, GRACE, and TerraSAR-X GPS RO data (2001–2013). The *solid white line* denotes the mean TP height (courtesy of T. Schmidt, GFZ)

small atmospheric temperature trends. This is also one reason for the current use of GPS RO data to validate a new model system for of mid-term climate forecast, which is, for example, currently developed in Germany.

To ensure a high data quality, especially for the RO climate applications, the international RO science community started in 2009 an important activity. RO products from different processing centers are compared regularly for the determination of the structural uncertainty in climate data records and the stability of trends (Fig. 38.21). These multicenter-based results ensure a high quality of the RO data analysis and provide more complete and reliable climatological information as derived from the results of only one center [38.85, 86].

### The Tropopause: Indicator for Climate Change

The TP region separates the troposphere and stratosphere that have fundamentally different characteristics with respect to chemical composition and static stability. Therefore, the determination of TP parameters, such as altitude or temperature, on a global scale is an important goal for many branches in atmospheric research [38.104]. With regard to the current climate change discussion, TP parameters have received more attention in recent years since they are used to describe climate variability and change. The global mean TP altitude shows an increase in re-analyses and radiosonde observations over the last decades and seems to be a more sensitive indicator for climate change than the Earth's surface temperature [38.105]. Another ap-

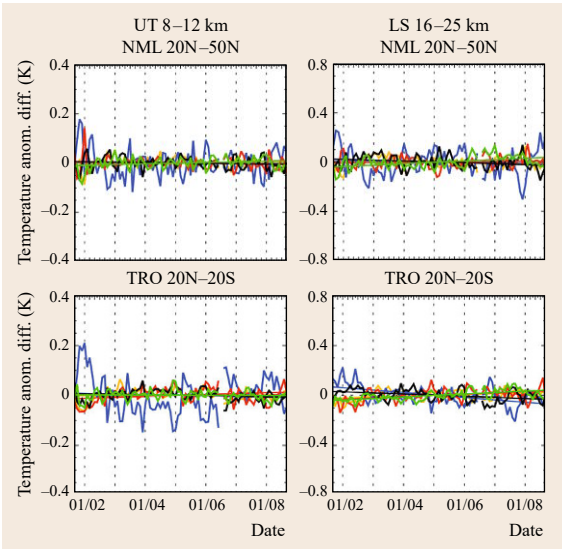

**Fig. 38.21** Structural uncertainty in RO temperature records from different processing centers: DMI Copenhagen (*yellow*), GFZ Potsdam (*blue*), JPL Pasadena (*red*), UCAR Boulder (*black*), and WEGC Graz (*green*). Shown are difference time series of temperature anomalies for each center (with respect to the all-center mean) for the upper troposphere (left) and the lower stratosphere (right), for northern mid-latitudes (top) and the tropics (bottom). The overplotted difference trends are close to zero and indicate the stability of the RO data record (courtesy of A. Steiner, Wegener Center)

plication area of TP studies deals with the role of the TP region in the stratosphere–troposphere exchange. In this context, multiple tropopauses or TP break regions are important because in these regions most of the exchange processes take place (e.g., [38.106]).

One important data source for the determination of TP parameters is radiosondes. Despite good vertical resolution of the radiosonde data, global coverage is impossible. In contrast, the RO technique offers both global coverage and good vertical resolution as well and is therefore of particular relevance for detailed TP studies. First GNSS RO results for the tropical TP region were already published based on GPS/MET data [38.107, 108]. An example for the TP-related investigations is shown in Fig. 38.22 based on the investigations described in [38.109]. A significant increase of the global mean TP height of about 6 m/year between 2001 and 2011 was found associated with a warming in the upper troposphere. This could be an indication for a warming (extension) of the entire TP (connected with the cooling of the stratosphere), but longer data sets are needed to get more confidence of these early GNSS RO results for climate change research.

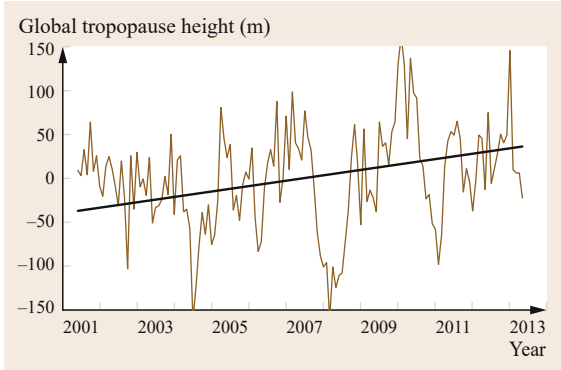

**Fig. 38.22** Global TP height trend (*black line*) based on CHAMP, GRACE, and TerraSAR-X GPS RO data (2001–2011). The *brown line* indicates the monthly mean global TP height, derived from these RO missions (courtesy of T. Schmidt, GFZ)

### Gravity Waves

Another important and climate change detection related application of the GNSS RO data is the derivation of atmospheric wave parameters on a global scale. Most relevant in this respect are gravity waves (GWs, wave phenomena, where the force of gravity tries to restore equilibrium), which play an important role for the general atmospheric circulation due to the related transport of energy and momentum between different regions of the atmosphere. Therefore, their analysis is of great interest for local weather forecasts and global climate modeling.

Early studies were initiated with GPS/MET data [38.110] and focused on vertically propagating waves. Recent studies (e.g., [38.111]) use much larger databases from multisatellite constellations and indicate the potential to derive also horizontal wave properties. Figure 38.23 shows the momentum flux (MF) distribution for July as a mean of 4 years (2007–2010) within the altitude range of 20–25 km. High values of MF along the southern Andes and at the east of the Andes are due to strong steady west wind crossing the mountains in that region. In the tropical regions, the high gravity wave activity, which induces high values of MF, is due to intense convection. The northern hemisphere is rather quiet in the local summer, therefore showing low MF values (Fig. 38.23). Atmospheric waves, for example, tides, can also be detected in spatiotemporal signatures of ionospheric irregularities (Sporadic E layer), detected using the GNSS RO technique [38.112].

### The Planetary Boundary Layer

Recently scientists recognized more and more importance of the dynamics of the planetary boundary layer

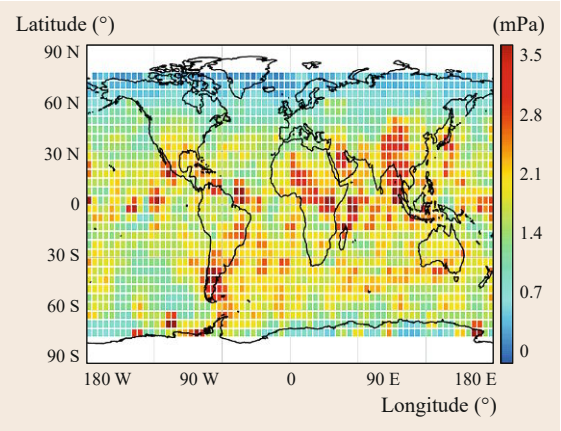

**Fig. 38.23** Horizontal momentum flux (MF, a measure for horizontal energy transport by gravity waves) distribution generated from groupings of three co-located GPS RO profiles from the FormoSAT-3/COSMIC mission as 4-year mean values (2007–2010) for July for the altitude range of 20–25 km (courtesy of A. Faber, GFZ)

(PBL) inversions to the overall climate system. The PBL is the lowermost atmospheric layer directly affected by the Earth's surface. Commonly, the boundary between this turbulently mixed layer and the stably stratified atmosphere above is characterized by a temperature inversion and the decrease of relative and absolute humidity, especially in the moist tropics and subtropics. The top of the PBL is sharper and horizontally more homogeneous in the subtropics, where it is often called a trade wind inversion, than in the tropics and over oceans compared to land. The depth of the PBL is an important parameter for numerical weather prediction and climate models. The key property of GNSS RO for monitoring the PBL is global coverage and high vertical resolution; especially, the top of the PBL is associated with sharp vertical refractivity gradients, which can be clearly identified with GNSS RO (Fig. 38.24).

Several studies from different research groups were performed in recent years [38.94, 113, 114]. For example, in [38.113], three-year climatologies of mean PBL heights, derived from GNSS RO (Fig. 38.24) and ECMWF Reanalysis Interim (ERA-Int), show similar spatial and seasonal variations, but the GNSS RO heights were higher by 500 m, and the standard deviation was also higher from GNSS RO, especially in the tropics, which was analyzed in more detail for various regions, as the Pacific Ocean and the Sahara desert. The results suggest that the underlying causes of the bias between GNSS RO and ERA-Int likely vary from region to region. Another main result of this study is the statement that GNSS RO profiles actually contain vertically resolved information above and within the PBL, information which can be difficult to obtain through any other satellite measurement.

### 38.2.9 Synergy of GNSS Radio Occultation with Reflectometry

Recently, GNSS signals reflected off the surface of the Earth are in focus of intense international GNSS research (GNSS-Reflectometry, GNSS-R). These signals promise a broad range and numerous geophysical applications for remote sensing (e.g., [38.115, 116]) and are in more detail focused in Chap. 40 of this book. Whereas GNSS atmosphere sounding is already fully recognized as an established atmospheric remote-sensing technique, GNSS-R needs more and concentrated international research to exploit its full and

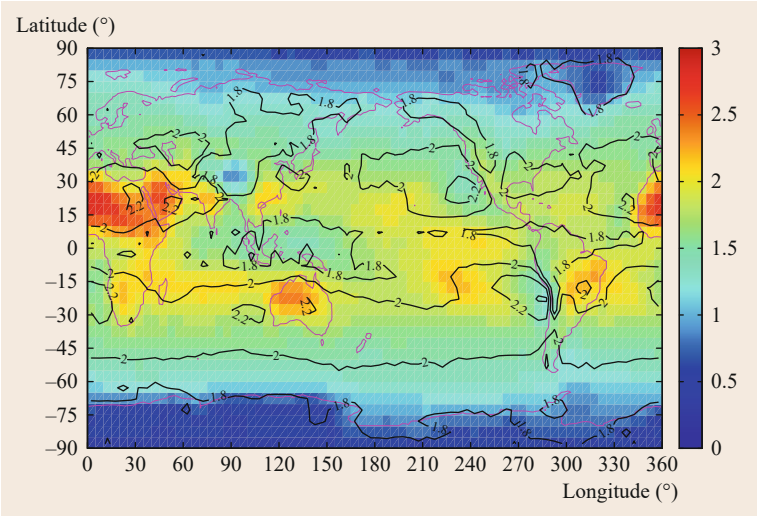

**Fig. 38.24** Height of the mean global PBL (resolution $5 \times 5°$, derived from five years of GPS RO data from the FormoSAT-3/COSMIC mission (2007–2011) (courtesy of C.O. Ao, JPL)

unique potential for the remote sensing of water, ice, and land surfaces but also for atmosphere/ionosphere sounding. Important milestones for this development are the dedicated satellite missions CYGNSS (CYclone Global Navigation Satellite System, National Aeronautics and Space Administration (NASA), [38.117]) and GEROS-ISS (GNSS Reflectometry Radio Occultation and Scatterometry aboard the International Space Station; European Space Agency (ESA) [38.115]), which focus on a global application of the GNSS reflectometry.

Part of these activities is the investigation of the potential of the carrier-phase interferometry between the reflected and direct occultation signals (coherent reflectometry), which was initially demonstrated using the measurements from GPS/MET and CHAMP [38.118–120], see Fig. 38.25. These studies indicated that submeter sensitivity on the surface heights can formally be reached with this technique, which offers potential altimetric applications of ocean and ice surfaces. Improved and specific GNSS-tracking software probably can improve this reached accuracy in future with combined occultation/reflection experiments. A major advantage of the coherent reflectometry compared to nadir-viewing reflectometry is that only a low-gain limb-viewing antenna is required, which allows the application also aboard small satellites in future GNSS remote-sensing constellations. But for such application, a more detailed evaluation of the accuracy potential of the coherent reflectometry is required.

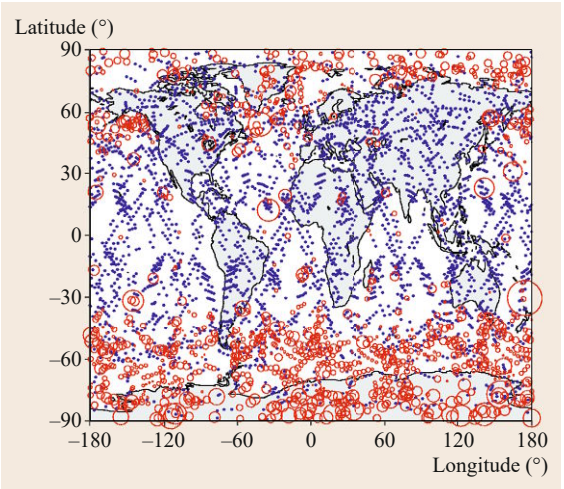

**Fig. 38.25** Geographical distribution of 3783 occultation events observed between 14 May and 10 June 2001. *Blue dots* indicate 2571 observations without reflection signatures; 1212 reflection events are marked as *red circles*. Circle diameter is proportional to the reflected intensity (courtesy of G. Beyerle, GFZ)

## 38.3 Outlook

Ground- and satellite-based atmosphere sounding techniques with their broad spectrum of applications, especially in weather forecast and climate change-related research, were introduced. An overview of the main applications is presented in Table 38.2. Today many thousands of continuously operating ground-based stations exist. Some hundreds are coordinated globally by the IGS and many more are coordinated on a regional or local (national) level. For real-time applications such as weather forecasting, the most important information is the temporal variations, the timing of moving air masses. This does not necessarily require an absolute calibration and homogeneous processing. In this aspect, the monitoring of the water vapor content over decades, for climate change studies, is much more demanding in terms of homogeneous networks and processing in order to draw correct conclusions for the very tiny trends that are expected.

The ground-based data have so far mainly been acquired from sites on land. Platforms on ships or bouys, have more logistics involved and suffer of some extent from the need for simultaneous estimates of the vertical coordinate. The concept has been demonstrated (see [38.121, 122]) and assuming more efficient data communication in the future this may offer a much improved global coverage.

Beginning with the initial and very successful measurements from GPS/MET and by the follow-on missions, as, for example, CHAMP, GRACE, FormoSAT-3/COSMIC and Metop, the innovative GNSS RO method became an established atmospheric remote-sensing technique within the last two decades. A series of new missions is planned and will be realized within the coming years. Our general conclusion is that GNSS atmosphere sounding, ground as well as satellite based, underwent a revolutionary development especially during the last decade and are now fully recognized atmospheric remote-sensing techniques. This development is documented by a broad variety of scientific and also operational applications, most visible is the continuous use of ground- and satellite-based GNSS data for the improvement of numerical weather forecasts since 2006.

The recent GNSS developments will further push these activities. There are upcoming and modernized transmitter systems, continuously increasing receiver

**Table 38.2** GNSS meteorology applications for remote sensing of the neutral atmosphere

| Application | Ground-based receivers | Satellite-based receivers |
|---|---|---|
| **Weather forecasting** | | |
| IWV timeseries | Yes | – |
| Bending angle/Refractivity profiles | – | Yes |
| **Climate** | | |
| IWV trends | Yes | – |
| Annual and diurnal IWV signals | Yes | – |
| Global Temperature trends | – | Yes |
| Tropopause characteristics | – | Yes |
| **Atmospheric research** | | |
| Atmospheric convection regional scale | Yes | – |
| Atmospheric waves | – | Yes |
| Complement other sensors (e.g., infrared) | – | Yes |
| Large scale atmospheric circulation | – | Yes |
| Planetary boundary layer | – | Yes |
| Tropical cyclones | – | Yes |
| Upper troposphere and lower stratosphere | – | Yes |
| 3D-Distributions of water vapor | Yes | – |
| Spatiotemporal variability in the IWV | Yes | – |

infrastructure, with the extension of ground networks and more GNSS flight receivers, but probably also new marine, ground and flight platforms in the near future, not to forget the *everyones* receivers such as smartphones.

These developments will not only increase the number of atmospheric GNSS measurements, but probably also will allow a better data quality. It will further stimulate the existing applications but probably also will open the door for new and innovative applications. GNSS atmosphere sounding is a story of success, which will be continuously updated.

# 39. Ionosphere Monitoring

Norbert Jakowski

Global navigation satellite system (GSSS)-based monitoring of the ionosphere is important in a twofold manner. Firstly, GNSS measurements provide valuable ionospheric information for correcting and mitigating ionospheric range errors or to warn users in particular in precise and safety of life (SoL) applications. Secondly, spatial and temporal resolution of ground- and space-based measurements is high enough to explore the dynamics of ionospheric processes such as the origin and propagation of ionospheric storms.

It is discussed how ground- and space-based GNSS measurements are used to create global maps of total electron content (TEC) and to reconstruct the highly variable three-dimensional (3-D) electron density distribution on global scale under perturbed conditions. Thus, the monitoring results can be used for correcting ionospheric errors in single-frequency applications as well as for studying the driving forces of space weather-induced perturbation features at a broad range of temporal and spatial scales. Whereas large- and medium-scale perturbations affect accuracy and reliability of GNSS measurements, small-scale plasma irregularities and plasma bubbles have a direct impact on the continuity of GNSS availability by causing strong and rapid fluctuations of the signal strength, known as radio scintillations.

It is discussed how better understanding of space weather-related phenomena may help to model and forecast ionospheric behavior even under perturbed conditions. Hence, ionospheric monitoring contributes to the successful mitigation of range errors or performance degradation associated with the ionospheric impact on a broad spectrum of GNSS applications.

The ionosphere is a highly variable propagation medium, mainly formed by the highly energetic part of the electromagnetic and corpuscular radiation of the Sun and its changes. Closely connected with the highly variable Sun and other geospheres, the ionosphere itself is an integral part of space weather. Complex coupling processes are not yet well understood and therefore need further exploration. Additionally, the ionospheric impact on modern technical infrastructures relying on communication, navigation and remote sensing technologies requires permanent and reliable ionosphere monitoring and forecasting to inform users on ionospheric threats in the course of ionospheric storms according to their needs.

## 39.1 Ground-Based GNSS Monitoring

As pointed out in Sect. 6.3.5 of this Handbook, dual-frequency GNSS measurements can, in principle, be utilized to derive the total electron content (TEC) along the measured ray path or link. Considering their accuracy and near-real-time availability, which is permanently growing, ground-based GNSS measurements have been well established as a powerful tool for monitoring the ionosphere and related space weather effects for about two decades.

To derive TEC from ground-based Global Positioning System (GPS) measurements, various techniques have been developed [39.1–6].

Generally speaking, the procedure to derive TEC from GNSS measurements contains several steps.

In the first-order approximation, the differential phase is proportional to the integral of the electron density along the slant ray path (STEC). The differential code $p$ and carrier phases $\varphi$ can thus be written as

$$\begin{aligned}\Delta p &= p_2 - p_1 \\ &= \frac{K\left(f_1^2 - f_2^2\right)}{f_1^2 f_2^2}\mathrm{STEC} + \Delta b_\mathrm{C} + \Delta\varepsilon_\mathrm{C}\end{aligned} \tag{39.1}$$

and

$$\begin{aligned}\Delta\varphi &= \varphi_1 - \varphi_2 \\ &= \frac{K\left(f_1^2 - f_2^2\right)}{f_1^2 f_2^2}\mathrm{STEC} + \Delta b_\mathrm{L} + \Delta\varepsilon_\mathrm{L}\,.\end{aligned} \tag{39.2}$$

Here $\Delta b_\mathrm{C}$ and $\Delta b_\mathrm{L}$ designate the remaining instrumental delays including ambiguities in case of carrier phase measurements, whereas $\Delta\varepsilon_\mathrm{C}$ and $\Delta\varepsilon_\mathrm{L}$ designate the residual noise terms and

$$K = \frac{\mathrm{e}^2}{8\pi^2\varepsilon_0 m_\mathrm{e}} \approx 40.309\,\mathrm{m^3\,s^{-2}} \tag{39.3}$$

(Sect. 6.3.2).

Since the absolute travel time (pseudorange) measurements at coded signals are noisy due to strong multipath effects, in particular at low elevation angles, it is common practice to level the much less noisier carrier-phase measurements into the code observations (Fig. 39.1). Thereafter the leveled differential carrier-phases must be calibrated because satellite and receiver devices cause also a delay, which is commonly unknown. Instrumental biases can smoothly change, for example due to oscillator drift in the electronic circuits as a function of permanently changing conditions at satellites and receivers environments, such as the temperature. Principally there is one bias for each satellite and for each GNSS station, which is commonly assumed to be practically constant over a period of several days. Since this calibration procedure requires some assumptions about the ionosphere, different research groups have developed different approaches.

### 39.1.1 Calibration of TEC Measurements

As mentioned above, the calibration requires an ionospheric model, for example simplified by a polynomial approach. Naturally, the chosen approaches are different for different research groups. Here we focus on a method that uses a well-qualified TEC model for calibration that can adequately adapt to the real ionospheric behavior [39.5–7].

The calibration approach uses the global Neustrelitz TeC model (NTCM) (Sect. 6.3.4) for TEC at epoch $i$ according to

$$\mathrm{STEC}^i_\mathrm{Meas} = \mathrm{STEC}^i_\mathrm{NTCM} + b_\mathrm{RX} - b^\mathrm{SAT} + \varepsilon\,, \tag{39.4}$$

where $\mathrm{STEC}^i_\mathrm{Meas}$ is taken from the leveled carrier-phase measurement in (39.2), $b_\mathrm{RX}$ and $b^\mathrm{SAT}$ represent the interfrequency or differential code biases of GNSS receiver and corresponding GNSS satellite respectively. The term $\varepsilon$ explicitly represents the residual errors. The term $\mathrm{STEC}_\mathrm{NTCM}$ stands for slant TEC derived from the used NTCM model that depends on typical geophysical parameters and current solar activity level approximated by the solar radio flux index F10.7 [39.7]. Since the TEC model provides geometry-free vertical TEC, the required $\mathrm{STEC}_\mathrm{NTCM}$ must be converted from ver-

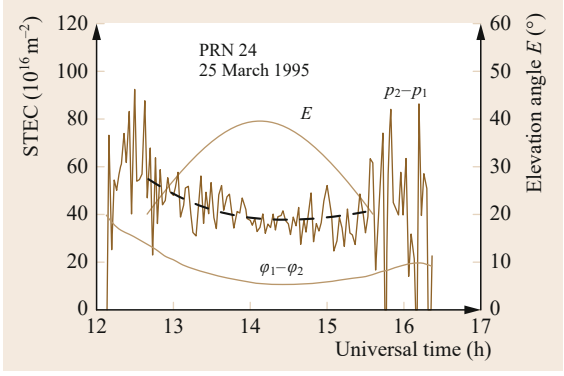

**Fig. 39.1** Differential code ($p_2 - p_1$) and carrier ($\varphi_1 - \varphi_2$) phases of GPS signals (PRN24) measured in Neustrelitz on 25 March 1995. The *dashed line* indicates the least squares leveled differential carrier-phases used for further computation (after [39.5])

tical to slant TEC using an elevation ($E$)-dependent obliquity factor or mapping function $M(E)$ as considered in Sect. 6.3.4.

Now (39.4) can be rewritten as

$$\mathrm{STEC}^{i}_{\mathrm{Meas}} = M(E)\,\mathrm{VTEC}^{i}_{\mathrm{NTCM}} + b_{\mathrm{RX}} - b^{\mathrm{SAT}} + \varepsilon \tag{39.5}$$

in which the local TEC model values at ionospheric piercing points are directly used for the subsequent calibration procedure. The model approach allows for the choosing of an autonomous model like NTCM with fixed coefficients or an operational model $\mathrm{NTCM_{op}}$ with reduced dependencies and variable coefficients, which better fits the actual ionospheric conditions. If data coverage is sufficient, the latter method is recommended, whereas in the case of poor data coverage the autonomous model should yield best results.

The model coefficients and interfrequency biases (IFB) $b_{\mathrm{RX}}$ and $b_{\mathrm{SAT}}$ are then obtained by weighted least squares fit of (39.5) to the observation data at all measured radio links for a previous 24 h period [39.5].

Since the instrumental biases in (39.5) cannot be separated, and to find a comparable measure of satellite biases, the common practice is to introduce an additional equation that defines

$$\sum_{i} b^{\mathrm{SAT}_i} = 0 \tag{39.6}$$

for all satellites and measurements.

Thanks to the model-assisted calibration technique, the calibration of IFBs and the subsequent generation of TEC maps can be carried out in near-real time. A satellite bias sample of GPS satellite G07 monitored over some days in October 2010 is shown in Fig. 39.2.

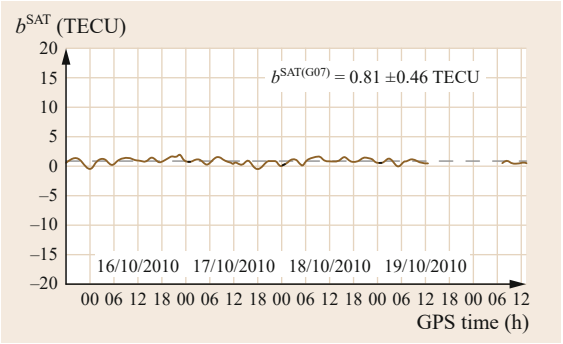

**Fig. 39.2** Sample of bias computation results on a few selected days in October 2010 providing a satellite bias of $b^{\mathrm{Sat(G07)}} = 0.81$ TECU at a root mean squared (RMS) uncertainty of 0.46 TECU (1 TECU $= 10^{16}$ electrons/m$^2$)

## 39.1.2 Global Ionosphere Maps

The ionosphere may cause signal delays in GNSS observations that correspond to link-related range errors of up to 100 m. Whereas this error can mostly be corrected in dual-frequency measurements by a linear combination of these two measurements, single-frequency measurements need additional information to mitigate the ionospheric error. Knowing that the first-order range error is proportional to TEC, it becomes evident that ionospheric corrections can be provided by a TEC model or by TEC maps, for example deduced from corresponding GNSS measurements. Whereas current TEC models provide only climatological data, actual TEC maps can provide more realistic correction data. The latter method is typically used in satellite-based augmentation systems (SBAS) such as WAAS, EGNOS, GAGAN or MSAS. Here a number of reference stations provide the basic information for computing regional TEC maps. Such a map provides TEC values at a regular grid with spacings of $5° \times 5°$ in latitude and longitude respectively. It is obvious that the accuracy and spatial resolution of generated TEC maps depends on the availability of ground-based GNSS measurements over the area in view.

As noted earlier, different approaches have been developed by different research groups. *Jakowski* et al. [39.5, 6], for instance, use a model-assisted technique for calibrating and mapping the measured TEC over Europe since 1995, over the polar areas since 2001 and globally since 2010.

TEC maps are generated by assimilating available observations into a specific background model [39.7] as considered in Sect. 6.3.4. This procedure has the advantage that even in the case of poor or uneven data coverage, for example over the oceans, climatological TEC estimations are available for range error corrections by customers.

The TEC data assimilation procedure starts with a least squares adjustment of the background model with respect to all observations. Assuming that the adjustment value at measurement epoch $i$ is $\mathrm{VTEC}^{i}_{\mathrm{adj}}$, the deviations at all $N$ ionospheric piercing points $j$ are computed according to

$$\Delta\mathrm{VTEC}^{i}_{j} = \mathrm{VTEC}^{i}_{j} - \left(\mathrm{VTEC}^{i}_{\mathrm{NTCM}j} + \mathrm{VTEC}^{i}_{\mathrm{adj}}\right). \tag{39.7}$$

The model adjustment takes care that the sum of positive and negative deviations of all $N$ observations $j$ from

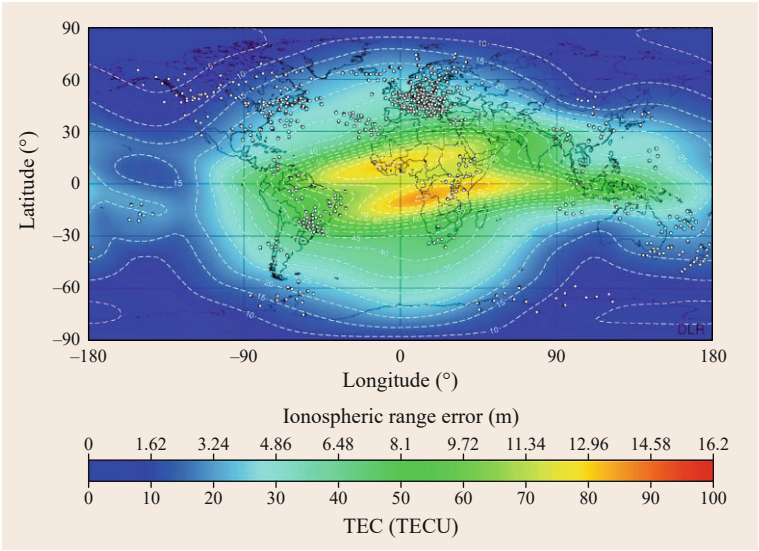

**Fig. 39.3** Sample VTEC map on 17 October 2011 at 14:00 UT. Ionospheric piercing points of GPS ground stations are marked by *dots*

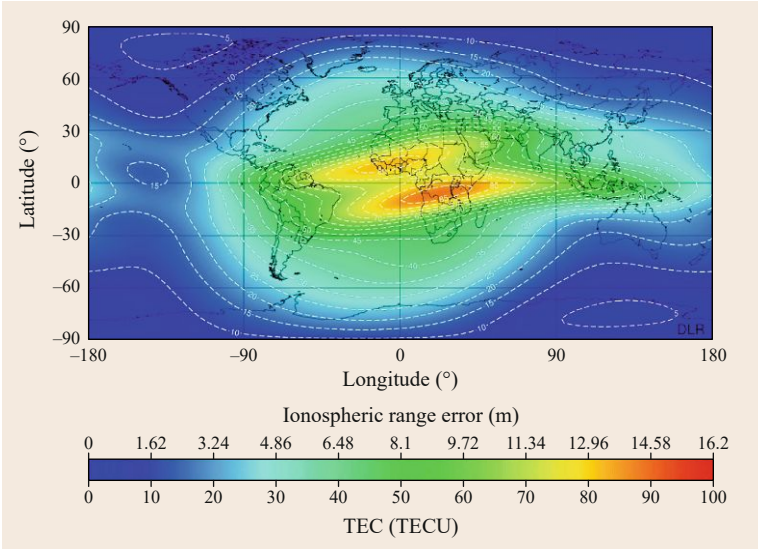

**Fig. 39.4** Map of the VTEC background model corresponding to the VTEC map shown in Fig. 39.3

the model surface is equal to zero

$$\sum_{j=1}^{N} \Delta\mathrm{VTEC}_j^i = 0\,. \tag{39.8}$$

$\Delta$VTEC values at grid points (GP) $(k,l)$ are simply computed by summing up weighted deviations of surrounding piercing points. The weight decreases with the distance using a Gaussian-type weighting function. The width of the weighting function is a tuning parameter that defines the influence of individual piercing-point values in the sense of a correlation length. So for instance the parameter can be set small at high data density and big at poor data coverage. To reduce mapping errors at low elevation angles, an elevation-dependent weighting function can be added. The VTEC (vertical total electron content) values at grid points GP$(k,l)$ are finally computed as

$$\mathrm{VTEC}^i(k,l) = \Delta\mathrm{VTEC}^i(k,l) + \mathrm{VTEC}^i_{\mathrm{NTCM}}(k,l) + \mathrm{VTEC}^i_{\mathrm{adj}}\,. \tag{39.9}$$

The final results represent measured TEC values in the vicinity of the piercing points, whereas at greater distances from measurements somewhat modified model values are derived. Following this procedure, VTEC

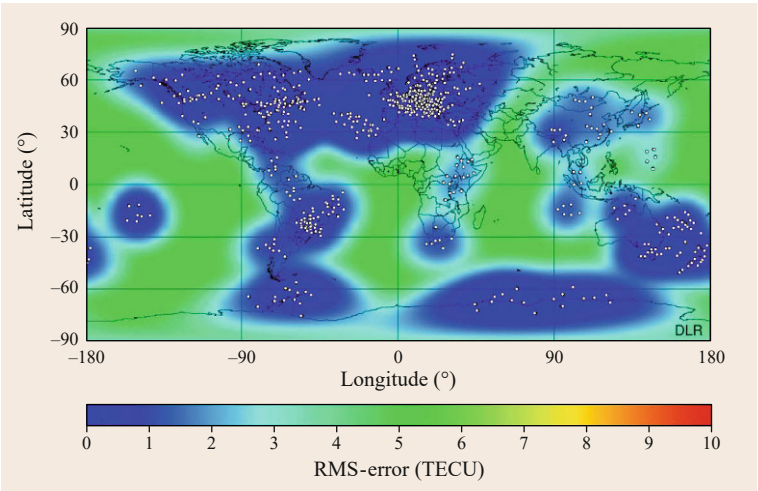

**Fig. 39.5** Error map of VTEC that corresponds to the generation of the sample VTEC map shown in Fig. 39.3

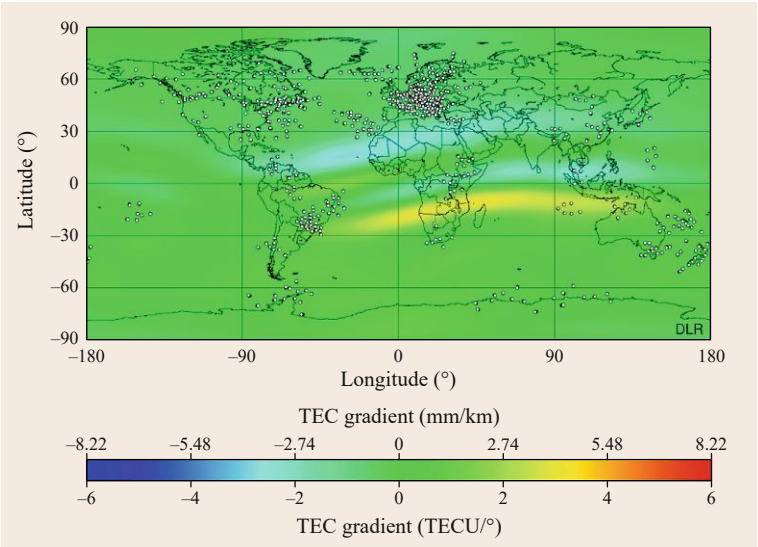

**Fig. 39.6** Map of latitudinal gradients of VTEC corresponding to the VTEC map shown in Fig. 39.3

maps and related products have generated in the Space Weather Application Center (SWACI) at DLR Neustrelitz for many years [39.8].

A global sample map of vertical TEC is shown in Fig. 39.3 for illustration. Most data originate from the geodetic network of the international GNSS service (IGS) network [39.9]. Related piercing points are indicated in the map by small circles. Grid values are spaced by $2.5° \times 5°$ in latitude–longitude. The corresponding map of the operational background model $NTCM_{op}$ is shown in Fig. 39.4.

Since the difference between the model and the derived TEC map is obviously not very big, the model approach fits quite well to the ionosphere in this geomagnetically quiet day. This can be checked when inspecting the corresponding error map as shown in Fig. 39.5. The residual range error is in the order of less than 1 TECU (16.2 cm at L1 GPS frequency) in those regions where good data coverage exists. Over regions not covered by data, for example over the oceans, TEC remains uncertain to a higher degree related to the applied model.

Once TEC maps have been derived from observational data, a multitude of secondary information can be derived such as TEC gradient or rate-of-TEC (RoT) maps. Taking into account also the high temporal resolution of 1 s used in operational processing, perturbation processes can be monitored in detail as considered in Sect. 39.5. Since TEC gradient information is important for precise positioning and navigation and safety of life applications [39.10, 11], TEC gradients as shown in Fig. 39.6 can be used for a first-order estimate of po-

tential problems that might be caused by the handling of ionospheric gradients in an operational system.

The derived TEC gradients are rather small compared with those in the order of 100 mm/km and more, which might cause problems in SoL applications. TEC map-derived gradients are smooth due to the fact that only large-scale phenomena are imaged at grid spacings of more than 100 km. Thus, for deriving TEC gradient-induced ionospheric threats, original slant TEC measurements must be analyzed [39.11].

## 39.2 Space-Based GNSS Monitoring

Space-based dual-frequency GNSS measurements use the same observation equations (39.1) and (39.2) for deriving ionospheric information as used in ground-based techniques.

GNSS measurements on board low Earth orbiting (LEO) satellites may essentially contribute to monitoring of the geoplasma. Thus, GNSS radio occultation measurements are capable of monitoring the vertical ionization of the ionosphere on global scale [39.12–14]. Additionally, regular navigation data used for satellite positioning can effectively be utilized to monitor the three-dimensional electron density distribution of the topside ionosphere/plasmasphere near the orbit plane [39.15]. The effectiveness of radio occultation measurements has been demonstrated by several satellite missions such as Microlab-1 with the GPS/MET experiment [39.12], CHAMP [39.14] and in particular by the COSMIC/Formosat-3 mission in recent years [39.16].

### 39.2.1 GNSS Radio Occultation

GNSS radio occultation is a limb-sounding technique that enables the retrieval of the vertical refractivity profile of planetary atmospheres. What is measured is the ray path bending and/or the phase of the radio wave while approaching the planetary surface in the limb-sounding geometry.

Radio occultation techniques were successfully applied for exploring planetary atmospheres from Mars and Venus using Mariner IV and Venera 4 signals respectively. In the late 1980s *Yunck* et al. [39.17] proposed applying the radio occultation techniques also to the Earth's atmosphere sounding using the L-band signals of GPS, which has just been established. The GPS/MET experiment on board the Microlab 1 satellite mission that was launched in April 1994 has convincingly demonstrated that the GPS radio occultation technique is a powerful tool for remote sensing of the Earth's neutral atmosphere and ionosphere [39.12]. A few years later other satellite missions such as SAC-C, Oerstedt, CHAMP and GRACE followed to exploit the new technique for exploring the lower and middle atmosphere and the ionosphere. A breakthrough was the launch of six LEO satellites (COSMIC/Formosat-3 mission) in 2006 [39.16]. Whereas a single-satellite mission like CHAMP can provide about 200–400 measurements, the multisatellite COSMIC/Formosat-3 mission can provide up to ≈ 2500 occultations per day.

The radio occultation geometry is schematically shown in Fig. 39.7. The refraction angle $\alpha$ between ray path asymptotes of LEO and GNSS satellites has to be derived from GNSS carrier-phase measurements on board the LEO satellite with high accuracy. Since the bending angle is principally less than one degree, the orbit data must be measured precisely (centimeter range) and clock drifts have to be corrected. The refraction angle $\alpha$ is related to the refraction index $n$ via the integral equation

$$\alpha(a) = -2a \int_{r_0}^{\infty} \frac{1}{\sqrt{r^2 n^2 - a^2}} \frac{\mathrm{d}\ln(n)}{\mathrm{d}r} \mathrm{d}r \,. \tag{39.10}$$

Here the impact or approaching parameter $a$ describes the refractive distance of the asymptotic ray paths from the center of the Earth. The vertical refractive index profile is then retrieved as a function of $\alpha$ and $a$ by applying the Abel integral transform [39.18] to integrate (39.10).

Considering only the upper part in ionospheric heights and the ionospheric range error formula (6.85) in Chap. 6, it becomes clear that the Abel inversion

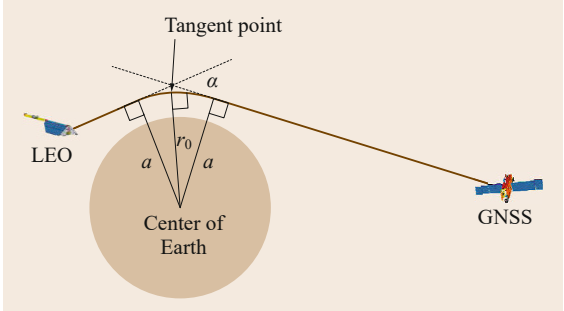

**Fig. 39.7** GNSS radio occultation geometry for retrieving vertical refractivity profiles in the troposphere and ionosphere

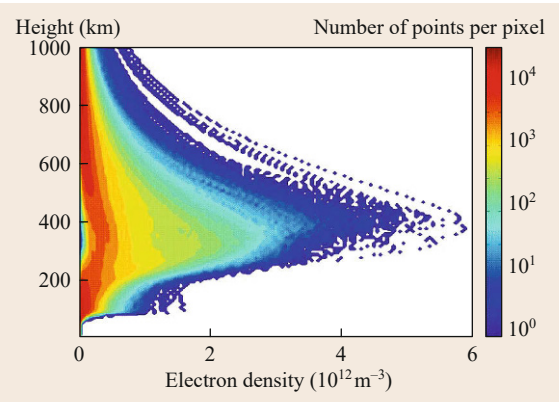

**Fig. 39.8** Superposed plots of 30 000 vertical electron density profiles obtained from IRO measurements on board CHAMP in 2002, a year of high solar activity (after [39.14])

of (39.10) provides the vertical electron density profile from the satellite orbit height down to the bottom side ionosphere. In the lower atmosphere the vertical refractive index profile reveals the neutral gas temperature in conjunction with the water vapor profile [39.19]. Due to the dispersive nature of the ionosphere, *ionospheric radio occultation* (IRO) measurements can directly use differential GNSS carrier-phases from dual-frequency GNSS measurements on board the LEO satellite for retrieving vertical electron density profiles.

Assuming a commonly used sampling rate of 1 Hz, the height resolution is in the order of a few kilometers. Accuracy can be improved by taking into account ray path bending effects [39.20, 21]. Continuous IRO measurements on satellites such as CHAMP, COSMIC or GRACE allow for the collection of massive datasets well suitable for ionospheric studies (Fig. 39.8) and for developing and/or improving models of ionospheric key parameters such as the peak density NmF2 [39.22] or the peak height hmF2 of the F2 layer [39.23].

Averaged IRO measurements show typical ionospheric features such as the equatorial anomaly and the mid-latitude or main trough at nighttime as illustrated in Fig. 39.9.

The worldwide distribution of the electron density indicates a striking geomagnetic control of the F2 layer [39.24]. The most distinctive features are the so-called crest regions of maximum electron density appearing at both sides of the geomagnetic equator at a distance of about 15°, known as the equatorial anomaly. The equatorial anomaly is usually more pronounced around noon than around midnight. The ionospheric mid-latitude or main trough [39.25] is a zone of low electron density located between about 50° and

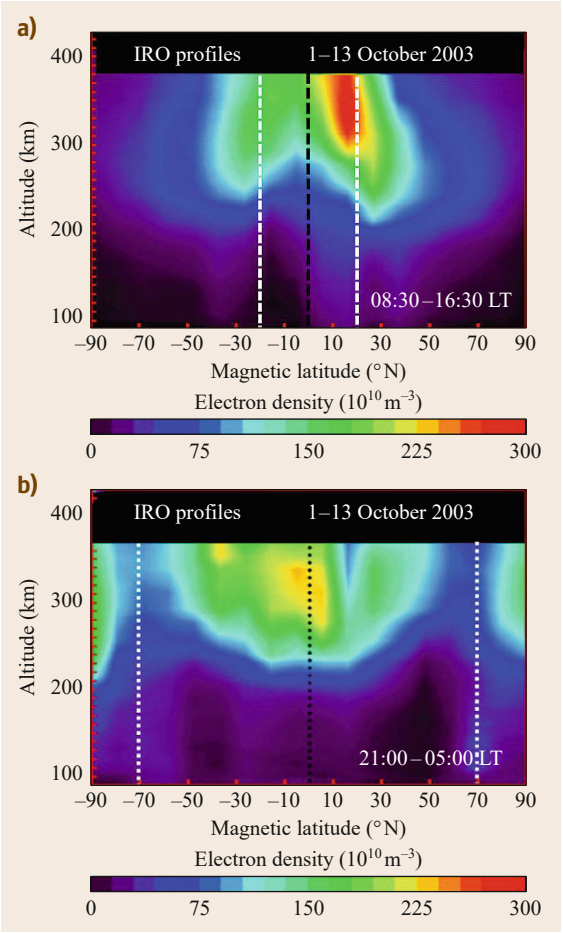

**Fig. 39.9a,b** Averaged IRO profiles retrieved from 1–13 October 2003 at daytime **(a)** and at nighttime **(b)**. The geomagnetic equator is marked by a *black dashed line*, whereas crest and trough latitudes are marked by *white dashed lines*

70° geomagnetic latitude. The main trough lasts from about 18:00 to about 06:00 magnetic time and its width is about 500–1000 km [39.26]. The electron density inside the trough is drastically reduced by as much as a factor of two at 1000 km height and as much as an order of magnitude at the F2 layer peak height.

### 39.2.2 Ionosphere/Plasmasphere Reconstruction

Dual-frequency GNSS data measured on board LEO satellites for positioning can effectively be utilized for ionospheric monitoring in the same way as ground-based measurements. The moving receiver on board the LEO satellite enables the collection of numerous measurements during one satellite revolution. Usually

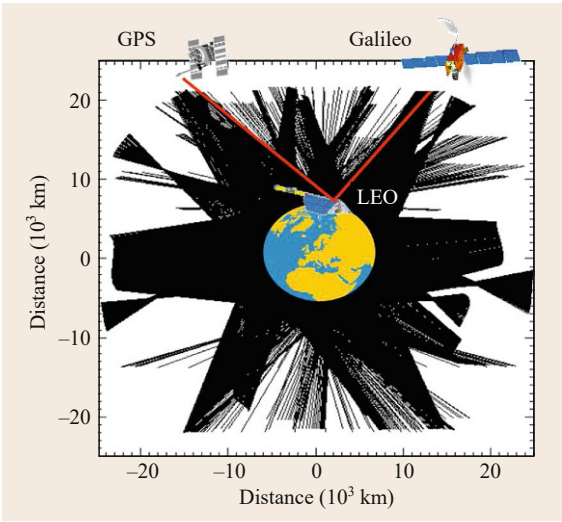

**Fig. 39.10** Illustration of the distribution of radio links between GNSS and a LEO satellite in the LEO orbit plane during one satellite revolution

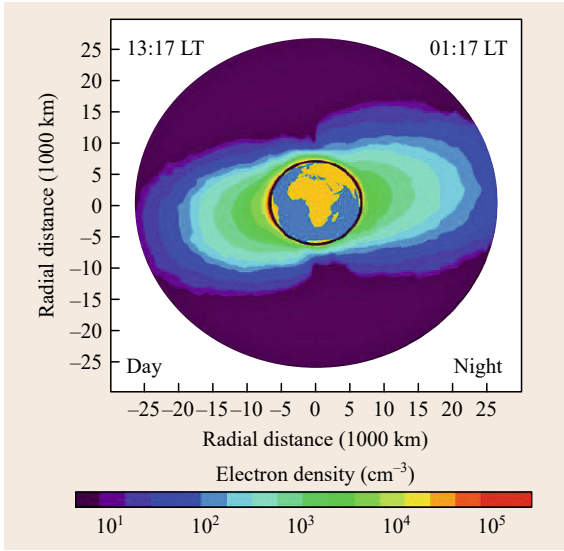

**Fig. 39.11** Reconstruction of the electron density distribution of the topside ionosphere based on GPS data received on board CHAMP. The reconstruction is generated from medians at 21:00 UT over ten consecutive days in August 2005. The *right side* shows the ionosphere/plasmasphere shortly after midnight, whereas the *left side* represents the ionosphere shortly after noon

the data are not homogeneously distributed as demonstrated in Fig. 39.10.

One satellite revolution enables up to about 4000 GPS measurements, a number that would increase if signals from other GNSSs could be used in addition. In a first-order approach the ionosphere is assumed to be static during one revolution (93 min). In agreement with the available data coverage this assumption is justified for monitoring large-scale phenomena in the electron density distribution near the satellite orbit plane. To overcome problems related to inhomogeneous data distribution and data gaps as seen in Fig. 39.10, the reconstruction of the electron distribution can be realized in a reasonable way by assimilating link-related calibrated TEC data into a reliable background model. Following [39.15] the spatial electron density distribution is numerically defined in a specific voxel structure, which is initialized by a model, here by the parameterized ionospheric model (PIM) [39.27]. To meet all link-related TEC measurements, an iterative process is carried out that modifies the electron density inside the voxels crossed by the CHAMP-GPS radio links until the residuals are less than a certain cutoff level. The iterative procedure resembles the well-known multiplicative algebraic reconstruction technique (MART).

To illustrate the achieved results, Fig. 39.11 shows a typical reconstruction of the electron density distribution from CHAMP to GPS orbit heights in the CHAMP orbit plane.

Although the reconstruction will not be an absolutely correct reproduction of the real state of the topside ionosphere and plasmasphere, the result is an improved model output. Independent of data coverage the result is always stable and physically reasonable. The assimilation process results in a three-dimensional electron density distribution near the CHAMP orbit plane. The associated distribution in the orbit plane is seen in Fig. 39.11. It is obvious that the global view on the three-dimensional structure of Earth's plasma environment enables the study of magnetospheric-ionospheric coupling processes.

In Fig. 39.11 the compression of the plasmasphere due to the solar wind is nicely seen at day-side, whereas the night-side clearly shows an enlarged extension of the plasmasphere. Since the field-aligned structure of this geoplasma is sensitive to space weather changes it becomes evident that space-based GPS measurements can essentially contribute to space weather monitoring and studying ionosphere-magnetosphere coupling processes. To enhance the spatial resolution, a multi-LEO satellite constellation capable of using signals from different GNSSs would be beneficial in the future.

## 39.3 GNSS-Based 3-D-Tomography

The three-dimensional reconstruction of the electron density distribution of the full global ionosphere and plasmasphere systems is a challenging task for upcoming years. Only the knowledge of the three-dimensional electron density distribution will provide sufficient insight for the understanding of physical processes behind the observed dynamics of the ionosphere. Additionally, reliable high-frequency (HF) communications and accurate knowledge of ionospheric errors in GPS-based navigation systems are much needed by customers. In GNSS practice, due to the 2-D simplification of the 3-D ionosphere, TEC information may be insufficient in particular in regions of strong horizontal gradients of ionization. The growing availability of GNSS data will improve the conditions for 3-D or 4-D reconstruction of the electron density dramatically. The number of data increases due to densification of ground-based GNSS networks, due to the availability of more and more space-based GNSS data from satellite missions and due to the availability of several GNSS systems like GPS, GLONASS, Galileo or Beidou/Compass. As in case of TEC mapping the reconstruction of the 3-D electron density distribution of the ionosphere and plasmasphere systems in near-real time or postprocessing will benefit from ground- and space-based measurements considered in previous sections.

### 39.3.1 Reconstruction Techniques

Since the first idea thought up by *Austen* et al. in 1986 [39.28] to apply tomographic techniques to the imaging of the ionospheric electron distribution, various methods have been developed to reconstruct the electron distribution from integral TEC measurements. In the early years of ionospheric tomography, TEC from dual-frequency beacon measurements was used [39.29]. Receiving beacon signals, for example those of the forerunner of GPS, the Navy Navigation Satellite System (NNSS), along a chain of ground receivers, multiple intersecting measurements can be made for imaging the vertical electron density along the receiver chain for a selected satellite pass. When GPS signals became available, the imaging was not spatially restricted to a plane defined by the satellite orbit in conjunction with the beacon receiver chain and not restricted in time due to the permanent availability of at least a few GPS satellites needed for positioning [39.30]. A common geometrical constraint exists both for beacon as well as for ground-based GNSS measurements. This is the lack of horizontal measurements causing an uncertainty in the vertical structure of the resulting image. To overcome this ill-posed dataset in order to get stable solutions, one has to include some constraints in the reconstruction procedure, which may differ and lead to a wide range of approaches that cannot be considered here.

The inverse problem of ionospheric tomography is the following: for a given set of path integrals of electron density (TEC) along known transionospheric paths, find the electron density distribution that satisfies all measurements in an optimal way.

The first reconstructions by *Austen* et al. [39.28] used the iterative algorithm of the algebraic reconstruction technique (ART) to image intersecting TEC measurements. Here the initial state is modified by adding corrections that are a function of the difference between the measured TEC and the initial TEC. The solution is achieved after iterating the algorithm several times until the result converges. The multiplicative algebraic reconstruction technique (MART) is similar to ART, however, in this case, the ionospheric state is modified with a factor for correction instead of adding a correction term. This approach ensures that the relative electron density along the ray path remains unchanged, i. e., the electron density cannot become negative. This type of reconstruction technique has been applied in principle for imaging the 3-D topside ionosphere/plasmasphere electron density distribution in the vicinity of the CHAMP orbit plane considered in the previous section [39.15]. Here the initial information is provided by the parameterized ionospheric model (PIM) [39.27] in which the data are assimilated.

Most of the powerful imaging approaches that have been developed in recent years are assimilative since they combine actual measurements with background information provided by an empirical or physical model or at least by empirical orthonormal functions derived from Chapman profiles [39.31–36]. Assimilation techniques commonly use Kalman filtering and 3-D variational techniques [39.37].

Some of these techniques are the ionospheric data assimilation three dimensional (IDA3-D) developed by *Bust* et al. [39.31, 32] the multi-instrument data analysis software (MIDAS) developed by *Mitchell* and *Spencer* [39.34] and physics-based techniques such as the global assimilation ionospheric model (GAIM), developed by *Schunk* et al. [39.33] at Utah State University, and JPL-GAIM, developed by the Jet Propulsion Laboratory (JPL) and the University of Southern California [39.36].

The electron density assimilative model (EDAM) has been developed by *Angling* and *Cannon* at QinetiQ (UK) [39.35] to assimilate ionospheric measurements, in particular ground- and space-based GNSS measure-

ments, into the IRI 2007 model [39.38]. The background model is modified by the difference between the observation vector and the observation operator, which links the geometry of observations to the background model. Before the update starts, this difference is scaled with a weight matrix, which is composed of the error covariance matrices of the background model and the observables. The assimilation is based on a form of minimum variance optimal estimation, also referred to as best linear unbiased estimation (BLUE) that provides an expression for an updated estimation of the ionospheric state. Using the background model, electron densities are established on a 3-D grid of voxels in a magnetic Sun-fixed coordinate system.

MIDAS (multi-instrument data analysis software) is a three-dimensional, time-dependent algorithm for imaging the ionosphere. MIDAS uses phase data from dual-frequency GNSS data to measure relative TEC between satellites and ground receivers. As a priori information a set of orthonormal profiles derived from Chapman functions are used to constrain the vertical profile, so only a small number of coefficients is needed to estimate electron densities above a selected geographic location. The horizontal distribution is determined by a spherical harmonic expansion. Since MIDAS uses differential carrier-phase data for estimating biased TEC, the procedure requires a time-dependent algorithm to gain ionospheric information from ionospheric changes when GNSS satellites move across the sky. Thus, MIDAS can be considered as being a 4-D imaging technique.

The first-principle ionospheric physics-based background model global assimilative ionospheric model (GAIM) of JPL is a global, fully three-dimensional, and time-dependent ionospheric model. It numerically solves for ion and electron densities through the hydrodynamic equations for ions and incorporates state-of-the-art Kalman filter and four-dimensional variational (4DVAR) approaches that enable the assimilation of various types of ionospheric measurements. The space weather model *global assimilation of ionospheric measurements* (GAIM) developed by the Utah State University team at the Space Weather Center, is similar to the tropospheric weather models run by NOAA. This model provides real-time specifications and forecasts for global distributions of upper atmosphere/ionosphere densities, temperatures, and winds. The GAIM space weather model originally became an operational Air Force model in December 2006. The data types currently being used in GAIM include line-of-sight TEC measurements deduced from ground-based GPS receiver networks and space-borne GPS receivers, satellite ultraviolet (UV) limb scans, and ionosonde data. Intensive validation has also been conducted using various independent data sources, including vertical TEC measured using satellite ocean altimeter radars (such as those aboard TOPEX and Jason-1 missions), ionosondes, and incoherent scatter radars.

### 39.3.2 Near-Real-Time Reconstruction

Whereas ionospheric research doesn't require near-real-time imaging of the ionospheric electron density, precise GNSS applications benefit from accurate 3-D images to solve phase ambiguities in near-real time. The availability of 3-D images avoids mapping errors due to serious simplifications of the vertical ionospheric structure in TEC-based ionospheric delay estimates. However, the 3-D reconstruction is only beneficial when the reconstruction is sufficiently accurate. Since temporal and spatial resolution in conjunction with the accuracy of 3-D images depends to a great extent on the imaging technique and on the density of reliable data, further investigation is required to fulfill challenging customer needs. Nevertheless, several attempts are currently being made to provide three-dimensional electron density reconstructions in near-real time that still need comprehensive validation via international cooperation (Sect. 39.7).

## 39.4 Scintillation Monitoring

Radio scintillations as discussed in Sect. 6.3.3 impact in particular the availability of GNSS signals, for example for positioning, navigation and time transfer (PNT) services. Hence, any signal failure could cause serious problems in complex infrastructures. Severe scintillations may cause loss of lock of GNSS signals [39.39] thus reducing the availability of GNSS services. Based on a better understanding of the physics of the ionospheric plasma and its irregularities, forecast tools shall be developed to forecast the onset of scintillation activity 3–6 h in advance. The estimation of the scintillation probability up to several hours in advance is an important issue to enhance the reliability of GNSS.

### 39.4.1 Climatology of Radio Scintillations Deduced from GNSS Observations

The $S_4$ index introduced in Sect. 6.3.3 as a well-accepted measure of radio scintillation activity depends strongly on geophysical conditions, such as local time,

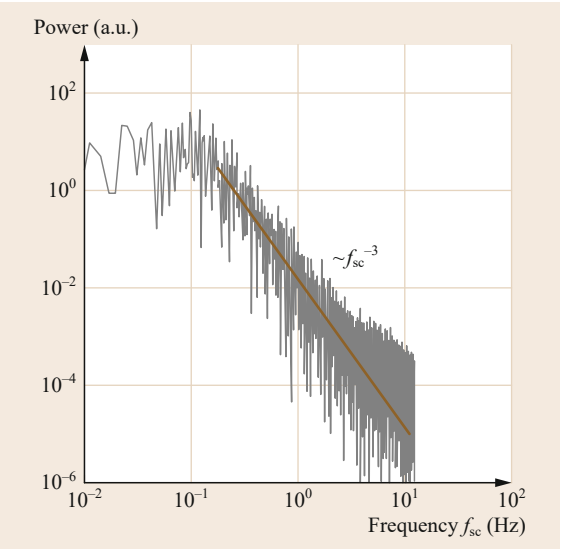

**Fig. 39.12** Spectral power density of GNSS amplitude fluctuations measured on 5 April 2006 in Bandung, Indonesia

season, latitude, and solar activity level [39.40, 41]. Since the fluctuation rate of typical GNSS scintillations is up to 10 Hz and more, GNSS-based scintillation monitoring for scientific analysis requires well-qualified GNSS receivers with high sampling rate in the order of 50 Hz or more (Fig. 39.12). In principle all high-rate GNSS receivers providing access to the signal intensity can be used in the measurement praxis. It is worth noting that a broad science community uses a special scintillation receiver (Novatel GSV 4000) for scintillation monitoring.

Long-term studies on scintillations have shown a strong dependence on solar activity and geophysical conditions such as location, season and daytime. As already pointed out in Sect. 6.3.3, scintillations can primarily be observed at high and low latitudes where they are generated by different physical processes. Scintillation effects observed at a high-latitude station are shown in Fig. 39.13.

In the auroral and polar cap latitudes, any significant magnetic storm activity can produce scintillation effects. Severe amplitude and phase scintillations have been observed in coincidence with steep TEC gradients, a characteristic of the edge of polar cap patches. Such gradients may result in the production of small-scale irregularities caused by the gradient-drift instability [39.42, 43]. Due to this storm-driven behavior there is no clear dependence on local time reported. Furthermore, it is a well-known fact that high-latitude scintillations are not as severe as those measured in the near-equatorial belt. However, high-latitude scintillations can last for many hours, even days. The observation results shown in Fig. 39.13 confirm the statement that phase scintillations are much more pronounced than signal-strength fluctuations at high latitudes. This indicates a predominance of refractive index fluctuations $\Delta n$ versus diffraction or scattering effects in this region.

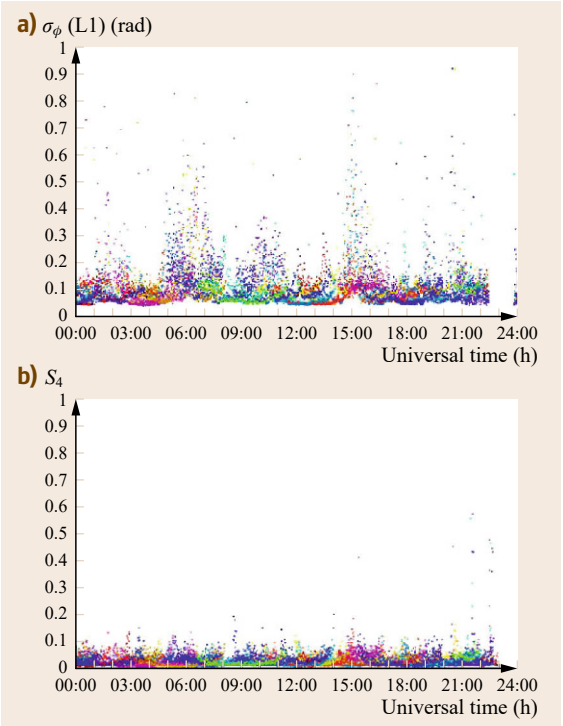

**Fig. 39.13a,b** $S_4$ and $\sigma_\phi$ indices observed at Kiruna station (67.84°N; 20.41°E) on **(a)** 7 and **(b)** 8 March 2012

The maximum fading depth observed on GPS signals from the north polar cap region was approximately 10 dB, whereas in the equatorial anomaly region the fading depth is observed as much as 25 dB [39.44]. In general the peak-to-peak fading depth can be estimated by the formula [39.45]

$$P_{\mathrm{Fluc}} = 27.5\, S_4^{1.26}\,. \tag{39.11}$$

At low latitudes the occurrence probability of scintillations is more regular due to solar illumination-driven thermosphere/ionosphere coupling processes. Thus, significant enhancements of the $S_4$ index can be observed at low latitudes regularly after sunset except during low solar activity conditions (Fig. 39.14).

GNSS measurements at the low-latitude station at the Bahir Dar University, Ethiopia, show a strong enhancement of signal strength fluctuations immediately after sunset that is surely associated with the Rayleigh–

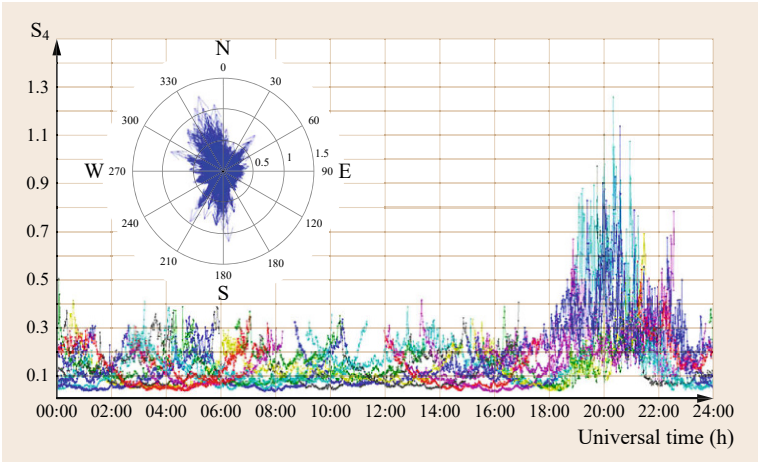

**Fig. 39.14** $S_4$ scintillation measurements at Bahir Dar, Ethiopia (11.6° N; 37.4° E) on 14 April 2012 made on all available satellites (color marked). Onset of enhanced activity starts after sunset

Taylor plasma instability. The increased $S_4$ activity lasts typically a few hours until midnight (Fig. 39.14). As expected, scintillation activity is most pronounced in the north-south direction because Bahir Dar at (11.5° N; 37.4° E) is located between the northern and southern ionospheric crest over Africa.

Long-term observations of scintillation activity allow estimation of the occurrence probability of scintillations besides scintillation strength or fading depth.

Although the solar activity was very low in 2006, scintillations have been observed in Bandung at an occurrence probability of about $6.0 \cdot 10^{-3}$ for severe scintillations with $S_4 \geq 0.8$. Long-term studies shall further improve the reliability of occurrence statistics. Although the seasonal dependence usually shows maxima around the equinoxes at the Asian sector as in Bandung, this is not valid at the American low-latitude sector, where scintillation probability is higher during solstices than during equinoxes.

It is worth mentioning that signal-strength fluctuations are closely associated with rapid phase changes of TEC at low latitudes. This relationship has been tested by a direct comparison of simultaneous $S_4$ and rate-of-TEC (RoT) measurements in Bandung [39.46] as Fig. 39.15 shows.

TEC rate measurements are effective in detecting plasma bubbles whose occurrence is associated with enhanced scintillation activity as described in [39.47, Sect. 6.3].

TEC depletions occur when one or more plasma bubbles drift across the line of sight between the GPS receiver and the satellite. Therefore, sudden TEC depletions in link-related dual-frequency GNSS measurements can be considered as a manifestation of equatorial plasma bubbles. Occurrence characteristics of plasma bubbles derived from global ground-based GPS receiver networks were studied by *Nishioka* et al. [39.48]. The standard deviation of RoT, which is commonly known as rate of TEC change index (ROTI), is used to identify small-scale fluctuations. ROTI is often used to investigate ionospheric fluctuations [39.49, 50]. In analogy to the low-latitude $S_4$ behavior the diurnal variation of ROTI shows a strong enhancement in the evening hours between sunset and midnight.

Large-scale structures associated with ionospheric storms may also cause large TEC depletions resulting

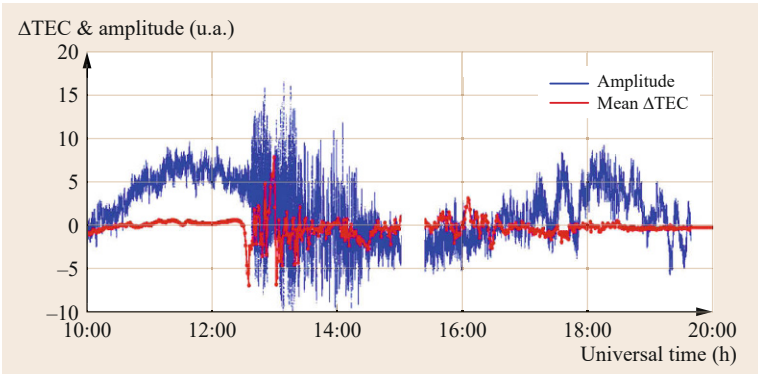

**Fig. 39.15** Comparison of signal amplitude (*blue*) and TEC rate (*red*) measured simultaneously in Bandung, Indonesia on 5 April 2006 (after [39.46])

in enhanced scintillation activity as found over Africa during a moderate geomagnetic storm on 24–25 October 2011 [39.47]. High scintillation activity may lead to a loss of lock of the GNSS signals. To avoid problems in accurate and safety-critical applications, a more comprehensive understanding of physical processes behind radio scintillations is still needed for developing mitigation techniques and forecast tools. International initiatives encouraging systematic and worldwide monitoring of ionospheric irregularities are very helpful on this matter.

### 39.4.2 Scintillation Measurement Networks

Since space weather impact on L-band signals of GNSS cannot be ignored, tremendous international efforts are underway to measure and model ionospheric irregularities and resulting scintillation effects at radio signals. As pointed out in the previous section, GNSS measurements essentially help to collect representative datasets for comprehensive theoretical and empirical data analysis.

Whereas the US Air Force Research Laboratory (AFRL) is establishing the low latitude SCINDA (SCINtillation and Decision Aid) ground station network [39.51], the European Space Agency (ESA) is supporting the global deployment of scintillation receivers within the PRIS and MONITOR projects [39.52, 53].

In addition to SCINDA the US Air Force Research Lab has initiated the launch of the communication/navigation outage forecast system (C/NOFS) satellite in 2008 [39.54]. The main goal is developing forecast tools for scintillation occurrence probability. The estimation of the scintillation probability up to several hours in advance is an important issue to enhance the reliability of GNSS.

Besides ESA activities in supporting coordinated scintillation monitoring in regional and global networks, several European countries have been active in establishing national GNSS networks, contributing to improving our knowledge on scintillations. Among them are a high-latitude network operated by Istituto Nazionale di Geofisica e Vulcanologia (INGV), Rome called *ionospheric scintillations arctic campaign coordinated observation* (ISACCO) [39.55] and the north-south scintillation monitoring chain of DLR [39.43]. Such networks allow monitoring of regional scintillation activity or tracking scintillation-associated perturbations propagating from high towards low latitudes or vice versa.

Over South America the LISN multisensoral monitoring network [39.56] contributes essentially to the understanding of the complex physical background of

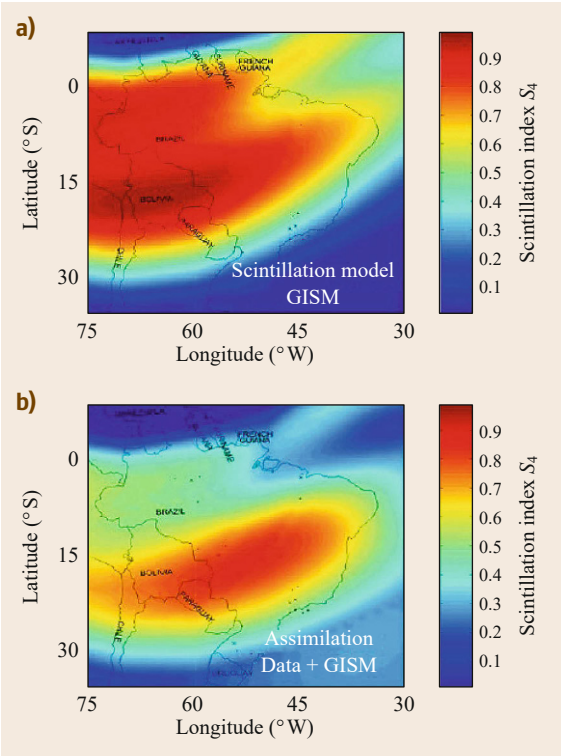

**Fig. 39.16** **(a)** $S_4$ scintillation map generated by the GISM model for 11 January 2002, at 00:30 UT, solar radio flux $F10.7 = 150$, background electron density model is NeQuick. **(b)** $S_4$ scintillation map after assimilating measured scintillation data from six Brazilian GPS stations into the GISM background model. More details in [39.52]

the generation and propagation mechanism of ionospheric scintillations. In practical applications single-station information is helpful but usually not sufficient. Regional and/or local GNSS scintillation monitoring networks allow for computation of scintillation maps covering the area in view. Although ionospheric irregularities causing radio scintillations are characterized by small scales, smoothed scintillation maps can provide more reliable information on the current state than climatologic models can do. This may help users at sites where practically no measurements of scintillation activity are available. Thus, actual scintillation measurements assimilated into a climatological scintillation model such as the WBMOD [39.57] and GISM [39.58] improve the model by introducing current geophysical as well as space weather conditions. These conditions have much larger temporal and spatial scales than the irregularities justifying the procedure in a certain sense.

Utilizing GISM as the background model for computing the scintillation activity over Brazil for 10–

18 January 2002, scintillation data obtained from the Brazilian National Institute for Space Research (INPE) were merged into the model [39.52]. Assimilating these actual scintillation data into the GISM model, the obtained scintillation map as seen in Fig. 39.16 is well adapted to the real conditions. The more measurements are available, the higher is the spatial resolution of the maps. The assimilation procedure is similar to that used for routine generation of TEC maps in DLR since 1995 [39.5, 6].

## 39.5 Space Weather

According to the definition given in the national space weather plan of the USA in 1996, space weather refers to the conditions on the Sun and in the solar wind, magnetosphere, ionosphere and thermosphere that can influence the performance and reliability of space-borne and ground-based technological systems and can endanger human life or health. The ionosphere is an integral element of space weather, closely linked to the intensity and the energetic spectrum of electromagnetic and corpuscular radiation emitted from the Sun. The utilization of ground- and space-based GNSS signals is attractive for monitoring space-weather-driven effects in the ionosphere in a twofold manner. FIrstly, space-weather-initiated processes can effectively be investigated by probing the ionosphere with high temporal and spatial resolution. Secondly, monitoring results help to develop correction models, mitigation techniques and *ionospheric threat models* to further reduce the ionospheric impact in numerous GNSS applications. The latter point is of interest since requirements on accuracy, spatial resolution, integrity, and continuity of GNSS are permanently growing. In parallel, the robustness of ionospheric measurements, their temporal and spatial resolution and accuracy permanently improve due to the rapidly growing number of ground- and space-based radio links.

As pointed out in Sect. 6.3, the ionospheric ionization is mainly controlled by solar radiation at wavelengths of $< 130$ nm and energetic particles originating from the solar wind. Principally, there is a close correlation between TEC and the solar radiation. Whereas photoionization acts immediately, the total ionization follows the solar cycle and solar irradiation changes [39.59] with a delay of 1–2 d [39.60].

To distinguish from climatological effects, in this chapter we focus on space weather effects characterized by timescales of less than about 10 d. Timescales of a few days are typical for the duration of ionospheric storms. Shorter radiation events in the range of minutes are related to solar radiation bursts known as solar flares.

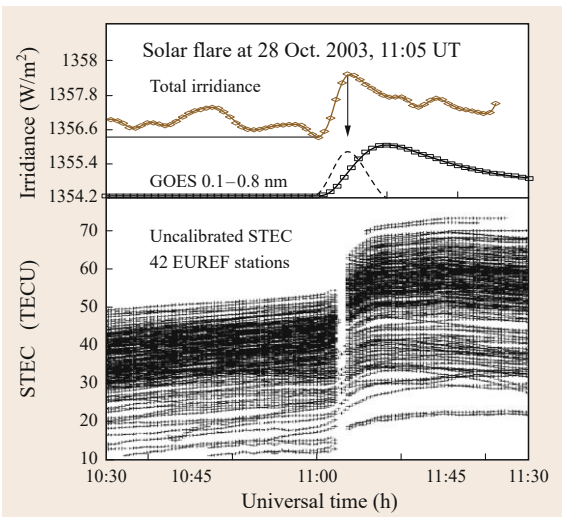

**Fig. 39.17** Uncalibrated TEC response of the solar flare on 28 October 2003 at 11:05 UT. Enhancement of the total solar irradiance by 267 ppm caused a TEC jump at all GPS measurements over Europe (range error up to about 3.5 m)

### 39.5.1 Direct Impact of Solar Radiation and Energetic Particles

If the solar emission spectrum contains a strong enhancement of the ionizing extreme ultraviolet (EUV), the ionospheric range error of GNSS may increase by several meters within a minute. Associated rapid phase changes may lead to problems at receiver level, i. e., seriously degrade positioning and monitoring capabilities. During solar flares the Sun emits electromagnetic waves at a broad frequency spectrum from Gamma via X-rays down to radio waves. This may lead to a sudden increase of TEC (SITEC), as known for many years [39.61, 62].

As shown in Fig. 39.17 (*bottom panel*) STEC may rapidly jump by 20 TECU or even more during a SITEC event and therefore might reduce accuracy and reliability of GNSS applications to an intolerable extend.

The number of available GPS measurements dropped down from 30 to only 7. *Afraimovich* et al. [39.62] have discussed the response of global GNSS measurements to faint and bright solar flares. These data can effectively be used to detect in particular solar flares with a strong EUV component in the spectrum [39.63].

Besides energetic ionizing radiation, also wideband radio waves may be emitted, called radio bursts. On 6 December 2006 the radio burst intensity at GPS frequencies at L1 = 1575.42 and L2 = 1227.60 MHz was extremely high, causing severe interference problems with GPS measurements at the sunlit side of the Earth [39.64].

SITEC measurements were performed many years ago mainly based on Faraday rotation measurements at linearly polarized beacon signals from geostationary satellites such as ATS 6. Nowadays GNSS measurements are well suited to measure flare-related ionization events. Coinciding with the approach to the 24th solar cycle expected maximum, the interest for a better observation capability of solar flare events, considered as space weather precursors, has grown significantly. In particular, better accuracy and temporal resolution of the changes within the flux of photons are becoming important to get a better understanding of the Sun-Earth relationships [39.65]. GNSS measurements may help to estimate rapid EUV photon flux increases during solar flares [39.63].

Besides electromagnetic radiation, corpuscular radiation of solar origin may also noticeably increase the ionospheric ionization level. The associated TEC increase is measurable both by ground- and space-based dual-frequency GNSS measurements. Since precipitating electrons of magnetospheric origin ionize in particular the bottomside ionosphere, IRO retrievals are well suited to detect associated enhancements of electron density. Thus, numerous IRO datasets of CHAMP and COSMIC/Formosat-3 datasets have been systematically screened to select those profiles that indicate higher ionization at E-layer heights than at F2 layer heights [39.66]. This E-layer-dominated ionosphere (ELDI) is a clear indication of space-weather-related particle precipitation at high latitudes (Fig. 39.18).

As Fig. 39.18b shows, the selected ELDI profiles are well distributed around the auroral oval where fascinating polar lights can be observed. The shape of this Arctic oval has been described by an ellipse indicated by a yellow line in Fig. 39.18b [39.66].

During ionospheric storms the particle precipitation is essentially enhanced, often associated with disruptions of GNSS measurements and services like EGNOS at high latitudes [39.43].

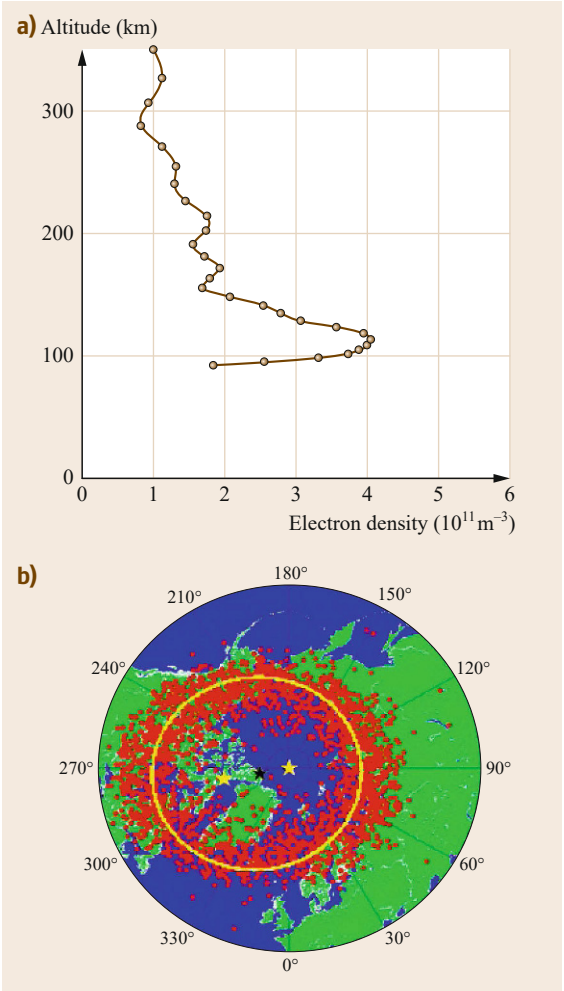

**Fig. 39.18** **(a)** Selected electron density profile retrieved from CHAMP IRO measurements over the South Pole on 29 October 2003 to demonstrate a typical ELDI profile. **(b)** Ellipse fit to the distribution of COSMIC/Formosat-3 profiles obtained over the Northern hemisphere in January and February 2007 satisfying the ELDI condition. The *yellow stars* mark the focal points of the ellipse, the *black star* marks the center of a less accurate circle fit (further details in [39.66])

## 39.5.2 Ionospheric Perturbations and Associated Effects

Ionospheric storms are space-weather-induced large-scale disturbances of the ionospheric structure and dynamics. Due to the strong electrodynamic coupling with the magnetosphere they are closely related to geomagnetic storms. Therefore, ionospheric storms are mostly characterized by geomagnetic indices. Nevertheless, due to the complexity of ionospheric storms, geomagnetic indices fail in describing the storm behavior of the ionospheric plasma. To overcome this problem, attempts are made to characterize ionospheric storms by more specific ionospheric indices [39.67].

Due to the strong coupling with the magnetosphere and the solar wind, enhanced space weather impact is expected in particular at the high-latitude ionosphere

where the geomagnetic field lines come down to the Earth. During severe space weather events a huge amount of solar wind energy couples into the thermosphere/ionosphere/magnetosphere systems thus generating large perturbations in the high-latitude ionosphere and thermosphere. These perturbations are characterized by significant changes in plasma density, composition and temperature accompanied by large-scale plasma transport processes [39.66, 68–71].

A severe ionospheric storm was globally observed at the end of October 2003, called the Halloween storm. The storm was initiated by a huge solar flare of class X17 on 28 October (Fig. 39.17) followed by two severe coronal mass ejections (CMEs) on subsequent days. Whereas there was an immediate TEC response on the flare by more than 10 TECU, persistent large-scale perturbations were observed later when the CMEs reached the Earth on 29 and 30 October 2003. Electromagnetic coupling of the CME plasma cloud with the Earth's magnetosphere causes a complex system of electric fields and currents in the magnetosphere/ionosphere systems. Thus, the magnetospheric dawn-dusk electric field maps down to ionospheric heights along geomagnetic field lines and drives the day-side plasma to the night-side across the poles, creating a so-called tongue of ionization. This is nicely seen in the polar TEC distribution on 29 October at 06:00 and 08:00 UT in Fig. 39.19.

Additionally, huge electric currents in the order of one million ampere are generated in the auroral E-layer ionosphere. The resulting Joule heating of the thermosphere results in numerous effects, such as an expansion of the thermosphere, generation of neutral winds and composition changes. So the ionosphere is heavily disturbed over Europe causing TEC enhancements of about 200% at high latitudes. Upwelling of the thermosphere and associated winds initiate transport processes towards lower latitudes, for example large-scale traveling disturbances (LSTIDs) [39.72], which are indicated in Fig. 39.20 by a perturbation pattern derived from ground-based GNSS data.

The related perturbation pattern derived from wavelet analysis is quite useful for studying general features of ionospheric storm generation and propagation [39.73].

The storm pattern seen in Fig. 39.20 indicates quite different plasma transport processes, such as the instantaneous uplifting of plasma throughout all latitudes shown here at about 6:30 UT as a simultaneous enhancement of TEC along all latitudes. This is due to the immediate action of the convection electric field before the ring current has been developed. From 58° N towards the north pole we see the trace of the tongue of ionization seen also in Fig. 39.19. Subsequently a number of perturbation traces are directed towards southern Europe. The slopes indicate velocities in the order of 600 m/s typically for a large-scale perturbation pattern [39.73]. In the afternoon around 15:00 UT the equatorward motion of the mid-latitude trough begins, which separates polar patches in the north from more regular transport processes in the south. The velocity of the southward trough motion is in the order of about 50 m/s.

In the further course of the storm on 29 October 2003 strong plasma uplifting can be observed at the Southern hemisphere at 20:00 UT, i. e., around noon at the right side of corresponding electron density distribution of topside ionosphere/plasmasphere presented in Fig. 39.21.

Strong ionization enhancement is shown also in the equatorial region indicating the action of a very strong eastward-directed electric field, which is consistent with the southward motion of the mid-latitude trough in the evening hours at the European sector, noted before.

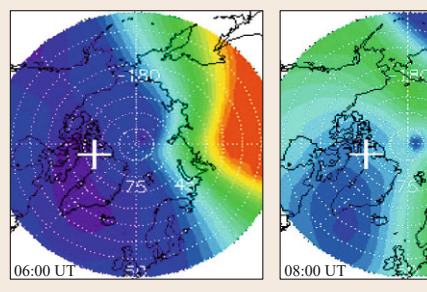

**Fig. 39.19** Formation of the tongue of ionization in polar TEC on 29 October 2003 at 06:00 and 08:00 UT. TEC has been derived from ground-based GPS measurements of the IGS station network in DLR (after [39.6])

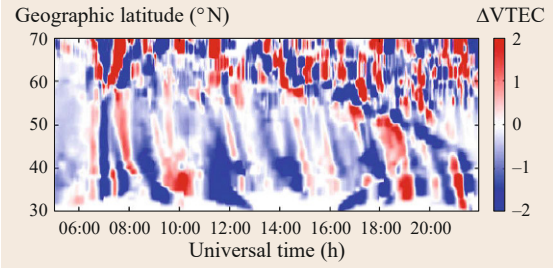

**Fig. 39.20** TID storm pattern in TEC observed during the Halloween storm on 29 October 2003 along the 12° E meridian across Europe

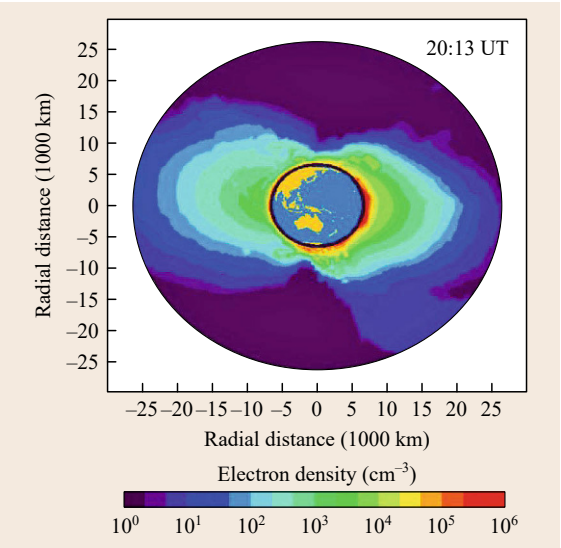

**Fig. 39.21** Topside reconstruction of the electron density distribution in the CHAMP orbit plane on 29 October 2003 at 20:13 UT, (after [39.74])

It is worth mentioning that also the corresponding IRO measurements on board CHAMP are consistent with this interpretation. They provide even more insight into the dynamics of the ionosphere during the severe Halloween storm [39.74]. Summarizing, it can be stated that ground- and space-based dual-frequency GNSS measurements provide a powerful tool for probing the ionosphere, in particular under perturbed conditions when other techniques such as vertical sounding may fail.

Considering the GNSS user side, this Halloween storm has demonstrated the reality of ionospheric threats on global scale, for example when WAAS over the US failed for several hours [39.75].

### 39.5.3 Prediction of Space Weather Phenomena

Space weather studies reported in the previous sections shall provide an improved understanding of the physics behind space weather phenomena in order to better forecast space-weather-related effects and their impact on technical systems. Principally, the GNSS user community is interested in warnings and forecasts of the ionospheric behavior in particular during perturbations. This is a challenging task that cannot be managed on the basis of empirical models such as IRI or NeQuick, which are principally climatological. Therefore, physics-based models are needed that are permanently updated by current observation data. Data-driven physics-based models such as GAIM developed at Utah State University [39.33] or the CTIPe model operated at the Space Weather Prediction Center (SWPC) in Boulder, Colorado, [39.76] have the principal capability to forecast ionospheric behavior in a sufficient way. These complex models suffer from the lack of specific input data needed to get unambiguous solutions of the system of commonly used physical equations, such as the continuity equation, equations of motion and energy equations. Taking into account that the data situation with respect to ground- and space-based GNSS and complementary ionospheric data sources is permanently improving, the develop-

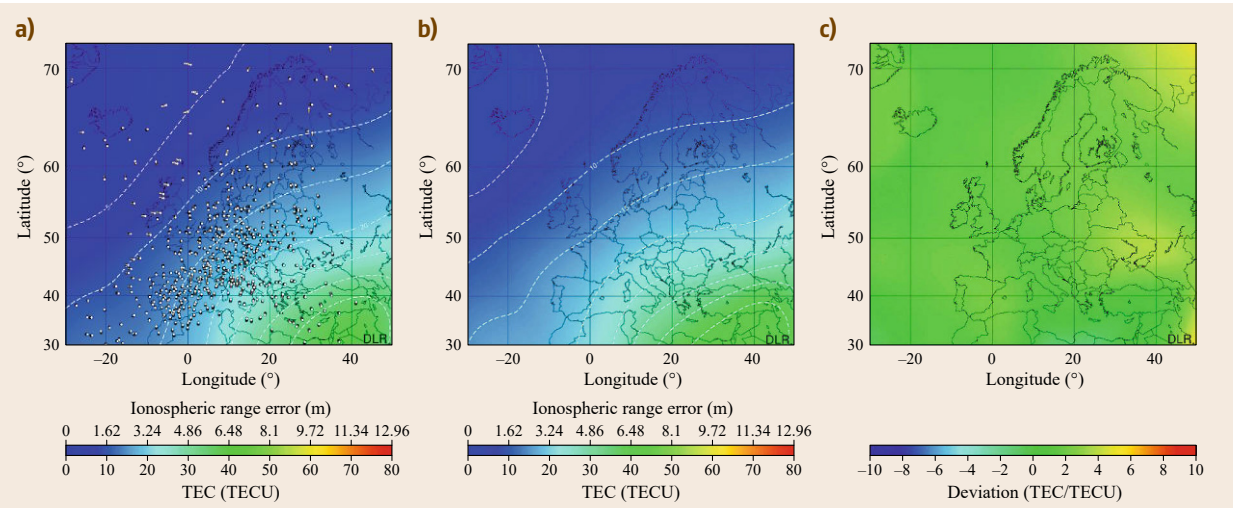

**Fig. 39.22a–c** VTEC map over Europe on 17 June 2012, 06:00 UT as provided via SWACI **(a)**, 1 h VTEC forecast for Europe **(b)**, quality of forecast released at 05:00 UT for 06:00 UT **(c)**

ment of data-driven physics-based models is the only way to get reliable forecasts of the ionospheric behavior under perturbed conditions in the future. In the meantime pragmatic solutions based on near-real-time measurements of the current state of the ionosphere and its drivers like solar radiation and solar wind are still justified. Accordingly, there are still some international efforts to derive forecasts from a combined use of actual data and empirical models or neural networks. To learn more about physics-based models, comparison of results obtained from physics-based models and GNSS-derived TEC maps or 3-D reconstructions of the electron density are very helpful [39.76].

As an example, TEC map forecasts of 1 h ahead are made routinely via the SWACI service of DLR [39.8], which is based on the current ionospheric behavior and a background model (Fig. 39.22). To estimate the quality of the previous forecast, it is checked with real data 1 h later when the forecast time is reached. The corresponding difference plot is available for users allowing immediate estimation of the quality of the forecast. Mean forecast errors of the SWACI service are usually less than 10% of the original values.

To further improve the current forecast quality, the development of an empirical storm model controlled by solar wind parameters received from the ACE satellite is envisaged.

## 39.6 Coupling with Lower Geospheres

Although space weather impacts on the ionospheric plasma clearly dominate, ionospheric plasma may be affected by processes propagating from lower geospheres such as the lower atmosphere and even the litho- or hydrosphere. Such processes are briefly discussed in the two subsequent sections.

### 39.6.1 Atmospheric Signatures

The Earth's atmosphere is periodically excited by solar radiation. Taking into account the rotation of the Earth, the permanently changing inclination and the gravity impact of the Moon, various wavelike processes are excited in the atmosphere on planetary and regional scale. In addition to these well-defined regular processes, the solar radiation as the main driving force shows quasiperiodical variations, for example associated with the mean solar rotation period of 27 d and the solar cycle period of about 11 y.

Here we consider a kind of *second-order effect* on the balance of ionospheric plasma, namely the impact of wave phenomena that have been excited in the lower atmosphere due to the above-mentioned natural circumstances.

The propagation of hydrodynamic motions such as gravity waves, tides and planetary waves has been discussed already for more than five decades. Assuming conservation of energy flux of an upward propagating wave, their amplitude increases rapidly with height due to the exponential decrease of neutral gas density. This is the main reason why waves that are small at low heights may reach amplitudes that are sufficiently large to be measurable at ionospheric altitudes. Having a more detailed view, one has to consider in practice characteristics of the atmospheric filter function for the vertical propagation of atmospheric waves like planetary waves (PWs).

Planetary waves depend in particular on the varying vertical component of rotation with geographic latitude. These waves manifest in large-scale variations in neutral wind, density and pressure propagating zonally and vertically from troposphere-stratosphere regions towards middle atmosphere and lower thermosphere regions. Their oscillation periods are in the order of 2–20 d with main periods at 2, 5, 10 and 16 d [39.77].

Another type of wave occurring in the atmosphere are called gravity waves. In the case of an initial perturbation, for example heating or vertical displacement in a stratified atmosphere, the restoring force is gravity.

Both wave types distinguish further in their capabilities to propagate upward. Whereas planetary waves cannot penetrate the turbopause region at about 110 km height due to physical reasons, gravity waves are able to propagate through it. Although there is an upper boundary for upward propagating planetary waves, planetary-type oscillations of the ionospheric plasma up to F2 layer heights have been observed by airglow and radar measurements and ionospheric sounding [39.78].

Since PWs cannot overcome the 110 km barrier, some supporting mechanism must exist to convert the wave energy of PWs into another atmospheric process that becomes visible in higher ionospheric layers. Observational evidence has shown that the ionospheric system of currents in the E-layer or dynamo region at around 100 km height might directly be modulated by planetary waves [39.78]. The observation of typical PW oscillation periods in the equatorial electrojet indicates a significant influence of planetary waves on plasma parameters of the equatorial ionosphere. The associated electric field could also be responsible for observed nighttime F-

layer height oscillations at PW periodicities. Generally speaking, there are many possible scenarios to explain planetary wave signatures in the ionosphere [39.77]. Considering the episodic character of PW and the difficulty of distinguishing their ionospheric signatures from solar or more complex space weather forcing [39.79], TEC measurements will substantially help to explore the physics behind the related atmosphere-ionosphere coupling, in particular if dense GNSS networks are available. To give an example, Fig. 39.23 shows the existence of PW-type oscillations in TEC [39.80], which may contribute to the range error in GNSS as pointed out earlier. Although a number of observations provide experimental evidence for the existence of PW-type oscillations even in the F2 layer ionosphere, more comprehensive studies are required to get deeper insight into the vertical coupling processes of planetary waves in the mesosphere, thermosphere and ionosphere.

Besides planetary waves or space-weather-driven large-scale storm patterns, medium-scale traveling disturbances (MSTIDs) can also be monitored by ground- [39.81] and space-based [39.82] TEC measurements.

MSTIDs, which may affect precise positioning, can be considered as ionospheric signatures of atmospheric gravity waves (AGWs) reaching amplitudes of up to few TECUs. Wave periods are in the order of several minutes up to about 1 h at horizontal wavelengths of a few hundred kilometers and velocities reaching from 50–300 m/s [39.81]. The observed AGWs may be associated with meteorological phenomena such as thunderstorms, solar eclipses or the solar terminator. GNSS networks are well suited to analyze amplitude, horizontal direction, speed, frequency and wavelength of such waves.

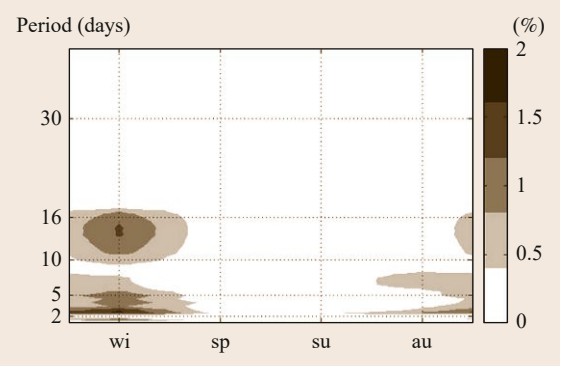

**Fig. 39.23** Sample for the occurrence of typical planetary wave periods (westward directed waves of wave no.1) in the total electron content of the ionosphere representative for thre months in the four seasons winter (wi), spring (sp), summer (su) and autumn (au). More details in [39.80]

Thus, the solar terminator (ST) may excite two types of AGWs; a long-period AGW (≈ 60 min) with amplitudes in the order of 0.5–1 TECU and a short-period one ≈ 15 min) one with amplitudes in the order of 0.05–0.1 TECU [39.83].

Due to the presence of wavelike perturbations in the ionosphere, positioning errors in networks for real-time kinematic (RTK) positioning (Chap. 26) can reach about 25 cm for a 25 km baseline [39.85]. Since MSTIDs are moving structures such as LSTIDs shown in Fig. 39.20, their effect on positioning varies with the baseline orientation. Thus, if a given baseline is oriented perpendicular to the MSTID propagation direction, the related positioning error will be smaller than that observed for a baseline oriented parallel to the propagation direction. GNSS-based ionospheric monitoring contributes to the mitigation of this problem by investigating the physical processes causing the temporal and spatial characteristics of MSTIDs in the application region. Amplitudes, typical speeds, and direction of propagation were, for example, analyzed for numerous datasets in relation to geophysical conditions in [39.84]. To give an example, velocities and propagation direction of MSTIDs derived from GPS measurements in California between 2004 and 2011 are shown in Fig. 39.24.

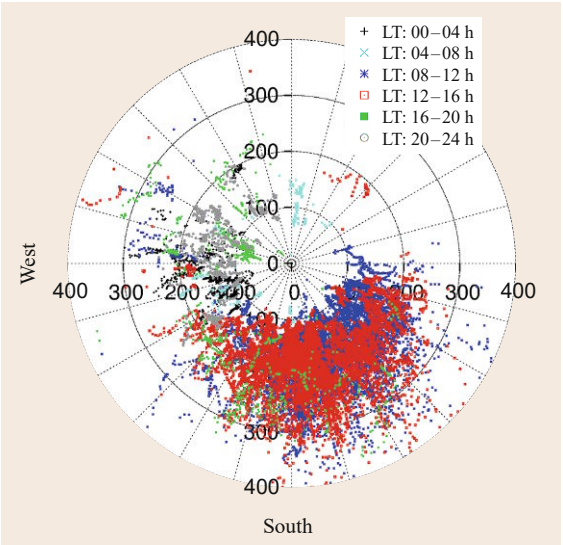

**Fig. 39.24** Polar plot of MSTID velocities (m/s) as a function of azimuth representative for winter season in California averaged over years 2004–2011. Local time dependence is parameterized by colors: *black* for LT 00–04 h, *light blue* for LT 04–08 h, *dark blue* for LT 08–2 h, *red* for LT 12–16 h, *green* for LT 16–20 h and *gray* for LT 20–24 h (after [39.84], courtesy of John Wiley)

Taking into account these relationships, an empirical model has been developed in [39.84] that describes climatological features of MSTIDs as a function of geophysical and solar activity conditions. Besides characterizing wavelike processes in the ionosphere whose origin is still a matter of research, the model helps to estimate ionospheric threats in RTK positioning.

### 39.6.2 Earthquake Signatures

Besides atmospheric perturbations, also strong perturbations in the Earth's litho- and hydrosphere may generate signatures in the ionospheric plasma density via atmospheric-ionospheric coupling processes. Due to the sensitivity of the differential carrier-phase to ionospheric ionization changes, ground- and space-based dual-frequency GPS measurements offer a unique opportunity for detecting earthquake and tsunami signatures in the ionosphere. Vertical displacements of the Earth's surface may excite pressure or acoustic waves that propagate upward. Despite their small amplitude also tsunami waves may excite the above-lying atmosphere by generating gravity waves that propagate obliquely upward.

Since the atmospheric density decreases almost exponentially with altitude, energy conservation implies that the wave amplitude increases exponentially as mentioned already in the previous section. Hence, the amplification may reach a factor of $10^4$–$10^6$ in a limited frequency range with periods in the order of 2–6 min. GPS-based detection of earthquake signatures in the ionosphere was first reported by *Calais* and *Minster* [39.86]. While analyzing the Denali earthquake on 3 November 2002, further evidence was brought that differential GPS phases can measure ionospheric plasma changes induced by upward-propagating atmospheric acoustic waves [39.87, 88]. Earthquake-associated acoustic waves need approximately 10 min to reach the F-layer of the ionosphere, where the close coupling between the neutral atmosphere and ionized plasma results in a wavelike variation of the electron density. Differential GPS measurements made at Sampali, Indonesia (3.62° N; 98.71° E) during the severe earthquake on 26 December 2006 in Indonesia indicate a significant signal about 10 min after the earthquake shock (Fig. 39.25). About 2 h after the event the ionosphere was completely recovered [39.88].

Besides earthquake signatures also associated oceanographic tsunami signatures can be seen in the ionosphere plasma [39.89, 90]. They may excite gravity waves in the troposphere, which propagate upward toward F-layer heights. In contrast to the acoustic waves these waves have longer periods in the typical range of

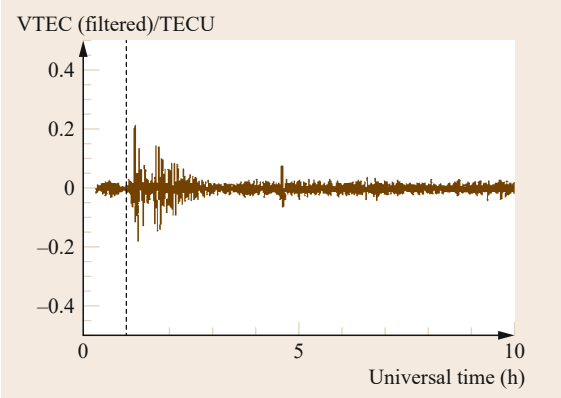

**Fig. 39.25** Band-pass filtered VTEC (2.5–10 min) data from GNSS station Sampali at 3.62° N; 98.71° E during the severe Sumatra earthquake on 26 December 2004 in Indonesia. Onset of the earthquake is indicated by a *dashed line* at 00:58:53 UT (after [39.88])

10–30 min. The travel time to reach ionospheric heights is about 2 h.

Although various earthquake parameters such as the depth influence the detectability of related signatures in the ionosphere, it can be stated that earthquakes of magnitude 6 and higher are detectable by GNSS measurements in general. Related GNSS studies help to explore the coupling mechanisms between lithosphere, hydrosphere and ionosphere including different atmospheric layers. A big advantage of the GNSS technique used for tsunami detection is the large observation range reaching up to more than 1000 km from the ground station over the ocean. For estimating the statistical significance of the measurement results, the availability of dense and widespread networks of permanent GNSS receivers is required.

Instead of measuring after effects it would be of great social importance to detect precursor effects of earthquakes a few hours or days in advance. There exist several publications on this matter suggesting diverse mechanisms for how precursor effects could act and trying to provide evidence for the existence of precursor effects by various types of observations, among them GNSS observations [39.91].

Although pre-earthquake TEC anomalies were found in some studies [39.92] there was no statistically significant correlation observed between TEC anomalies and the occurrence of earthquakes in southern California for the period 2003–2004 [39.93]. Since the key question of whether precursor effects in the ionosphere exist is still open, the search for ionospheric precursor effects continues. GNSSs provide a powerful tool for monitoring associated ionospheric effects and might serve as part of an earthquake warning system.

## 39.7 Information and Data Services

Ionospheric disturbances can adversely affect ground- and space-based systems and operations, including over-the-horizon radars, HF communications, PNT services and remote sensing radars. Hence, operators of these systems are interested in the newest information on current space weather conditions.

The International Space Environment Service (ISES) is a collaborative network of space weather service-providing organizations around the globe. The task of ISES is to improve, to coordinate, and to deliver operational space weather services. ISES is organized and operated for the benefit of the international space weather user community. The service currently includes 14 regional warning centers, four associate warning centers, and one collaborative expert center. ISES is a network member of the International Council for Science World Data System (ICSU-WDS) and collaborates with the World Meteorological Organization (WMO) and other international organizations.

A few of the ISES centers provide GNSS-derived near-real-time regional TEC maps: INPE (Brazil), NICT (Japan), NOAA (USA), and the Radio and Space Weather Services, Bureau of Meteorology (Australia).

Near-real-time (delay $\leq 30$ min) global TEC maps are generated and provided by DLR (Germany), UPC (Spain), International GNSS Service (IGS), JPL (USA), and Utah State University Space weather Center (USA).

Space-based GNSS data and related retrievals, for example GPS radio-occultation data, from LEO satellites such as COSMIC/Formosat-3 and GRACE are provided by DLR (Germany), Taiwan Analysis Center for COSMIC (Taiwan) and UCAR (USA).

In order to permanently monitor the ionospheric state and in particular to detect and trace space weather effects, powerful GNSS-based monitoring services have been established in European countries.

Within their Space Situational Awareness (SSA) program the European Space Agency (ESA) is establishing five expert service centers related to solar weather, space radiation, ionosphere, geomagnetic field and heliosphere. The SSA preparatory program was started in 2009. The SSA space weather segment is planned to be further developed in upcoming years by exploiting the European expertise in the space weather area under the coordination of ESA.

The WMO supports international coordination of space weather activities and services. In May 2010, WMO established the interprogram coordination team on space weather (ICTSW) with a mandate to support space weather observation, data exchange, product and services delivery, and operational applications. ICTSW involves experts from numerous countries and international organizations.

*Acknowledgments.* The author would like to express his gratitude to colleagues from DLR's Institute of Communications and Navigation and Earth Observation Center for the close collaboration on many projects, e.g., related to satellite missions CHAMP and GRACE and the space weather project SWACI. He would like to thank the international geodetic community, in particular the International GNSS Service, for providing free access to high quality GNSS data for more than two decades.

# 40. Reflectometry

Antonio Rius, Estel Cardellach

This chapter discusses the use of properties of global navigation satellite system (GNSS) signals after their reflection on the Earth's surface. Global navigations satellite system reflectometry (or GNSS-R) is a multistatic radar that uses the GNSS constellations to extract information on the properties of the reflecting surfaces. Experiments have demonstrated that useful information can be extracted from such reflected signals. GNSS-R instruments have been installed in ground and coastal platforms, aircraft, stratospheric balloons, and spacecrafts. As a natural consequence it has been proposed by space agencies for the deployment of dedicated space missions. In the first part of this chapter the properties of the GNSS reflected signals on different components of the Earth's surface are discussed, and the technical principles sustaining different types of GNSS-R instruments are presented. The second part of this chapter presents methods to retrieve geophysical information from the GNSS-R signals, results obtained in different experiments and plans for future space missions.

GNSS reflectometry (GNSS-R) is an emerging technique aimed at inferring geophysical properties by means of analyzing the GNSS signals reflected off the Earth's surface. It thus exploits the remote sensing capabilities of the GNSS for Earth monitoring, in the form of a multiple bistatic radar (radar in which the transmitter and the receiver are at significantly distant locations), also called multistatic capabilities. The multistatic nature of the concept is based on the fact that each visible GNSS transmitter reflects onto a different area. If the GNSS-R receiver is at a sufficiently high altitude, this represents a set of simultaneous remote sensing observations covering a wide geographical zone, providing synoptic-view capabilities to the technique. Originally suggested in [40.1] as a system to perform mesoscale altimetry, it was later also identified as a scatterometric concept for ocean surface wind applications [40.2]. A review on GNSS-R can be found in [40.3, Chaps. 8–11].

Since then, a large number of experiments have been conducted. These experiments have used dedicated GNSS-R or software receivers, given that in most of the Earth's surfaces, and in particular over the ocean, the reflection process is essentially diffuse, inducing random and frequent shifts in the total phase of the electromagnetic field that impede standard GNSS tracking algorithms. Most of these GNSS standard applications obtain the primary observables, phases and pseudoranges, around the maximum of the cross-correlation between the GNSS signals and its mathematical replica, as explained in Chap. 14.

In contrast, the GNSS-R techniques extract the geophysical information from a wider extension of the cross-correlation function. These measurements are the primary observables in the GNSS-R case.

Reflectometry is a special form of multipath, but in most cases it is so extreme and diffuse that it cannot be modeled and analyzed as near-field multipath presented

in Chap. 15. Depending on the GNSS-R applications, the observables are linked to different aspects of the correlation function. While GNSS-R altimetry requires delay measurements, in the GNSS-R scatterometry case the observables are embedded in the shape of the distorted waveform.

The formulation of the GNSS-R observables is given in Sect. 40.1; models for the reflected signals and their noise components are compiled in Sect. 40.2; a set of GNSS-R applications will be described in Sect. 40.3, and finally various GNSS-R spaceborne missions are presented in Sect. 40.4.

## 40.1 Receivers

In this section we present the basic concepts used to collect the GNSS-R observables at the receiver level. Chaps. 13 and 14 of this Handbook present receiver architectures and signal processing techniques for GNSS navigation. In general, these do not work well for diffusely scattered signals that are characterized by low signal-to-noise ratio (SNR), signal fading events, and random phase behavior. This section therefore compiles basic information on architecture and signal processing adapted to GNSS-R.

We assume that a single-GNSS transmitted signal is received at a GNSS-R receiver through different paths, as sketched in Fig. 40.1:

- The direct path connects directly the transmitter T and the receiver R as in the standard GNSS applications, and
- The reflected path establishes the connection T–R after its reflection on a surface $\Sigma$.

This setup is similar to the one encountered in the *Lloyd's mirror* two-beam interference experiment, where a mirror creates a *virtual coherent image* of a source [40.4]. A difference is that in this chapter we assume that the surface $\Sigma$ has *spatial incoherence*: (a) any pair of points of the source are statistically independent, and (b) a transmitted signal after its reflection on the incoherent surface $\Sigma$ produces, at large distances, a coherent radiation that will interfere with the direct signal.

The primary GNSS-R observable is the *mutual coherence*, or *cross-correlation*, of these two separate GNSS signals created coherently by a single GNSS transmitter and collected by a single instrument, a GNSS-R receiver. Reference [40.4] covers in detail the study of the correlation functions of partially coherent light beams in the optical domain, and [40.5] apply these concepts to radio waves.

A GNSS-R receiver based on the measurement of the coherence of the reflected and direct beams will be termed interferometric or codeless. If a model of the code of the transmitted signal is known, the direct signal could be substituted by its known functional representation. We will use the terms clean-replica or code to refer to this case. We should mention that the clean-replica GNSS-R receivers are conceptually close to the standard GNSS navigation receivers [40.6], while the interferometric receivers are close to the first geodetic quality codeless Global Positioning System (GPS) receivers [40.7] and the Very Long Baseline Interferometers [40.8].

The receiver can be understood as a system that collects signals and transforms them into other signals following specified procedures. We can assume that these signals can be modeled using mathematical functions expressing a statistical relation with experimental data.

Within this chapter, procedures and models will be indicated using the following conventions:

- When a signal $B$ is the result of a process $A$, we will use the notation $B := A$.
- When we consider that a mathematical function $A$ is an approximation of the dataset $B$, we will express such relation as $B \approx A$.

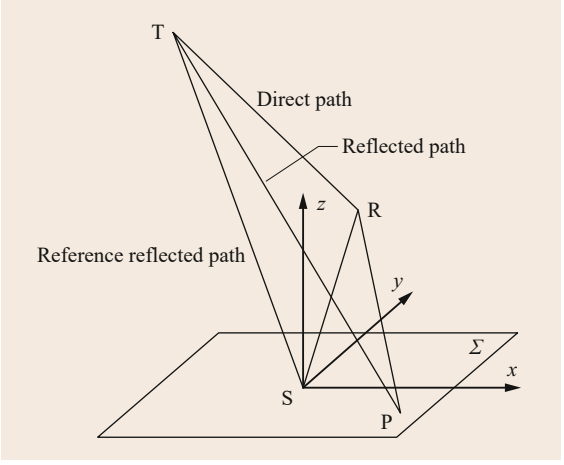

**Fig. 40.1** Geometry of a GNSS reflection, and conventions used along this chapter. A signal transmitted at T is collected at R through direct and reflected paths. Point P is a generic point of the reflecting surface $\Sigma$. S is a point taken as a reference to compute the relative delays between the reflected and the direct signals as recorded in R

### 40.1.1 GNSS-R Receivers

We consider initially the interferometric GNSS-R case, as sketched in Fig. 40.1, where only one member T of the GNSS constellations transmits a band-limited radio frequency (RF) signal. Two antennas placed at the receiver position R collect samples of this signal. One, the uplooking antenna, provides samples of the signal traveling through the direct path. The other, the downlooking antenna, provides samples of the same signal after its reflection on the points P of surface $\Sigma$, traveling through a diversity of reflected paths.

The collected signals are real-valued functions. In this chapter we will use its associated analytic function, as used in communication theory. This allows a simpler mathematical formulation (see, for instance, [40.9] or [40.5, App. 3.1]).

The direct samples $V_D(t)$, where $t$ is the time as measured by the instrument clock, will be represented by the functional model

$$V_D(t) \approx A_D(t) e^{+2\pi j \nu_0 t} , \tag{40.1}$$

where $A_D(t)$ is a complex covariance-stationary stochastic process that modulates a tone at the frequency $\nu_0$.

We assume that the transmitted signal arrives also to the receiver after its reflection on the surface $\Sigma$ as function of the time $t$, as the complex signal $V_R(t)$,

$$V_R(t) \approx A_R(t - \tilde{\tau}(t)) e^{+2\pi j \nu_0 (t - \tilde{\tau}(t))} , \tag{40.2}$$

where $A_R(t)$ is a complex covariance-stationary stochastic process and $\tilde{\tau}(t)$ is a model that predicts the relative delay between a signal reflected in a reference point S and the direct signal. In the following discussion the reference point selected is the specular point. Note that the processes $A_R(t)$ and $A_D(t)$ at the input of the GNSS-R receivers are filtered versions of the nominal values.

To align the direct signal, we delay the direct signal using the model $\tilde{\tau}(t)$, to obtain the delay compensated signal defined as

$$\begin{aligned} V_D^c(t) &:= V(t - \tilde{\tau}(t)) , \\ V_D^c(t) &\approx A_D(t - \tilde{\tau}(t)) e^{+2\pi j \nu_0 (t - \tilde{\tau}(t))} . \end{aligned} \tag{40.3}$$

Because the granularity of the sampling process is too coarse, the alignment requires some form of interpolation. This may be accomplished in several ways. Time delay interpolation procedures can be found in [40.10] and [40.11] and their frequency-domain counterpart in [40.8].

Once both signals are aligned, we compute the coherence, or cross-correlation, of both signals using

$$\begin{aligned} \Gamma_{RD}(t_c, \tau) &:= \left\langle V_R(t+\tau) V_D^{c\,*}(t) \right\rangle_{T_c} \\ &:= \frac{1}{T_c} \int_{T_c} V_R(t+\tau) V_D^{c\,*}(t) \mathrm{d}t \\ &:= V_R(t) \star V_D^c(t) , \end{aligned} \tag{40.4}$$

where the asterisk $^*$ indicates the complex conjugate value, $t_c$ is the epoch associated to the coherent averaging interval $T_c$, $\tau$ is the lag delay variable, $\langle \dots \rangle_T$ denotes the statistical average during the interval $T$, and $\star$ is the correlation symbol.

Using (40.1) and (40.3), and assuming that the cross-correlation $\Gamma_{RD}(t_c, \tau)$ is nearly time invariant, we obtain the corresponding mathematical model as

$$\Gamma_{RD}(t_c, \tau) \approx \langle A_R(t+\tau) A_D^*(t) \rangle_{T_c} . \tag{40.5}$$

The intrinsic variations of the surface $\Sigma$ and the movements of the transmitter and the receiver will limit the size of the interval $T_c$, according to the van Cittert–Zernike theorem (e.g., [40.4] and [40.5]). An expression to compute the order of magnitude of $T_c$ is given in Sect. 40.2.5.

To reduce thermal and speckle noise (see Sect. 40.2.6), the receiver delivers the waveforms $W_{RD}$ computed as the average of $|\Gamma_{RD}(t_c, \tau)|^2$ during an incoherent averaging interval $T_a$

$$\begin{aligned} W_{RD}(t_a, \tau) &:= \left\langle |\Gamma_{RD}(t_c, \tau)|^2 \right\rangle_{T_a} , \\ W_{RD}(t_a, \tau) &\approx |\langle A_R(t+\tau) A_D^*(t) \rangle_{T_c}|^2 . \end{aligned} \tag{40.6}$$

Here $t_a$ is the time associated with the averaging interval $T_a$. Note that these products will depend on the choice of $\tilde{\tau}$ as well as the duration of the intervals $T_c$ and $T_a$.

This formulation can be applied directly to the clean-replica case, assuming that the power of the signal arriving through the direct link is noiseless and has unit power. It should also be noted here that the amplitude of the direct $A_D(t)$ and the reflected $A_R(t)$ signals at the correlator input depend linearly on $\sqrt{P_T}$, where $P_T$ is the transmitted power and consequently the GNSS-R waveforms $W_{RD}(\tau)$ will depend quadratically on $P_T$. In the clean-replica approach $V_D$ is a replica or template with unity power at the correlator input. In this case the thermal input noise in the direct link is removed, and the output of of the receiver will depend only linearly on the transmitted power $P_T$. The normalized interferometric GNSS-R waveforms defined as

$$W_{RD}^n(t_a, \tau) := \frac{W_{RD}(t_a, \tau)}{P_T} \tag{40.7}$$

will be the equivalent to the clean-replica waveforms.

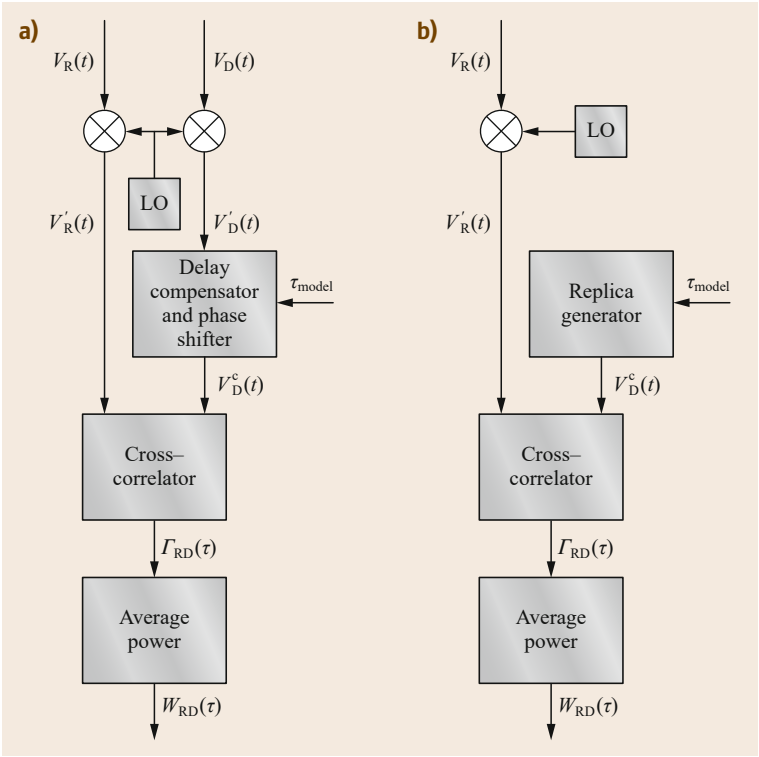

**Fig. 40.2a,b** Sketch of interferometric (**a**) and clean-replica (**b**) GNSS-R Receivers

### GNSS-R Receivers with Downconversion

The waveforms computed as per (40.6) require the direct sampling of the signal at the radio frequency (RF) band. As in the standard GNSS navigation receivers, it is preferred to downconvert the signal to baseband. We provide now a possible procedure.

An interferometric GNSS-R receiver with the correlation performed with lower sampling rate is represented conceptually at the left of Fig. 40.2. A clean-replica GNSS-R receiver is shown at the right in the same figure. The interferometric GNSS-R receiver accepts the direct $V_D(t)$ and reflected $V_R(t)$ signals and transforms them through the following steps:

*Downconversion*: The spectrum of both signals is shifted coherently from the RF band to a lower band. Assuming that the downconversion frequency is $\nu_0$, we have

$$V'_D(t) := V_D(t)e^{-2\pi j\nu_0 t} ,$$
$$V'_D(t) \approx A_D(t) , \tag{40.8}$$
$$V^c_R(t) := V_R(t)e^{-2\pi j\nu_0 t} ,$$
$$V^c_R(t) \approx A_R(t-\tilde{\tau}(t))e^{-2\pi j\nu_0\tilde{\tau}(t)} . \tag{40.9}$$

*Delay and Phase Compensation*: The remaining transformations are performed only over the direct signal. First, the direct downconverted signal is delayed according to the model $\tilde{\tau}(t)$ to obtain the shifted direct

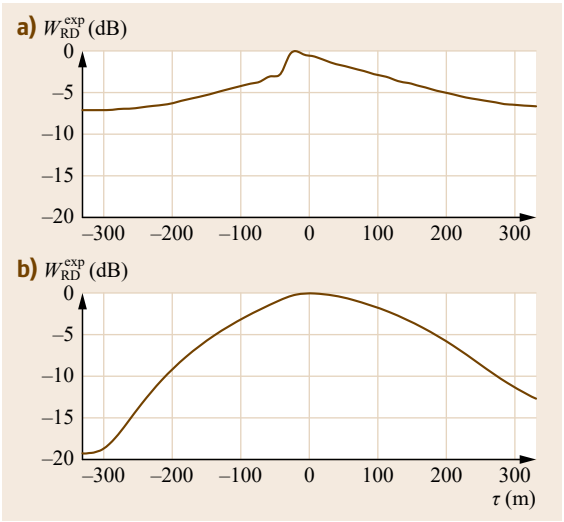

**Fig. 40.3a,b** Examples of waveforms $W_{RD}$ obtained simultaneously during a flight experiment. (**a**) Corresponds to an interferometric waveform, of a composite signal that included C/A, P(Y) and M codes. (**b**) Panel presents a C/A clean-replica waveform. Both waveforms have been divided by their maximum value ◄

downconverted signal $V'_D$

$$V''_D(t) := V'_D(t-\tilde{\tau}(t)) ,$$
$$V''_D(t) \approx A_D(t-\tilde{\tau}(t)) . \quad (40.10)$$

Subsequently, this shifted direct downconverted signal $V''_D$ is rotated by a phase angle $-2\pi\nu_0\tilde{\tau}(t)$ to obtain the downconverted and aligned signal $V^c_D(t)$

$$V^c_D(t) := V''_D(t)e^{-2\pi j\nu_0\tilde{\tau}(t)} ,$$
$$V^c_D(t) \approx A_D(t-\tilde{\tau}(t))e^{-2\pi j\nu_0\tilde{\tau}(t)} . \quad (40.11)$$

Comparison of the signal models given in (40.9) and (40.11) shows that the signal $V^c_D(t)$ has been aligned with the compensated reflected signal $V'_R(t)$. Consequently the waveforms obtained with a receiver with a baseband correlator will be equivalent to those obtained with a direct sampling correlation receiver.

In Fig. 40.3 we present two waveforms obtained simultaneously with interferometric and clean-replica receivers placed on an aircraft flying at 3000 m altitude. The accumulation periods were $T_c = 1$ ms and $T_a = 20$ s. In this example it can be noted that the dynamic ranges of these waveforms are 7 dB and 19 dB respectively. Also it should be noted that the leading edge of the interferometric waveform presents a steeper slope than the clean-replica waveform. Reference [40.12] provides a detailed account of this experiment.

## 40.2 Models

The purpose of this section is to outline the procedures to model the observed waveforms in terms of experimental parameters: positions, velocities, and roughness of the reflecting surface. As each point P in the surface $\Sigma$ will contribute signals with different delay and Doppler shifts to the waveform, we start assigning values for the expected delay and Doppler to each point. The second step will be to assemble the waveform model.

### 40.2.1 Delay-Doppler Coordinates

To build the model $\tilde{\tau}$ we assume, as a first approximation, that the positions of the transmitter T, the receiver R and the reflecting surface $\Sigma$ are known functions of time. At the epoch $t$, as measured by the receiver clock, we define the relative delay model $\tilde{\tau}(P)$ (expressed in distance units) as

$$\tilde{\tau}(P) := \rho(T,P) + \rho(P,R) - \rho(T,R) , \quad (40.12)$$

where $\rho(A,B)$ is the geometric range between two points A and B at this epoch.

Note that a more accurate model should take into consideration that at the epoch $t$ the recorded signals $V_D(t)$ and $V_R(t)$ were transmitted when the transmitter was at $T(t-\delta\tau_D)$ and $T(t-\delta\tau_R)$, where $\delta\tau_D$ and $\delta\tau_R$ are the propagation time from the transmitter to the receiver through the direct and the reflected beam respectively. For the purposes of aligning the direct and the reflected signals within the correlation window the model (40.12) is sufficient.

We will take as the reference the specular point S where $\tilde{\tau}(P)$ is a minimum. The quantity

$$\Delta\tau(P) := \tilde{\tau}(P) - \tilde{\tau}(S) \quad (40.13)$$

will be referred as the specular relative delay. The points P of the surface $\Sigma$ with $\Delta\tau(P) = \Delta\tau_0$ and $\Delta\tau_0 > 0$ define the isodelay curve $\Delta\tau_0$.

The effects of the changing geometry can be analyzed taking into account the velocities of the points T, P and R. In this case, the derivative of the relative delay model, as stated in (40.12), is

$$\frac{d\tilde{\tau}(P)}{dt} = \frac{d\rho(T,P)}{dt} + \frac{d\rho(P,R)}{dt} - \frac{d\rho(T,R)}{dt} . \quad (40.14)$$

This variation expresses the difference between the range rate of the signal reflected at P and the direct signal, or Doppler shift

$$\nu(P) = -\frac{\nu_0}{c}\frac{d\tilde{\tau}(P)}{dt} . \quad (40.15)$$

Here $c$ is the speed of light in vacuum and the quantity

$$\Delta\nu(P) = \nu(P) - \nu(S) \quad (40.16)$$

is the relative Doppler shift experienced by two signals reflected at P and S.

The points P of the surface $\Sigma$ where $\Delta\nu(P) = \Delta\nu_0$ define the iso-Doppler lines $\Delta\nu_0$. As a reference, in Fig. 40.4b we have represented a set of isodelay and iso-Doppler lines for a receiver placed at 3 km altitude with a horizontal velocity of 55 m/s.

### 40.2.2 The Ambiguity Function

To model the cross-correlation defined in (40.4) and (40.6), we start with the contribution of the reflected signal in the point P, whose delay-Doppler coordinates

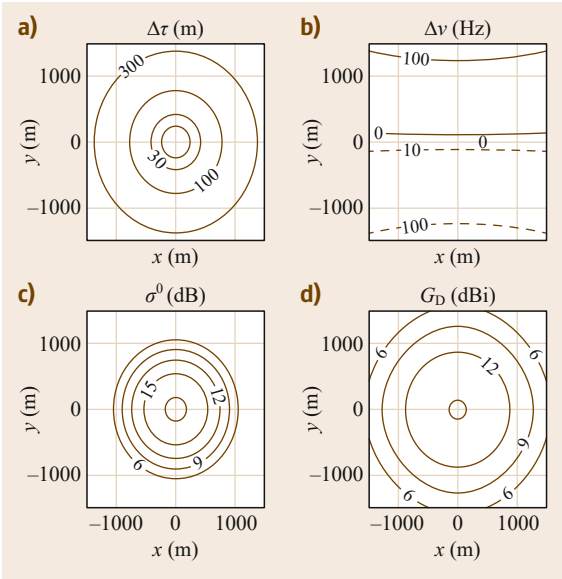

**Fig. 40.4a–d** Sketches of isolines in the reflecting surface corresponding to one experiment where a receiver was placed at 3 km altitude flying at 55 m/sec. The functions represented are relative delay $\Delta\tau(\mathrm{P})$ **(a)**, relative frequency $\Delta\nu(\mathrm{P})$ **(b)**, bistatic scattering coefficient $\sigma^0_{pq}(\mathrm{P})$ **(c)** and antenna gain $G_\mathrm{D}(\mathrm{P})$ **(d)**c

are $\Delta\tau(\mathrm{P})$ and $\Delta\nu(\mathrm{P})$

$$A_\mathrm{R}(\mathrm{P}, t+\tau) \approx \sqrt{P_\mathrm{R}(\mathrm{P})}\hat{A}_\mathrm{D}(t+\delta\tau) \times \mathrm{e}^{-2\pi\mathrm{j}\delta\nu t}\,, \tag{40.17}$$

where $\tau$ is the correlator delay, $\delta\tau = \tau - \Delta\tau(\mathrm{P})$, $\delta\nu = \Delta\nu(\mathrm{P})$, $P_\mathrm{R}(\mathrm{P})$ is the average power of the collected reflected signal coming from the point P, and $\hat{A}_\mathrm{D}(t) = A_\mathrm{D}(t)/P_\mathrm{D}$ where $P_\mathrm{D}$ is the average power of the direct signal.

The contribution of each point P of the reflecting surface to the correlator output will be

$$\begin{aligned} \Gamma_\mathrm{RD}(\mathrm{P}, \tau) &\approx \sqrt{P_\mathrm{R}(\mathrm{P})}\sqrt{P_\mathrm{D}} \\ &\quad \times \left\langle \hat{A}_\mathrm{D}(t+\delta\tau)\hat{A}^*_\mathrm{D}(t)\mathrm{e}^{-2\pi\mathrm{j}\delta\nu t}\right\rangle_{T_\mathrm{c}} \\ &\approx \sqrt{P_\mathrm{R}(\mathrm{P})}\sqrt{P_\mathrm{D}}\chi_{\hat{A}}(\delta\tau, \delta\nu)\,, \end{aligned} \tag{40.18}$$

where $\chi_{\hat{A}}$ is the function

$$\chi_{\hat{A}}(\tau, \nu) := \frac{1}{T_\mathrm{c}}\int_{T_\mathrm{c}} \hat{A}_\mathrm{D}(t+\delta\tau)\hat{A}^*_\mathrm{D}(t)\mathrm{e}^{-2\pi\mathrm{j}\delta\nu t}\mathrm{d}t\,. \tag{40.19}$$

The contribution of the signal reflected at point P to the waveform will be

$$W_\mathrm{P,RD}(\tau) := P_\mathrm{D}P_\mathrm{R}(\mathrm{P})|\chi_{\hat{A}}(\delta\tau, \delta\nu)|^2\,. \tag{40.20}$$

The function $|\chi_{\hat{A}}(\delta\tau, \delta\nu)|^2$ in the above equation is usually called the narrowband radar ambiguity function associated to $\hat{A}_\mathrm{D}(t)$ [40.13]. It represents the power radar return of a moving target whose delay and Doppler shift with respect to the nominal values are $\delta\tau$ and $\delta\nu$. The term *ambiguity* refers to the uncertainty of the delay and Doppler radar measurements. The function $|\chi_{\hat{A}}(\delta\tau, \delta\nu)|^2$ can be estimated from known correlation properties of the transmitted signals, or determined experimentally.

Two properties of the ambiguity functions are relevant to determine its overall structure. Along the axis $\delta\nu = 0$ the ambiguity function is the squared autocorrelation of the process $\hat{A}_\mathrm{D}(t)$

$$|\chi_{\hat{A}}(\delta\tau, 0)|^2 := \left|\frac{1}{T_\mathrm{c}}\int_{T_\mathrm{c}} \hat{A}_\mathrm{D}(t+\delta\tau)\hat{A}^*_\mathrm{D}(t)\mathrm{d}t\right|^2\,. \tag{40.21}$$

Within the GNSS-R literature, this value is commonly denoted as

$$|\Lambda(\delta)|^2 \equiv |\chi_{\hat{A}}(\delta\tau, 0)|^2\,. \tag{40.22}$$

In the case that $\hat{A}(t)\hat{A}^*(t) = 1$, the ambiguity function along the axis $\delta\tau = 0$ is

$$|\chi_{\hat{A}}(0, \delta\nu)|^2 := |\,\mathrm{sinc}(\pi\delta\nu T_\mathrm{c})|^2\,, \tag{40.23}$$

where the sinc function is defined as

$$\mathrm{sinc}(x) = \frac{\sin(x)}{x}\,. \tag{40.24}$$

In Fig. 40.5, we represent two examples of $|\chi(\delta\tau, 0)|^2$; a GPS C/A signal and a composite C/A-, P(Y)- and M-code modulated signal. The assumed effective isotropic radiated power (EIRP), defined as the product of the transmitted power $P_\mathrm{T}$ and the gain of the transmitter antenna $G^\mathrm{D}_\mathrm{T}$ in the direction of the receiver, for each component as the its modulations are given in Table 40.1. We have assumed that the precorrelation bandwidth is 24 MHz.

**Table 40.1** Signals used in the simulation. See Chap. 4 for a description of the individual modulation types

| Signal | EIRP | Modulation | Reference |
|---|---|---|---|
| C/A | 24.0 dBW | BPSK(1) | [40.6] |
| P(Y) | 21.3 dBW | BPSK(10) | [40.6] |
| M | 25.3 dBW | BOC(10,5) | [40.14] |

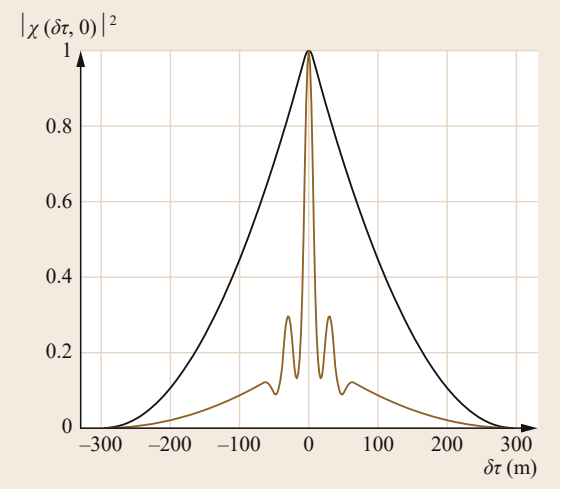

**Fig. 40.5** Examples of $|\chi(\delta\tau,0)|^2$: *black line* corresponds to a GPS C/A signal, and the *brown line* to a GPS signal composite of C/A-, P(Y)- and M-codes

### 40.2.3 The Noiseless Waveform Model

Adding all the contributions $W_{\mathrm{RD}}(\mathrm{P},\tau)$, defined in (40.20) from all the points P of the surface $\Sigma$ we obtain a model for the waveform

$$W_{\mathrm{RD}}(\tau) := P_{\mathrm{D}} \int_{\Sigma} P_{\mathrm{R}}(\mathrm{P}) |\chi_{\hat{A}}(\delta\tau,\delta\nu)|^2 \mathrm{d}\sigma \qquad (40.25)$$

and, according to the definition (40.7), the normalized waveform will read

$$W^{\mathrm{n}}_{\mathrm{RD}}(\tau) := \int_{\Sigma} P_{\mathrm{R}}(\mathrm{P}) |\chi(\delta\tau,\delta\nu)|^2 \mathrm{d}\sigma \,. \qquad (40.26)$$

The received power $P_{\mathrm{D}}$ in the (40.25) at the input of the correlator is related to the transmitter power by

$$P_{\mathrm{D}} := P_{\mathrm{T}} G^{\mathrm{D}}_{\mathrm{T}} G^{\mathrm{D}}_{\mathrm{R}} \left(\frac{\lambda}{4\pi R_{\mathrm{TR}}}\right)^2 , \qquad (40.27)$$

where $G^{\mathrm{D}}_{\mathrm{T}}$ and $G^{\mathrm{D}}_{\mathrm{R}}$ are the transmitter and receiver antenna gains for the direct link, $R_{\mathrm{TR}}$ is the distance between transmitter T and receiver R, and $\lambda$ is the signal wavelength. Similarly, the received power of the reflected signal is given by

$$P_{\mathrm{R}}(\mathrm{P}) := \frac{P_{\mathrm{T}} G_{\mathrm{T}}(\mathrm{P}) G_{\mathrm{R}}(\mathrm{P}) \sigma^0_{pq}(\mathrm{P}) \lambda^2}{(4\pi)^3 R_{\mathrm{T}}(\mathrm{P})^2 R_{\mathrm{R}}(\mathrm{P})^2} \,. \qquad (40.28)$$

Here, $\sigma^0_{pq}(\mathrm{P})$ is the bistatic scattering differential coefficient. For each point P of the surface $\Sigma$, this coefficient is defined as the ratio of the power scattered towards the receiver R with polarization state $q$ to the power incident with polarization state $p$, per unit area (see [40.15, p. 463] for details). This ratio depends on the probability density function (PDF) of the surface roughness slopes. Reference [40.16, App. B], presents a widely accepted $\sigma^0_{pq}(\mathrm{P})$ model, where the sea slopes PDF is a bivariate normal distribution, later introduced in Sect. 40.3.2.

As a reference, we have represented a set of isogain and iso-$\sigma$ lines that model the values corresponding to the aforementioned experiment at the bottom of Fig. 40.4.

### 40.2.4 Floor Noise Model

In this section we present a simple model to describe the noise to be added to the noiseless waveforms defined in (40.25).

We assume now that the compensated recorded signals $V^{\mathrm{c}}_{\mathrm{D}}(t)$ and $V^{\mathrm{c}}_{\mathrm{R}}(t)$ are

$$\begin{aligned} V^{\mathrm{c}}_{\mathrm{D}}(t) &\approx v^{\mathrm{c}}_{\mathrm{D}}(t) + n_{\mathrm{D}}(t) \,, \\ V^{\mathrm{c}}_{\mathrm{R}}(t) &\approx v^{\mathrm{c}}_{\mathrm{R}}(t) + n_{\mathrm{R}}(t) \,, \end{aligned} \qquad (40.29)$$

where $v^{\mathrm{c}}_{\mathrm{D}}(t)$ and $v^{\mathrm{c}}_{\mathrm{R}}(t)$ are the compensated noiseless signal terms and $n_{\mathrm{D}}(t)$ and $n_{\mathrm{R}}(t)$ the noise terms.

The coherence $\Gamma_{\mathrm{RD}}(t_{\mathrm{c}},\tau)$, defined in (40.4), will read

$$\begin{aligned} \Gamma_{\mathrm{RD}}(\tau) &:= (v^{\mathrm{c}}_{\mathrm{R}} + n_{\mathrm{R}}) \star (v^{\mathrm{c}}_{\mathrm{D}} + n_{\mathrm{D}}) \\ &= v^{\mathrm{c}}_{\mathrm{R}} \star v^{\mathrm{c}}_{\mathrm{D}} \\ &\quad + v^{\mathrm{c}}_{\mathrm{R}} \star n_{\mathrm{D}} + n_{\mathrm{R}} \star v^{\mathrm{c}}_{\mathrm{D}} + n_{\mathrm{R}} \star n_{\mathrm{D}} \end{aligned} \qquad (40.30)$$

and the corresponding waveforms is given by (40.6)

$$W_{\mathrm{RD}}(\tau) := W^{\mathrm{signal}}_{\mathrm{RD}}(\tau) + N \,, \qquad (40.31)$$

where $W^{\mathrm{signal}}_{\mathrm{RD}}(\tau)$ is the noiseless waveform, modeled as per (40.25), (40.27), and (40.28), and the term $N$ includes the contributions of the noise terms.

According to [40.17], the waveform noise term is given by

$$N = P_{\mathrm{D}} \frac{k_{\mathrm{B}} T_{\mathrm{R}}}{T_{\mathrm{c}}} + P_{\mathrm{R}} \frac{k_{\mathrm{B}} T_{\mathrm{D}}}{T_{\mathrm{c}}} + k_{\mathrm{B}} T_{\mathrm{R}} B \frac{k_{\mathrm{B}} T_{\mathrm{D}}}{T_{\mathrm{c}}} \,, \qquad (40.32)$$

where $k_{\mathrm{B}}$ is the Boltzmann constant, $B$ is the predetection bandwidth, and $T_{\mathrm{c}}$ is the coherent averaging interval, already introduced. $T_{\mathrm{D}}$ and $T_{\mathrm{R}}$ are the effective noise temperatures of the direct and reflected signals. They are defined as

$$T = T^{\mathrm{ant}} + (F-1)290\,\mathrm{K} \,, \qquad (40.33)$$

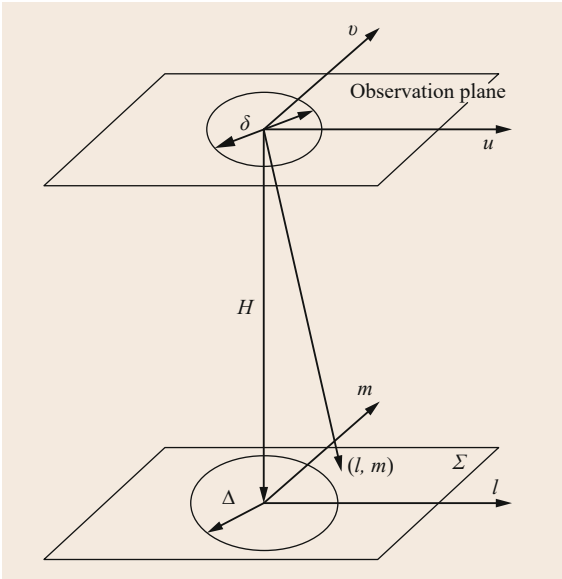

**Fig. 40.6** Sketch to show the $(u, v)$ and $(l, m)$ coordinates used in the formulation of the van Cittert–Zernike theorem. The distribution of the radiation intensity in the $\Sigma$ space and the coherence in the observation plane form a Fourier transform pair

where $T^{\text{ant}}$ is the corresponding antenna temperature and $F$ is the noise factor expressed in linear units.

In a clean-replica instrument $T_{\text{D}} = 0$, and the corresponding noise term will be

$$N^{\text{cr}} := P_{\text{D}} \frac{k_{\text{B}} T_{\text{R}}}{T_{\text{c}}} \,. \tag{40.34}$$

The quantities $N$ and $N^{\text{cr}}$ represent the effective waveform floor noise for the interferometric and clean-replica cases. Parts of waveforms with power below these quantities will not be observable.

To express the relation between the interferometric and clean-replica waveforms we introduce the interferometric noise factor $\eta$ defined as

$$\begin{aligned} \eta &:= \frac{N}{N^{\text{cr}}} \\ &:= 1 + \frac{1 + (S/N)_{\text{R}}}{(S/N)_{\text{D}}} \,, \end{aligned} \tag{40.35}$$

where the power signal-to-noise ratios at the correlator input are defined as

$$\begin{aligned} (S/N)_{\text{D}} &:= \frac{P_{\text{D}}}{k_{\text{B}} T_{\text{D}}^{\text{n}} B} \,, \\ (S/N)_{\text{R}} &:= \frac{P_{\text{R}}}{k_{\text{B}} T_{\text{R}}^{\text{n}} B} \,. \end{aligned} \tag{40.36}$$

As pointed out in [40.17], $\eta \to 1$ for $(S/N)_{\text{D}} \gg 1 + (S/N)_{\text{R}}$. In this case the noise in the interferometric waveforms do not increase substantially with respect to the clean-replica case. However, the situation is different in the low SNR regime. When $(S/N)_{\text{D}} \ll 1$, we have approximately

$$\eta \approx \frac{1}{(S/N)_{\text{D}}} \,, \tag{40.37}$$

i. e., the interferometric noise factor is inversely proportional to the signal-to-noise ratio of the direct signal.

### 40.2.5 Maximum Coherence Averaging Interval

In this section we attempt to provide an order of magnitude of the maximum coherence time $T_{\text{c}}$ to be used as the coherent averaging interval.

We assume that an incoherent extended source is placed in the surface $\Sigma$ (Fig. 40.6). The van Cittert–Zernike theorem ([40.4, 5] for background material, and [40.18] for its application to GNSS-R) states that the Fourier transform of the intensity of the source $I$ is the coherence function $\Gamma$ in the observation plane, assumed parallel to $\Sigma$

$$\Gamma(u, v) = \int_{\Sigma} I(l, m) \mathrm{e}^{-\mathrm{j}2\pi(ul + vm)} \mathrm{d}l \, \mathrm{d}m \,. \tag{40.38}$$

Here, $u$ and $v$ are spatial coordinates in the observation plane, expressed in wavelength $\lambda$ units, and $(l, m)$ are the direction cosines defined respect to the $(u, v)$ axis.

Assume now that the distance between both planes is $H$. A section of the surface $\Sigma$ of linear dimensions $\Delta$, when expressed in terms of the direction cosine has the size $\Delta/H$. The Fourier transform relationship implies that the dimensions of its image in the observation plane expressed in linear units will be $\delta = \lambda H/\Delta$.

The radius of the section of the surface $\Sigma$ limited by the isodelay line $\tau$, expressed in linear units, is $\sqrt{2\tau H}$. Then the dimensions in the observation plane produced by such a section will be

$$\delta = \frac{\lambda \sqrt{H}}{2\sqrt{2\tau}} \,. \tag{40.39}$$

If the receiver is moving at velocity $v_{\text{R}}$, the samples obtained within an interval

$$T_{\text{c}} < \frac{\delta}{v_{\text{R}}} = \frac{\lambda \sqrt{H}}{2\sqrt{2\tau}\, v_{\text{R}}} \tag{40.40}$$

will show coherence.

In the case of a coastal experiment, $v_R = 0$, and the previous expression should be substituted by a constant value expressing the intrinsic variability of the sea surface. Reference [40.19] indicates that this intrinsic variability is on the order of 100 msec.

### 40.2.6 Speckle Noise

Equation (40.20) expresses the contribution to the waveform $W_{RD}(\tau)$ of the different elements of surface $d\sigma$ of the reflecting surface $\Sigma$. The quantity $W_{RD}(\tau)$ for a particular value of $\tau$ will be built by the contributions of a large number $N$ of scatterers placed in the proximity of the isodelay line labeled $\tau$. Each scatterer $n$ will contribute with a signal $V_n e^{j\phi_n}$ to the sum

$$V(\tau) = V_e e^{j\phi} = \sum_{n=1}^{N_s} V_n e^{j\phi_n} . \qquad (40.41)$$

The amplitude of this sum, $V_e$, has a Rayleigh distribution, and its phase $\phi$ is uniformly distributed in the range $(0, 2\pi)$. The probability distribution associated to the power $P(\tau) = V^2(\tau)$ is exponential

$$p(P) = \begin{cases} \overline{P} e^{-P/\overline{P}} & \text{if } P \geq 0 \\ 0 & \text{if } P < 0 , \end{cases}$$

where $\overline{P}$ is the mean value and the standard deviation of the distribution. This large dispersion is reduced by averaging many individual waveforms gathered during the incoherent averaging interval $T_a$.

**Table 40.2** Main instrument and experiment parameters. Labels D and R corresponds to the direct and reflected signal respectively. RHCP: right-hand circular polarized, LHCP: left-hand circular polarized

| Variable | Value | Symbol |
|---|---|---|
| Antenna gain (D) (R) | 15 dBi | $G_R$, $G_D$ |
| Polarization (D) | RHCP | $p$ |
| Polarization (R) | LHCP | $q$ |
| Antenna temp. (D) | 10 K | $T_D^{ant}$ |
| Antenna temp. (R) | 200 K | $T_R^{ant}$ |
| Noise factor (D) (R) | 3 dB | $F$ |
| RF bandwidth (D) (R) | 24 MHz | $B$ |
| Coherent ave. time | 1 msec | $T_c$ |
| Incoherent ave. time | 20 sec | $T_a$ |
| Mean-squared slope | $\approx 0.010$ | MSS |
| Incidence angle | $\approx 0°$ | $\theta$ |
| Height receiver | $\approx 3$ km | $h_{RS}$ |
| Velocity receiver | $\approx 55$ m/s | $v_R$ |

### 40.2.7 Observed versus Modeled Waveforms

In this section we analyze the waveforms shown in Fig. 40.3 in terms of the signal and noise models described in the two previous sections. They were acquired simultaneously during an aircraft experiment

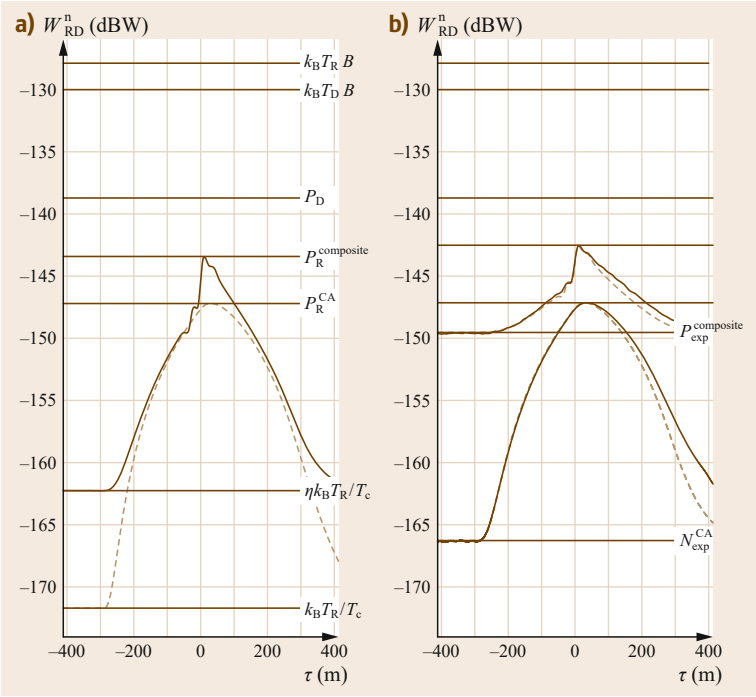

**Fig. 40.7** **(a)** Modeled waveforms for the clean-replica (*dashed line*) and interferometric (*brown*) cases. **(b)** Observed corresponding waveforms (*brown*), where its total power has been adjusted using the modeled values, and with the same dynamic range as from the experimental results

**Table 40.3** Modeled power levels and interferometric noise factor for the aircraft experiment

| Signal/Variable | dBW | Symbol |
|---|---|---|
| Precorrelation noise (D) | −130.2 | $k_B T_D B$ |
| Precorrelation noise (R) | −127.9 | $k_B T_R B$ |
| Peak composite waveform (D) | −138.7 | $P_D^{composite}$ |
| Peak composite waveform (R) | −143.4 | $P_R^{composite}$ |
| Peak CA waveform (R) | −147.2 | $P_R^{CA}$ |
| Floor noise composite | −160.9 | $N$ |
| Floor noise CA | −171.7 | $N^{cr}$ |
| Interferometric noise factor | 10.8 | $\eta$ |

described and analyzed in [40.12]. The relevant parameters describing the experiment are indicated in Table 40.2. We have included in this table the approximate values for the mean squared slopes (MSSs), incidence angle of the signal $\theta$, and the height $h_{RS}$ and the nearly horizontal velocity $v_R$ of the receiver needed for modeling the corresponding waveforms.

The model $\hat{\tau}(t)$, needed to align the direct and the reflected signals, has been obtained using GPS and Inertial Measuring Unit observables acquired during the experiment, and International GNSS Service (IGS) GPS precise orbits.

In Fig. 40.7 we have represented, in the left panel, interferometric and a clean-replica waveforms modeled as per (40.31), and normalized as before. In Table 40.3 we have indicated different values of the power.

**Table 40.4** Experimental floor power levels and inteferometric noise factor

| Signal/Variable | dBW | Symbol |
|---|---|---|
| Floor noise composite | −149.5 | $N_{exp}$ |
| Floor noise CA | −166.2 | $N_{exp}^{cr}$ |
| Interferometric noise factor | 16.7 | $\eta_{exp}$ |

In the left panel of Fig. 40.7, we have represented model and experimental waveforms. We have adjusted the position of observed waveforms to the corresponding position of the model. The floor noise of this real waveforms has been used to define the floor noise for the composite and C/A modeled waveforms. These experimental floor noise values $N_{exp}^{composite}$ and $N_{exp}^{CA}$ are given in Table 40.4.

The difference of 6 dB between the experimental and modeled interferometric noise factor can be attributed to known model limitations in the parametrization used. Among others, these include:

- Losses before the low noise amplifiers
- Quantization noise
- Atmospheric attenuation, and
- Power transmitted in each code.

## 40.3 Applications

As it has been shown in the previous sections, GNSS reflectometry can be seen as a particular form of bistatic radar with capabilities for multistatic coverage.

The rich amount of available GNSS signals covering the entire globe (e.g., Fig. 40.8), and being transmitted at least at two frequencies of the L-band spectrum (all weather propagation), are some of the advantages of the technique. The density of observations that this concept can offer from space-based platforms potentially results in a high spatiotemporal resolution compared to some dedicated techniques. On the other hand, the fact that these signals have not been designed for remote sensing purposes makes them suboptimal in some aspects, especially when compared to dedicated remote sensing concepts. Some of the limiting factors are the transmitted powers, and the bandwidth and pulse resolution.

Despite these limitations, and because of the high and quick coverage of the Earth, the technique has potential to fill some gaps in the current Earth observational system. Examples of these gaps include mesoscale altimetry and scatterometry, both within a few days' time resolution and unaffected by the weather conditions (rain in particular).

The growing interest for these reflectometry techniques has boosted the development of dedicated instrumentation and experimental campaigns. Since the late 1990s and until October 2013, the amount of GNSS-R experiments conducted aboard aircrafts was greater than 270, executed with more than 20 different GNSS-R receivers. These experiments have been conducted in different geographic localizations, and they captured reflections off the ocean, bare soil, growing crops, lakes and rivers, sea ice, glaciers, mid-latitudes and Antarctic snow. Some of these datasets are available for research purposes at a web server [40.20] and documented in [40.21]. Moreover, the feasibility of receiving GNSS signals reflected off the Earth's surface from spaceborne platforms has also been proven. The first GNSS reflection captured from outer space was collected with the SIR-C instrument aboard the Space Shuttle [40.22]. A dedicated GNSS-R instrument with a moderate antenna gain (11.8 dBi) also gathered reflected signals off ocean, ice, and land surfaces from 700 km aboard one of the UK Disaster Monitoring Constellation (UK-DMC) satellites [40.23–25]. Sets of GNSS-R data obtained with the UK-DMC Low Earth

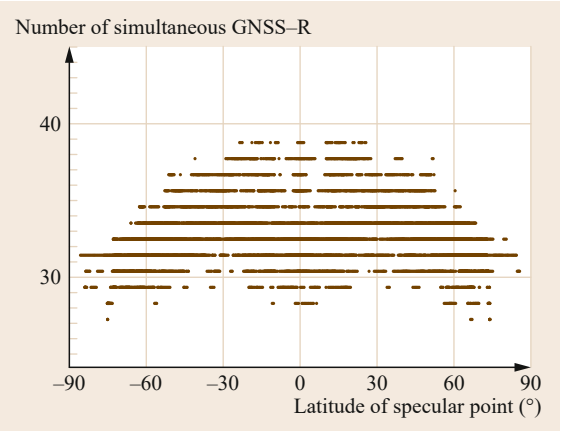

**Fig. 40.8** Number of simultaneously reflected GNSS satellites as a function of the latitude coordinate of their specular point on the Earth's surface, and accumulated in one day of observations. Two GNSS constellations (GPS and GLONASS) have been assumed, status as in 18 March 2012. These values might be doubled once Galileo and BeiDou-3 are fully operational

Orbiter are also available at [40.26]. Some of the applications that have resulted out of these studies are summarized in the following sections.

### 40.3.1 Sea Surface Altimetry

The oceanographic applications were the first to be identified as potential targets of the GNSS-R technique. In fact, the concept was conceived for sea surface altimetry in 1993 [40.1], and shortly after as a system to measure sea surface roughness (scatterometry) [40.2].

Ocean altimetry is one of the most challenging applications of the GNSS-R. In order to achieve the levels of precision needed for scientifically valuable products, the system requires demanding signal-to-noise ratios (SNR), maximizing the use of the bandwidth, and preserving the multistatic nature of the concept. Altogether, it introduces complexity at the hardware level (antennas, beam-formers, signal processors). Despite this complexity, accurate enough GNSS-R altimetric measurements have the potential to fill gaps in the current observational system, especially for its dense and quick global coverage, enabling the capture of ocean signals such as tsunamis (e.g., [40.27]), eddies and other mesoscale oceanic features. A large fraction of the ocean's kinetic energy is associated with spatial scales that cannot be resolved with a single radar altimeter mission. Mesoscale variability is key to understanding large-scale circulation and climate variability. The assimilation of GNSS-R data into ocean circulation models was first studied in [40.28], showing positive impact. Another benefit of the multistatic nature of the GNSS-R altimetry is its potential to resolve the sea surface slope (gradients in topography) in two dimensions, something that standard radar altimetric missions achieve only in the intersections of their ground tracks.

The scattering of GNSS signals off the sea surface tends to be diffuse, with little or no coherent part. The main consequence of diffuse scattering is that the phase of the reflected signal can barely be tracked, and the phase-delay observables cannot generally be obtained. As a consequence, the range measurements rely on group-delay measurements of lower precision. Therefore, this section focuses on group-delay ocean altimetry, while phase-delay altimetry is mostly used for ice applications (Sect. 40.3.4).

Chapter 14 shows that despite its higher accuracy, group-delay pseudoranges are far less precise than ranges measured with phase-delay observables, and describes how to extract the group-delay observables from the triangular GNSS waveform: the procedure can be summarized as the estimation of the delay of the peak of the triangle function resulting from cross-correlating the signals against their receiver synthesized replicas. This procedure is generally not suitable for reflected signals, since the waveform is strongly distorted by the severe and random multipath-like effect of reflections across a wide area on the surface; the glistening zone. The rougher the surface the wider the glistening zone, and thus the delay extension of multipath due to off-specular areas. This effect is illustrated in Fig. 40.9. The peak-delay estimator to extract the range of the reflected signals was nevertheless used in experiments over calm waters and low altitudes, such as in [40.29] or [40.30]. As described in Sect. 40.2.6, speckle is a major component of the noise, resulting in multiplicative dispersion following an exponential distribution of probability. Under these circumstances new approaches to identify the specular range within the distorted waveform are needed.

The procedure to identify the specular delay under diffuse scattering is composed by at least two steps: (1) sufficiently long incoherent averaging to reduce speckle; and (2) estimation of the specular delay. If the waveforms are obtained in real time (e.g., using a hardware receiver) some realignment of the waveforms along the delay axis might be required before integration, to correct for errors in the delay model applied by the receiver based on the real-time information. Integration without these corrections would result in blurred integrated waveforms. Two approaches are mainly used to estimate the delay location of the specular ray path. The first one found in the literature was based on fitting a model of the waveform, such as the one in (40.25). The model requires the assumption of

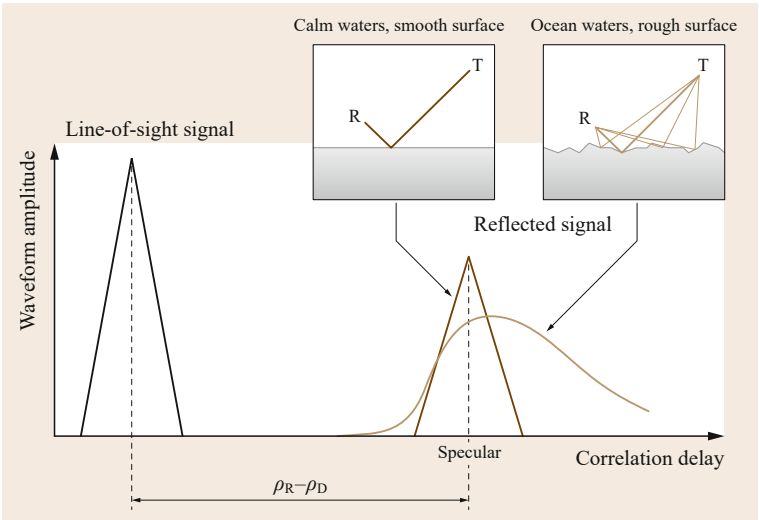

**Fig. 40.9** As illustrated in Fig. 40.10, one of the effects of diffuse scattering is a shift between the delay of the specular reflection and the peak of the waveform (cross-correlation function between the signal and the receiver synthesized replica). Reflections off smooth surfaces keep the triangular shape of the autocorrelation function, and its peak corresponds to the specular ray path. Reflections off rough surfaces contain multiple ray paths, which delay the peak of the total waveform with respect to the shortest ray path (specular). The delay of the specular point can be obtained either by fitting a model to the waveform, or as the point of maximum slope within its leading edge. Once the delay of the specular reflection has been extracted, the altimetric observable is its pseudorange $\rho_R$ in absolute terms or with respect to the direct pseudorange $\rho_D$: $\rho_R - \rho_D$

certain surface roughness status (more details will be given in Sect. 40.3.2 and (40.45)) or to estimate simultaneously both the specular delay and the roughness parameters (e.g., [40.31]). An alternative approach was suggested in [40.33] and later studied in [40.32], for which the delay of the specular ray path is identified as the point in the leading edge of the waveform of maximum slope (or equivalently, the peak of the derivative of the waveform, see Fig. 40.10).

Once the specular ray-path delay has been estimated through either fitting a model or looking at the derivative peak, this links to its pseudorange $\rho_R$, now given in units of length. The pseudorange can be given in absolute terms or with respect to the range of the line-

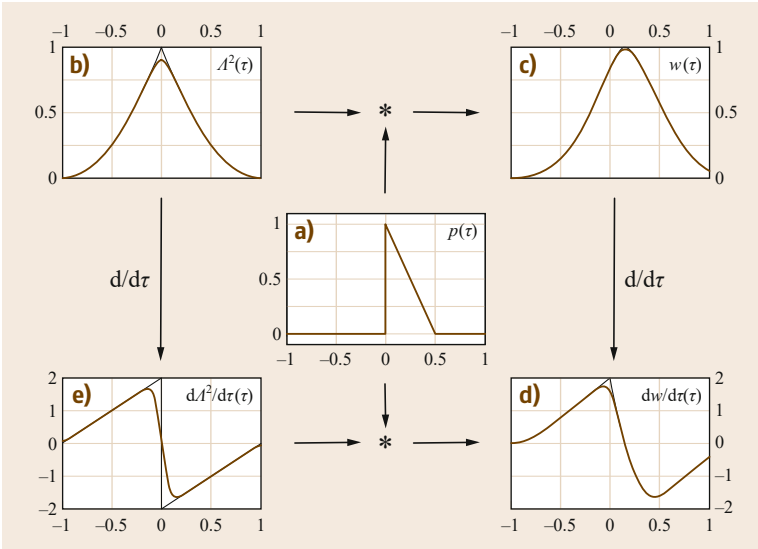

**Fig. 40.10a–e** The convolution between the power response of the sea surface when some power is scattered off nonspecular areas ((**a**) $p$ for $\tau \geq 0$, where zero is defined as the specular ray-path delay) and the power of the autocorrelation function of the C/A modulation code ((**b**) $\Lambda^2$) results in a waveform (**c**) the peak of which is delayed with respect to the specular delay. The derivative of this waveform presents a peak in the actual specular delay (**d**) and (**e**) shows the derivative of the power of the autocorrelation. Note that this would strictly hold for a receiver with infinite bandwidth (*thin black lines*), while actual receiver filtering smooths these figures and slightly shifts the delays (*thick brown lines*) (after [40.32], courtesy of Institute of Electrical and Electronics Engineers (IEEE))

of-sight radio link, $\rho_{\mathrm{D}}$. This is illustrated in Fig. 40.9. The pseudorange of the reflected signal has several contributions

$$\rho_{\mathrm{R}}(t) = \rho_{\mathrm{geo}}\left(\mathrm{R}(t), \mathrm{T}\left(t - \frac{\rho_{\mathrm{geo}}}{c}\right), \mathrm{S}(\mathrm{R}, \mathrm{T}, h)\right) + \rho_{\mathrm{iono}} + \rho_{\mathrm{tropo}} + \rho_{\mathrm{clk}} + \rho_{\mathrm{ins}} + \epsilon \ . \tag{40.42}$$

As in direct reception, the pseudorange has a geometric term, $\rho_{\mathrm{geo}}$, given by the actual distance between the transmitter position T and the specular point position S, and the distance between the specular point and the receiver position R. The location of the specular point S is a function of the locations of the source and the receiver, as well as the altitude of the reflecting surface, $h$, with respect to a well-known reference surface (Earth geoid or ellipsoid). Other terms that contribute to the pseudorange are the tropospheric and ionospheric delays ($\rho_{\mathrm{tropo}}$, $\rho_{\mathrm{iono}}$) discussed in Chap. 6, clock drifts ($\rho_{\mathrm{clk}}$), instrumental errors $\rho_{\mathrm{ins}}$ (such as those introduced by the antenna phase and cabling offsets), and, finally, other noise contributions $\epsilon$ (essentially thermal and speckle due to the random nature of the scattering surface). Note that the vertical component $h$ of the specular point location is the unknown parameter in altimetric applications. An a priori value is assumed, based on a topographic description of the Earth's surface S evaluated at the point such that generates the shortest reflection link between the transmitter and the receiver. This point also verifies the Fresnel law of reflection (equal incident and scattering angles). Because the a priori knowledge of the Earth's topography wants to be refined, local vertical corrections $h$ are expected, and solved for. The general form to solve $h$ is to minimize

$$\min\left\{\left|\rho_{\mathrm{R}}(t)^{\mathrm{obs}} - \rho_{\mathrm{R}}(t)^{\mathrm{mod}}(h)\right|\right\} \ . \tag{40.43}$$

The model of the pseudorange $\rho_{\mathrm{R}}^{\mathrm{mod}}$ must include correction terms for its nongeometric components and/or estimate them together with the alimetric solution $h$.

This general term can be greatly simplified when the receiver is located at low altitude and the Earth is locally flat. Then the range of the reflected signal relative to the direct line-of-sight range is simply

$$\Delta\rho = \rho_{\mathrm{R,geo}} - \rho_{\mathrm{D,geo}} = 2H\sin(E) \ , \tag{40.44}$$

where now $H$ is the vertical distance between the surface and the receiver altitude, and $E$ is the elevation angle of observation above the horizon (complementary to the incidence angle).

These techniques have been tested in a set of experimental campaigns, and their results published in specialized journals, as cited below. Four of them present altimetric performance from aircrafts at 1–3 km altitude using the C/A clean-replica approach. All of them, conducted with different equipment and relatively low antenna gains, agree that the uncertainty of one-second integrated altimetric solutions from single-GNSS satellite signals is of the order of 1.5 m at near-nadir observation geometries [40.32, 34–36]. Another airborne experiment, for which P(Y) GPS codes were accessible, showed that this level of precision was slightly improved when using precise codes ($\approx$ 1.4 m in one-second integration [40.31]). As can be deduced from Fig. 40.5, the range precision of the interferometric group-delay measurements should be better than the C/A clean-replica ones.

There are only two experimental campaigns in which the interferometric approach was tested, one from a bridge at 18 m altitude and over estuary waters [40.30], an another from an aircraft flying at 3 km altitude over open sea waters [40.12, 36]. Over open waters the interferometric performance was at the the 0.6 m level in one-second integration, but much better (~7 cm) over estuary waters. The factor of two between achieved altimetric precisions with the C/A clean-replica and the interferometric approaches was also predicted from a realistic stochastic model in [40.12], a study that indicates that this upper-bound factor might also occur from spaceborne receivers. A factor of three between both techniques was obtained from analytical models as shown in [40.37].

### 40.3.2 Sea Surface Scatterometry

As illustrated in Fig. 40.9, the roughness of the reflecting surface has a distorting effect in the received waveform. The analysis of this distortion thus permits the inference of the roughness properties of the surface. When the scattering surface is the ocean, the estimation of its roughness is linked to phenomena like surface winds and swell, of geophysical and civil interest. This is the aim of the sea surface scatterometric applications.

A model of the reflected waveform has been given in (40.25) to (40.28). The latter includes the bistatic scattering coefficient $\sigma^0$, the only factor affected by the roughness. A widely accepted expression for $\sigma^0$ at each location P on the sea surface is [40.16]

$$\sigma^0(\mathrm{P}) = \frac{\pi|R|^2 q^4}{q_z^4}\mathrm{PDF}\left(-\frac{\boldsymbol{q}_\perp}{q_z}\right) \ , \tag{40.45}$$

where $|R|$ is the Fresnel coefficient, which in turn depends on the permittivity of the water. The vector $\boldsymbol{q}$ is the scattering vector defined as

$$\boldsymbol{q} = k\left(\hat{\boldsymbol{u}}_{\mathrm{scatt}} - \hat{\boldsymbol{u}}_{\mathrm{inc}}\right) \ ,$$

where $k$ is the electromagnetic wave number and $\hat{\boldsymbol{u}}$ denotes unit vectors along the scattered and incident directions. Furthermore, $q_z$ and $\boldsymbol{q}_\perp = (q_x\ q_y)^{\mathrm{T}}$ are the vertical and horizontal components of the scattering vector. Note that those depend on the surface location P. The PDF is the probability density function of the two-dimensional (2-D) slopes $\boldsymbol{s} = (s_x\ s_y)^{\mathrm{T}}$ of the surface $\Sigma$. The particular slope given by $\boldsymbol{s} = -\boldsymbol{q}_\perp / q_z$ corresponds to the slope required at the point P of scattering vector $\boldsymbol{q}$ to forward the signal to the receiver location (Fig. 40.11). The slopes' PDF is thus a statistical description of the surface roughness state.

The sea surface slopes' PDF is generally assumed as a Gaussian distribution, parametrized by the variance of the slopes or mean squared slopes (MSS). This first approach might be too restrictive, since it assumes isotropic surfaces. The next level of complexity, introduced to account for anisotropy in the roughness model, is given by a bivariate normal PDF of the slopes, parametrized by the variances of the slopes in orthogonal directions

$$\mathrm{PDF}(\boldsymbol{s}) = \frac{1}{2\pi\sqrt{\mathrm{Det}(\mathbf{M})}} \mathrm{e}^{-\frac{1}{2}\boldsymbol{s}^{\mathrm{T}}\mathbf{M}^{-1}\boldsymbol{s}} \tag{40.46}$$

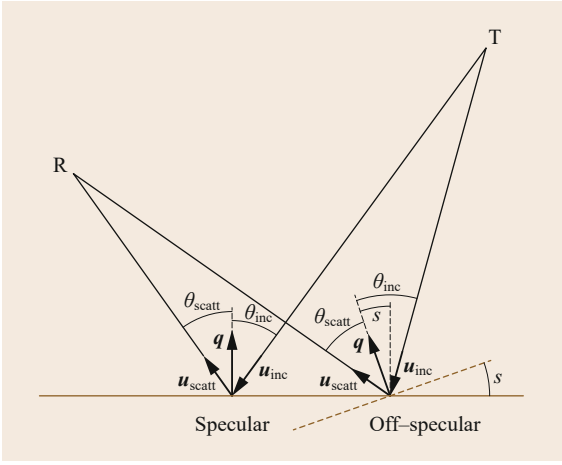

**Fig. 40.11** In the optical geometry limit, the reflection Fresnel law must apply locally, that is, $\theta_{\mathrm{inc}} = \theta_{\mathrm{scatt}}$. When reflection occurs off the specular point, the surface must be tilted to accomplish it. The tilt, of slope $s$, is given by the ratio between the horizontal and the vertical components of the scattering vector $\boldsymbol{q} = k(\hat{\boldsymbol{u}}_{\mathrm{scatt}} - \hat{\boldsymbol{u}}_{\mathrm{inc}})$. When the surface is locally oriented in this way, the signal reflected off that point can reach the receiver. The probability that the surface has such local tilt depends on its roughness state, through the PDF($\boldsymbol{s}$): the rougher the surface is, the higher is the probability of appropriate local tilts and hence the wider the glistening zone will be

with $\mathbf{M}$ denoting the slopes' covariance matrix

$$\begin{aligned}\mathbf{M} &= \begin{pmatrix} \kappa_{20} & \kappa_{11} \\ \kappa_{11} & \kappa_{02} \end{pmatrix} \\ &= \mathbf{R}(\phi_{\mathrm{w}}) \begin{pmatrix} \kappa_{\mathrm{w}} & 0 \\ 0 & \kappa_{\mathrm{c}} \end{pmatrix} \mathbf{R}(\phi_{\mathrm{w}})^{-1} .\end{aligned} \tag{40.47}$$

Here, $\kappa_{\mathrm{w}}$ and $\kappa_{\mathrm{c}}$ are variances along the wind direction and crosswind direction respectively, and $\mathbf{R}(\phi_{\mathrm{w}})$ is the rotation matrix by the angle $\phi_{\mathrm{w}}$ defined between the upwind direction and the $x$-axis. The isotropic MSS links to these variances through $\mathrm{MSS} = \kappa_{\mathrm{w}} + \kappa_{\mathrm{c}}$. More realistic slope distributions can be achieved by setting the PDF as a Gram–Charlier distribution [40.38] at the cost of a much larger number of parameters, which results in a much more complex inversion strategy.

The variances of the sea surface slopes can be obtained from the ocean wave spectrum $\Psi(\boldsymbol{k})$, given in the domain of the wave numbers $\boldsymbol{k}$, as

$$\begin{aligned}\mathrm{MSS} &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \left(k_x^2 + k_y^2\right) \Psi(\boldsymbol{k}) \mathrm{d}k_x\, \mathrm{d}k_y \\ &= \mathrm{MSS}_x + \mathrm{MSS}_y .\end{aligned} \tag{40.48}$$

Some examples of accepted sea-surface wave spectra are Pierson–Moskowitz [40.39], JONSWAP [40.40], and the most widely used in GNSS-R is given by [40.41]. These are all wind-wave spectra, to which low frequency components can be added to account for swell. These are also used to link wind speed information with slopes' variances, and thus permit direct inversion of the wind parameters.

### Extraction of the Roughness Parameters

The glistening zone is in general much larger than the Fresnel zone of coherent scattering. Glistening zones of a few hundred km extension for receivers in low Earth orbit (LEO) have been reported from theoretical studies (e.g., [40.42]) and checked from data of the UK-DMC mission [40.23]. As described in Sect. 40.2 the power gathered by the waveform comes from a certain area within the glistening zone, constrained by the ambiguity function $|\chi|^2$, which in turn depends on the delay of the correlation $\tau$ and the coherent integration time $T_{\mathrm{c}}$. The latter imposes a filter in the frequency domain, of $1/T_{\mathrm{c}}$ half-width, which splits the glistening zone into a set of frequency belts, the energy reflected from which will only be captured when the correlation is performed after shifting the central frequency to a frequency within each belt. This was illustrated in Fig. 40.4. Therefore, the waveform (also called delay map, DM) obtained at the frequency of the nominal specular point does not

capture the totality of the scattered energy, but only the signals reflected off the specular frequency belt. By varying the frequency at which the correlation is performed, it is then possible to obtain the delay maps over other belts. This corresponds to varying $\delta\nu$ in (40.25). The composition of all these delay maps, taken at different frequencies, is called a delay-Doppler map (DDM), and it is sketched in Fig. 40.12.

The first set of algorithms that were used to extract roughness information from the DM and/or DDM observables were based on fitting a model such as (40.25) to the data. Given the geometry of the observation and instrumental information such as antenna gains, the only unknown parameters are those related to the PDF of the surface slopes (variances or MSS, or their expressions as a function of the wind speed). Several experiments were conducted to perform sea surface scatterometric GNSS-R, in which the roughness was obtained by fitting a model to the data. In most of these cases the PDF of the slopes was assumed as either Gaussian or bivariate normal distributions. The retrieval using bivariate normal distributions aimed at obtaining anisotropic roughness information, such as wind speed and direction, or $\kappa_w$ and $\kappa_c$. To avoid singularities in the anisotropic retrievals it was necessary to use either the full DDM information and/or to combine DM information from multiple satellites.

Other algorithms to extract roughness information from the reflected waveforms are compiled in Table 40.5, together with their achievements and bibliographic references.

### 40.3.3 Sea Surface Permittivity

GNSS signals transmit L-band signals, a portion of the microwave spectrum sensitive to variations in the temperature and salinity of the surface water (through variations in its permittivity). In fact, two spaceborne radiometric missions have chosen L-band measurements to sense sea surface salinity (SMOS [40.54] and Aquarius [40.55]). Little work has been done with GNSS reflections to infer permittivity parameters of the ocean. The studies found in the literature are based on polarimetric observations, comparing either the power of co- and cross-polar components after the reflections (polarimetric ratio [40.21]), or the phase of these components (polarimetric phase interferometry, POPI [40.56]). Both observables present small sensitivity, for instance $\sim 4\%$ variations in the polarimetric ratio (as deduced from the Fresnel coefficients) when changing the surface salinity from 25–40 pps. The effects of roughness need to be addressed, as well as a proper model of the phase wind-up in reflected signals for the POPI technique [40.57].

### 40.3.4 Cryosphere: Ice and Snow

#### Snow Depth Around Ground-Based GNSS Stations

Geodetic institutions keep networks of permanent ground-based GNSS stations for precise monitoring of the Earth's crust. Some of these stations are in regions covered by seasonal snow. The reflection of the GNSS signals off the snow interferes with the line-of-sight sig-

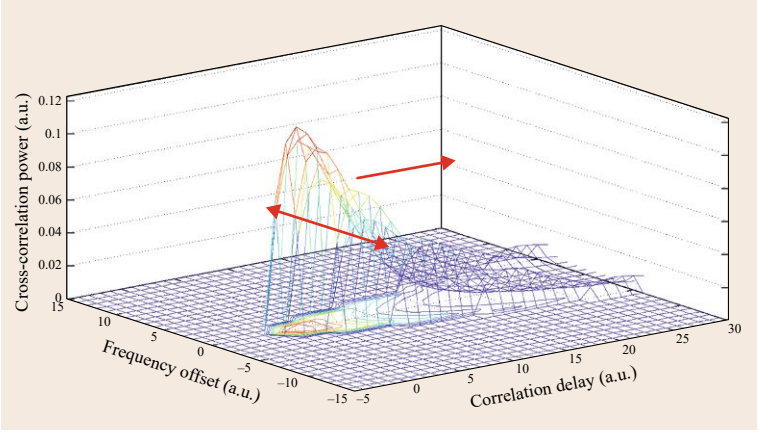

**Fig. 40.12** Sketch of a delay-Doppler map for GNSS signals after a diffuse scattering process such as reflection off ocean waters; the cross-correlation function (its power given in (40.25)) evaluated at different delay $\tau$ and frequency $\delta\nu$ values. All units are arbitrary in this illustration. As the roughness increases, the peak power decreases, and the energy spreads both along the delay and the frequency axis. This distortion is used to infer roughness information, for example through the slope of the trailing edge, or fitting theoretical models, or quantifying its volume and area (see Table 40.5 for other observables and inversion algorithms)

**Table 40.5** Summary of some GNSS-R experiments and their techniques for sea surface scatterometric applications

| Description | Achievements | Refs. |
|---|---|---|
| **Model fitting** | | |
| Fitting data from a single GNSS satellite to a waveform model that was generated with a slope's PDF parametrized directly with the wind speed parameter or the slope variances | 2 m/s agreement in wind speed retrieval up to 9 m/s wind speeds | [40.43, 44] |
| Same procedure but estimating wind direction ($\pm 180°$ ambiguity) by joint inversion of multiple simultaneous GNSS signals | 2 m/s wind speed and 30° wind direction agreement with a wind scatterometer, up to 10 m/s wind speeds | [40.45, 46] |
| Heuristic correction term in the relationship between MSS and wind $u$ (in m/s) to extend its validity to high wind speeds (hurricanes)<br>$\mathrm{MSS_w}(u) = 0.45(0.00316 f(u))$<br>$\mathrm{MSS_c}(u) = 0.45(0.003 + 0.00192 f(u))$<br>with<br>$f(u) = \begin{cases} u & (0 < u \le 3.49) \\ 6\ln(u) - 4 & (3.49 < u \le 46) \\ 0.411u & (46 < u)\,. \end{cases}$ | Wind speeds of up to over 40 m/s in hurricane conditions measured without saturation, $\approx 5$ m/s root mean square (RMS) accuracy compared to radiosonde measurements at high wind speeds. | [40.47, 48] |
| Fitting a model to the entire DDM | To extract anisotropic MSS from each single GNSS satellite | [40.49] |
| Fitting a model to the trailing edge of the DM solely | Wind speed with precisions better than 2 m/s, with winds up to 10 m/s | [40.16, 50] |
| **Integrated spectra** | | |
| Integration of the DDM along either the frequency axis to obtain the integrated delay function<br>$\mathrm{IDM}(\tau) = \int_{\text{Dopplers}} \mathrm{DDM}(\tau, f)\mathrm{d}f$<br>or along the delay axis to obtain the integrated Doppler spectrum<br>$\mathrm{IDS}(f) = \int_{\text{Delays}} \mathrm{DDM}(\tau, f)\mathrm{d}\tau\,.$<br>The width or spread of these functions relates to roughness parameters: the frequency width<br>$B_{3\mathrm{dB}} = 4\sqrt{2\ln 2}\sin E/\lambda \sqrt{\boldsymbol{v}_\mathrm{s}^\mathrm{T}\mathbf{M}\boldsymbol{v}_\mathrm{s} + \epsilon}$<br>being $\mathbf{M}$ the covariance matrix of the surface slopes, and $\boldsymbol{v}_\mathrm{s}$ the velocity of the specular point with respect to the receiver; and<br>$\mathrm{Var}(\tau) \propto \left(\kappa_{20}^2 + 2\kappa_{11}^2 \sin^{-2} E + \kappa_{02}^2 \sin^{-4} E\right)\,,$<br>being $\kappa$ elements of $\mathbf{M}$ | Theoretical study supported by experimental airborne data and later applied to UK-DMC LEO data | [40.23, 51] |

nals to generate interference patterns in the received data. These features were first used to extract the snow depth around these ground stations [40.58]. The observable analyzed to infer the snow depth is the frequency of the multipath-induced oscillations in the SNR, as pictured in Fig. 40.13. The technique has been applied to the USA UNAVCO's Plate Boundary Observatory (PBO) network, and resulting products made available to the public at [40.59] and documented in [40.60]. The technique has been improved in [40.61, 62]. Over-

**Table 40.5** (continued)

| Description | Achievements | Refs. |
|---|---|---|
| **Scatterometric delay** | | |
| The peak of the DM is delayed with respect to the specular ray path, and this effect depends on the MSS. | Near-real-time MSS from airborne campaigns at 0.001 MSS precision level | [40.52] |
| **DDM area and volume** | | |
| Direct link between the area or volume of the DDM (above a certain threshold) and the roughness state of the surface. | Experimental work done in the frame of SMOS L-band roughness corrections. | [40.19] |
| **Discrete PDF** | | |
| Rewriting the radar equation of the DDM to express it as a series of terms evaluated in cells of similar required slope $s_{ij}$ (slope needed for forwarding the signal towards the direction of the receiver). This series is linear with respect to the PDF of the slopes, which can thus be linearly inverted in the set of discrete values $s_{ij}$ $$W(\tau,f) = \sum_{s_{ij}} A_{s_{ij}}(\tau,f)\mathrm{PDF}(s_{ij}) \,.$$ | Data from airborne experiments have been inverted to discrete slopes' PDF. The results present robustness to selection of the discrete sampling; consistency with MSS values obtained from retrievals based on Gaussian and bivariate normal distributions; agreement with independent wind measurements at 2 m/s level; it sensed non-Gaussian features such as the sense of the wind, consistent with independent measurements | [40.53] |

all, the methodology performs within the limitations of both GPS and in situ measurement errors, resulting in a correlation of 0.98 and RMS error of 6–8 cm for observed snow depths of up to 2.5 m, with the GPS underestimating in situ snow depth by 10–15%. A similar project is being implemented in French geodetic networks [40.63].

A similar approach, but measured with a linear V-polarized antenna, was suggested in [40.64]. In that case, the information is obtained from the notches of the interference pattern (location and amplitude). Both techniques have also been used to extract other geophysical information such as soil moisture and vegetation cover (see Sect. 40.3.5).

### Sea Ice

Early experimental studies on the potential use of GNSS reflectometry for sea ice monitoring, conducted aboard an aircraft over Arctic sea ice [40.65], have shown that the peak power changed significantly along the track, with positive correlation with the backscattering measurements of the RADARSAT installed in the same aircraft. This positive correlation between forward and backward scattering was an indication of variations in the dielectric properties of the ice rather than roughness (roughness effects produce negative correlation between forward and backward scattering powers).

Sea ice roughness was tackled in [40.66], which evolved a mixed technique to separate roughness parameters from permittivity estimates of the sea ice: after renormalization of the reflected waveform, its peak

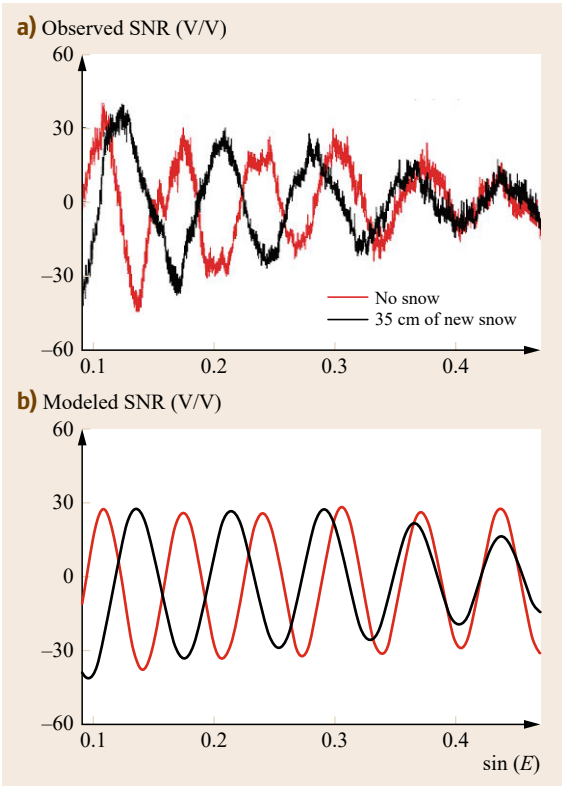

**Fig. 40.13** **(a)** Patterns captured in GNSS SNR observables in a geodetic station due to the interference between the line-of-sight signal and the signal reflected off the surrounding snow. **(b)** Modeled interference patterns. Both graphs show the variation of the signal-to-noise ratio (SNR) with the sine of the elevation angle $E$ (after [40.58], courtesy of Wiley) ►

power is mapped to an absolute ice skin permittivity via the cross-polar Fresnel coefficients, being the skin permittivity the effective permittivity of the ice at its upper layer, as thick as the penetration depth of the L-band signals. On the other hand, the inversion of the roughness parameter, in the form of MSS, was based on fitting a model to the shape of the renormalized waveform.

Polarimetric observations have also been proven to relate to the sea ice permittivity state. Figure 40.14 shows the polarimetric ratio defined as the copolar power divided by the cross-polar one, from an experiment on top of a cliff ≈ 700 m high, overlooking Disko Bay in Greenland. The geometry of the experiment forced the elevation angles to be around the Brewster angle, which in circular polarization separates reflectivity of the higher circular cross-polar component (above the Brewster elevation) from reflectivity of the higher circular copolar component (below the Brewster elevation).

Finally, another aspect of some types of sea ice is its relative smoothness compared to open waters. When this happens, the reflection has a strong coherent component, which enables the connection of the phase. Then, phase-delay measurements are possible as shown in [40.68, 69], even from space-based observations when in grazing geometries [40.70]. In nadir-like geometries from spaceborne platforms, phase-delay measurements have been proven to be more difficult, at least using the only two sea-ice reflection observations captured with the UK-DMC satellite [40.25].

In a similar way, glacial lake outburst floods have been monitored using GNSS-R techniques [40.71].

### Dry Snow

The first theoretical studies on the potential use of GNSS reflectometry to characterize the surface and interior of ice sheets was presented in [40.72]. The work derived a complex model to account for internal reflections and volumetric scattering, and conducted simulations to show that the reflected signals are sensitive to firn parameters such as snow accumulation rate.

The actual penetration of the GNSS signals into Antarctic dry snow was experimentally proven in [40.67, 73], with data obtained from a GNSS-R instrument installed at 45 m altitude, on the American Tower of Concordia Station. The study explained the unusual behavior of the GNSS-R data by means of a model that accounted for multiple coherent reflections occurring at several internal layers of the snow structure. These reflections were captured down to approximately 300 m depth. The observable used for this application is the lag hologram, inspired by the radio holograms developed in other fields such as in GNSS Radio occultations (Chap. 38).

Lag holograms present the spectral content of the received signal with respect to a reference signal (here

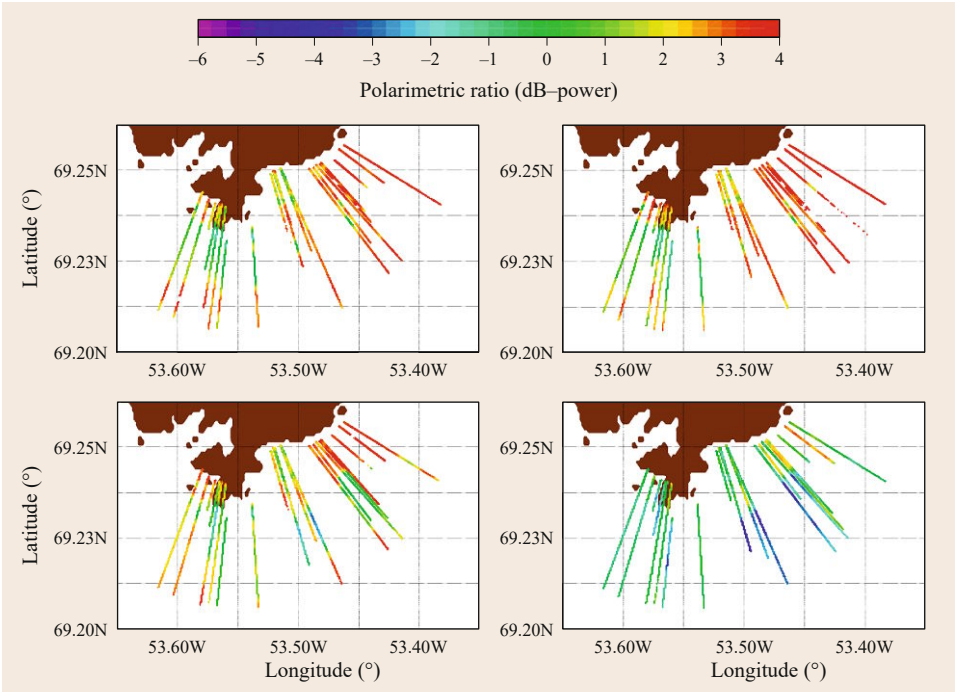

**Fig. 40.14** Polarimetric ratio of GNSS-R observations over Disko Bay, Greenland, taken from ≈ 700 m high cliff. It corresponds to four sequential days, day number 44 of year 2009 to day number 47. The temperature dropped during days 46 and 47 (*bottom*) (after [40.67])

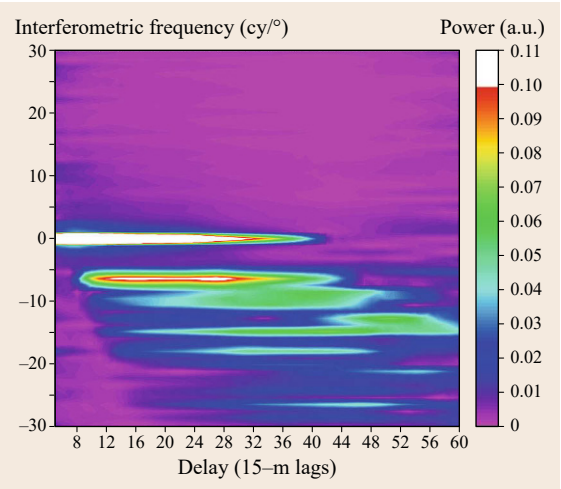

**Fig. 40.15** Example of a lag hologram extracted from a time series of 128 one-second complex waveforms in a GNSS-R dry snow experiment at Concordia Station (Antarctica). It corresponds to pseudo-random noise (PRN) 13, 16 December 2009, between 44.5° and 45.5° elevation. The $x$-axis is the correlation delay $\tau$, given in lags (15 meter interlag distance), and with respect to an arbitrary zero (being the delay of the direct signal at around lag number 20 and the delay of the surface reflection at around lag number 24). The frequency is given as interferometric cycles per degree elevation, which relates to the depth of the reflecting layer. The zero frequency corresponds to the reference field: the line-of-sight ray. The geometry of the observation results in frequencies more negatives than −5.8 cy/ deg corresponding to scattering off reflecting elements below the snow-air interface. Note different spectral content for different delay lags along the waveform (after [40.73], courtesy of Elsevier Ltd.)

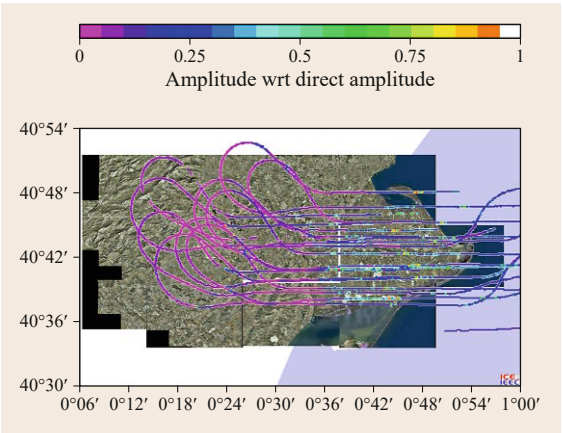

**Fig. 40.16** Flight over Ebro River delta with the GOLD-RTR GNSS-R dedicated receiver [40.52]: the amplitude of the reflected signals, normalized by the amplitude of the direct line-of-sight signals, is plotted over an approximate mosaic of aerial photographs. The delta of the river, covered by wetlands and rice crops, contrasts with the dry surrounding mountains, as captured by the GNSS-R signals

the direct line-of-sight one), for each of the waveform's correlation delays (lags). If the spectral information were obtained from the peak of the waveform solely (as it is done in radio occultation radio holograms), it would be limited by signals arriving up to one C/A-code chip delayed (~300 m). Because internal reflections can occur down to 300 m, their delay with respect to the peak can be as long as twice this range, and thus filtered out by the code modulation. Inspecting the spectral content of the entire waveform permits the extraction of information on deeper layers (see, e.g., the example of an Antarctic lag hologram in Fig. 40.15).

### 40.3.5 Land: Soil Moisture and Vegetation

For several reasons, the L-band, between frequencies of 1 and 2 GHz, is one of the spectral bands that work better for soil moisture monitoring. At these frequencies the atmosphere is effectively transparent and vegetation is semitransparent, the microwave measurement is strongly dependent on soil moisture, and the measurements are independent of solar illumination. The GNSS signals are sensitive to the moisture content in the upper layers (1–6 cm depth; see [40.74]).

The first algorithms to extract soil moisture information from GNSS reflectometry data were based on the peak power or amplitude of the reflected waveform, often renormalized as a way to calibrate geometric and instrumental issues. Examples of these early approaches can be found in for example [40.76, 77], and in the data shown in Fig. 40.16.

Despite vegetation being semitransparent to L-band signals, it does affect the reflection process, together with the surface roughness. Untangling the different components of the process requires complex modeling, which involves both the coherent and incoherent surface scattering, together with volumetric scattering through the vegetation structures. To help in inferring these components, either polarimetric (e.g., [40.78]) or interferometric (e.g., [40.75, 79, 80]) approaches have been followed. Figure 40.17 shows the theoretical sensitivity of the interferometric pattern to soil and vegetation parameters, as captured with a vertical-polarization antenna. This technique uses the location and amplitude of the interference notches, as it is also used for retrieval of snow depth (Sect. 40.3.4).

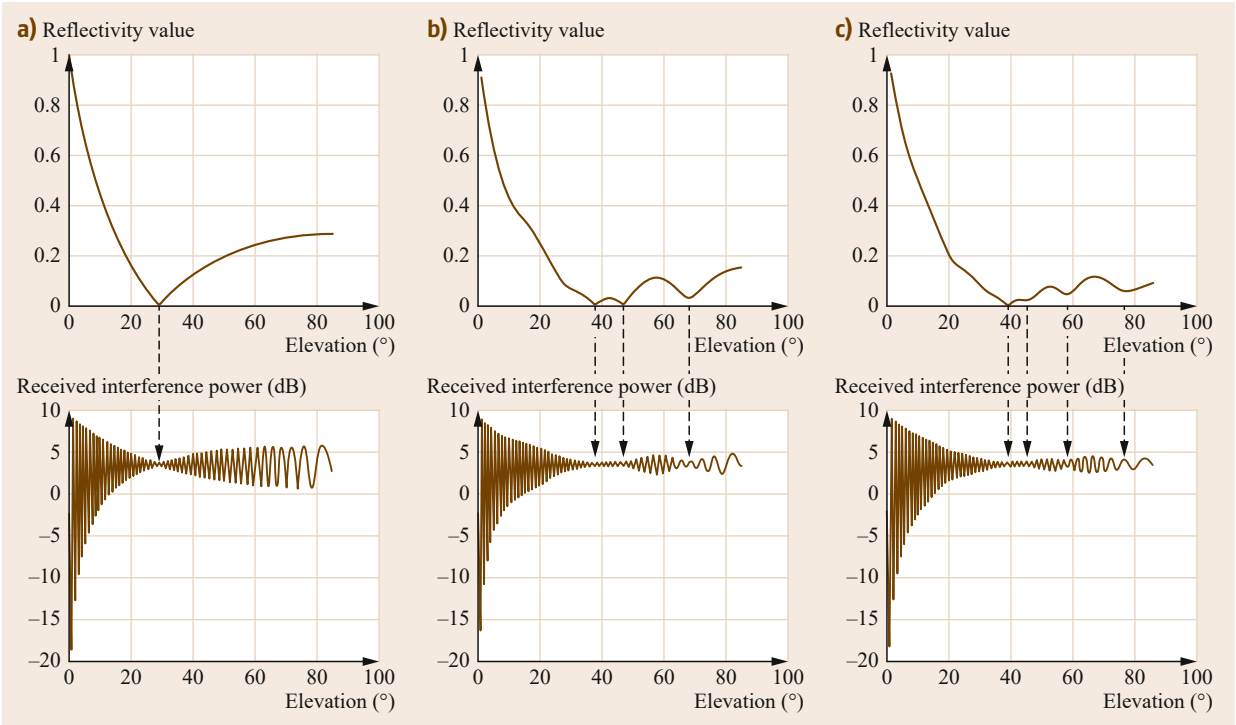

**Fig. 40.17a–c** Simulated interference power received versus reflectivity for three cases of vegetation-covered soils. **(a)** Bare soil produces one notch, **(b)** 60 cm vegetation layer + soil layer produces three notches, and **(c)** 90 cm vegetation layer + soil layer produces four notches (after [40.75], courtesy of IEEE)

## 40.4 Spaceborne Missions

Several GNSS-R experiments have been conducted from spaceborne platforms:

*Space Shuttle/SIR-C* The first GNSS reflection captured from the outer Space was collected with the SIR-C instrument aboard the Shuttle. The study, presented in [40.22], was conducted in postprocessing, searching for GPS signals in archived datasets obtained with the Space Shuttle imaging radar system. This achievement proved the possibility of receiving GNSS signals reflected off the sea surface from space.

*CHAMP* was a German geoscience satellite operating from 2000 to 2010, which included a payload for GNSS radio occultation (RO) observations (see Chap. 38 for details about this technique). *Beyerle* et al. [40.81] first showed that CHAMP RO data contained embedded GNSS signals reflected off the Earth's surface. *Cardellach* et al. [40.70] used GNSS reflected signals collected from the RO payload of CHAMP to perform phase-delay altimetry in polar regions.

*UK Disaster Monitoring Constellation (UK-DMC)* was a British satellite built by Surrey Satellite Technology Ltd. (SSTL) that included a dedicated GNSS-R payload for experimental purposes. The mission was active between 2003 and 2011. A limited set of GNSS-R data streams were acquired from $\approx 700$ km altitude with a moderate antenna gain (11.8 dBi) and postprocessed on the ground. The results, published in [40.23] to [40.25], proved the sensitivity of spaceborne GNSS-R to sea surface roughness and sea ice, and the possibility of receiving land reflections from space. Sets of GNSS-R data obtained with the UK-DMC Low Earth Orbiter are also available at [40.26].

*UK TechDemoSat-1 (UK-TDS1)* is a microsatellite (of about 50 kg payload) built by Surrey Satellite Technology Ltd. (SSTL). Among other payloads, it carries a new SSTL GNSS-R receiver (a clean-replica approach) for ocean roughness applications among other payloads. UK-TDS1 was successfully launched in July 2014, and since then it has been acquiring GNSS-R in duty cycles of two days out

of eight. Initial results from UK-TDS1 data can be found in [40.82].

After years of research, feasibility studies and technology development, the GNSS-R techniques are entering a maturity phase. Besides UK-TDS1, currently orbiting, two other spaceborne GNSS-R missions were launched in 2016. The missions use nano- to microsatellites, and the GNSS-R receiver technique will be of the clean-replica type. They are mostly focused on scatterometric applications:

[3]*CAT-2* is a six-unit CubeSat (<10 kg) built by the Politechnical University of Catalonia (UPC) that will carry UPC's PICARO receiver. The receiver uses a clean-replica approach, but will also attempt P-code retrievals [40.83]. It was launched in August 2016.

*CYGNSS* is a constellation of eight satellites, with three-unit CubeSat each, funded by the National Aeronautics and Space Administration (NASA) Venture program and led by the University of Michigan [40.84]. They will carry the new SSTL GNSS-R receiver tested in UK-TDS. The constellation will be allocated in low inclination orbits to monitor tropical storms. The mission was launched in December 2016.

In addition to the launch of these missions, another mission of the European Space Agency (ESA) is going through the initial stages of development (feasibility phase-A studies, technology breadboarding and prototyping, etc.). Its final launch and operations are not guaranteed at this stage of development. The main difference with respect to the other GNSS-R missions is the scientific objective, mostly focused on altimetric applications:

*GEROS-ISS* (GNSS rEflectometry Radio Occultation and Scatterometry on board the International Space Station) is an ESA experiment aboard the International Space Station (ISS), in low inclination orbit, the main objective of which is to perform mesoscale altimetry with GNSS-R without some of the physical constraints of the small satellite platforms [40.85]. The mission requirements and system requirements documents have been issued and two phase-A feasibility studies are being executed.

All of these missions will help to further advance the state-of-the art in spaceborne reflectometry and scatterometry, an emerging GNSS application that promises substantial scientific and social benefits.

*Acknowledgments.* The authors would like to acknowledge the support of the Spanish grant AGORA: Advanced GNSS and other signals of Opportunity Reflectometry for Accurate Climate Monitoring (ESP2015-70014-C2-R). The authors participate in the EUMETSAT ROM SAF.

# 41. GNSS Time and Frequency Transfer

Pascale Defraigne

Time and navigation are intimately linked and rely on each other. Global navigation satellite system (GNSS) positioning is based on the measurement of time intervals needed by the signal to travel from satellites to the receiving station on the Earth or nearby. The precision of GNSS positioning is reached thanks to atomic frequency standards onboard the satellites and the possibility to determine their synchronization differences at the subnanosecond level. Time is thereby the core of GNSS. Inversely GNSS is widely used for accurate time and frequency dissemination, as well as for the comparison of distant clocks as needed for time and frequency metrology. All these aspects of using GNSS for time/frequency applications will be presented in this chapter.

## 41.1 GNSS Time and Frequency Dissemination

As already mentioned in Chap. 19, the basis of the global navigation satellite system (GNSS) measurements is the time interval between the emission (satellite) and reception (receiver) of the pseudorandom noise (PRN) codes. The emission time $t_e(\text{sat})$ is read in the satellite clock, while the reception time $t_r(\text{rec})$ is read in the receiver clock. The pseudorange measurement can be denoted as

$$P = c(t_r(\text{rec}) - t_e(\text{sat})) \,, \tag{41.1}$$

where $c$ is the velocity of light. The satellite clock and the receiver clock being not synchronized, the synchronization error $(t_{\text{rec}} - t_{\text{sat}})$ between those clocks must be taken into account to get the true time interval $(t_r - t_e)$ between the emission and reception, as if it was measured with a same clock

$$(t_r(\text{rec}) - t_e(\text{sat})) = (t_r - t_e) + (t_{\text{rec}} - t_{\text{sat}}) + \text{errors} \,. \tag{41.2}$$

The true travel time $(t_r - t_e)$ multiplied by the velocity of light corresponds to the true distance between the satellite and the receiver. The pseudorange (41.1) can then be expressed as the sum of a distance, a clock synchronization error, and additional errors mainly due to atmospheric delays, multipath and noise, and hardware delays

$$P = \|\boldsymbol{x}_s - \boldsymbol{x}_r\| + c(t_{\text{rec}} - t_{\text{sat}}) + \text{errors} \,. \tag{41.3}$$

This equation contains four unknowns, three for the position and one additional which is the synchronization error $(t_{\text{rec}} - t_{\text{sat}})$ between the satellite and the receiver clocks. The fundamental of GNSS is to combine observations from several satellites to solve for these four unknowns. However, as the clocks carried by different satellites are not perfectly synchronized, the quantity $(t_{\text{rec}} - t_{\text{sat}})$ is different for all satellites and the total number of unknowns would be $3 + k$, where $k$ is the number of satellites observed at a given epoch. The system

could therefore not be solved. For this reason, the GNSS maintains a reference time scale and provides in the navigation message the quantity $(t_{sat} - t_{ref})$ which is the synchronization error of the satellite clocks with respect to this reference. Equation (41.3) hence can be decomposed as follows

$$P = \|\boldsymbol{x}_s - \boldsymbol{x}_r\| + c(\Delta t_{rec} - \Delta t_{sat}) + \text{errors} , \qquad (41.4)$$

where $\Delta t_{sat} = (t_{sat} - t_{ref})$ is known from the navigation message and $\Delta t_{rec} = (t_{rec} - t_{ref})$ is the synchronization error between the receiver clock and the reference time scale of the GNSS. With this formulation (41.4), $\Delta t_{rec}$ is the same unknown for all satellites observed at a given epoch, so that the number of unknowns is always four at any time, and the user can determine them continuously provided that a minimum of four satellites are simultaneously visible.

The reference time scale *ref* depends on the satellite clock products used. It is the reference time scale of the constellation when using the broadcast navigation messages, but various time scales are used as references in postprocessed products like those provided by the International GNSS Service (IGS) community (Chaps. 33 and 34).

For all timing applications, the most important information here is $\Delta t_{rec} = (t_{rec} - t_{ref})$, the synchronization error between the receiver and the reference. Getting this quantity for two receivers at a same epoch, whatever the distance between them, provides the difference between the two receiver clocks $(t_{rec,1} - t_{rec,2})$ at that epoch (Sect. 41.2). The present section is dedicated to the time information disseminated by the GNSS, allowing any user to get an accurate time and/or frequency.

### 41.1.1 Getting UTC from GNSS

Among the various procedures existing for time dissemination, GNSS is certainly the most popular when a submillisecond precision is required. It is for example extensively used for precise time tagging [41.1], banking, synchronization of communication and telecommunication networks [41.2], or the phase synchronization energy transport and distribution networks [41.3]. Each base station of the network being synchronized continuously on the accurate time disseminated by the GNSS satellites, this assures the synchronization between all the base stations.

The basis of any official time in the world is the Universal Time Coordinated (Chap. 2); local time and legal time can be directly obtained by adding the time zone corrections to Coordinated Universal Time (UTC). Each of the GNSS provides in its navigation message a second degree polynomial modeling the evolution of the difference between its reference time scale and a prediction of UTC. Combining this quantity with the $\Delta t_{rec}$ estimated from the GNSS code measurements gives at each observation epoch the synchronization error between the receiver clock and the prediction of UTC

$$(t_{rec} - t_{ref}) + (t_{ref} - \text{UTC}) = (t_{rec} - \text{UTC}) . \qquad (41.5)$$

This synchronization error can then be applied to the receiver internal clock time to produce a 1 pulse per second (pps) signal synchronized continuously with this prediction of UTC.

It must be noted that the true UTC does not exist in real time. It is indeed computed monthly in postprocessing by the International Bureau of Weight and Measurements (BIPM, Chap. 2). As a consequence, any user requiring precise timing information in real time can only rely on a prediction of UTC. The best predictions of UTC are realized by the time laboratories whose clocks are contributing to the clock ensemble providing UTC. These laboratories maintain a local realization of UTC, named UTC(k) where k is the acronym of the laboratory. After each month, when UTC is computed, the BIPM reports about the differences between each prediction UTC(k) and the true UTC, and their statistical uncertainties; this information is available freely on the BIPM website. This assures the traceability of all the UTC(k) realizations. BIPM recommends that all the UTC(k) realizations be maintained at less than 100 ns of UTC, but a good proportion of laboratories reach the level of some nanoseconds, as illustrated in Fig. 41.1 which shows two examples of UTC realizations, namely UTC (PTB) and UTC (United States Naval Observatory (USNO)), where PTB is the German National Metrology Institute, and USNO is the US Naval Observatory.

Each of the GNSS constellations relies on its own reference time scale and disseminates its own prediction of UTC, which is UTC(USNO) for the Global Positioning System (GPS), UTC(SU) for the Russian Global Navigation Satellite System (GLONASS), an average of five European UTC(k)'s for Galileo and UTC(NTSC) for BeiDou, where NTSC is the National Time Service Center in China. Also Quasi-Zenith Satellite System (QZSS) is providing a link to the prediction UTC(NICT) realized by the National Institute of Information and Communications Technology in Japan. As the link to UTC should be available in real time for the users, it is broadcast as a prediction to be used till the next update. Except for GLONASS, these predictions of UTC are broadcast worldwide with an uncertainty of only a few nanoseconds. This is not the

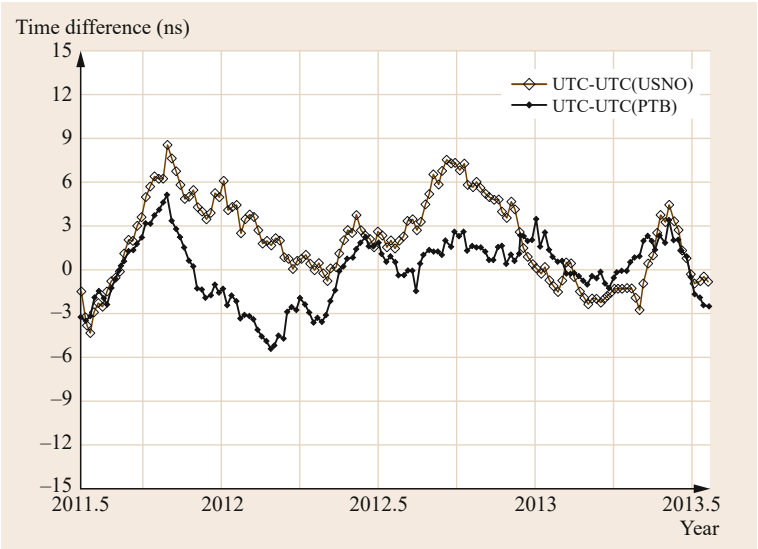

**Fig. 41.1** Differences between UTC and the realizations UTC (USNO) and UTC (PTB) over 2 years

case for GLONASS, limited by an uncertainty of hundreds of nanoseconds, but it is likely to be improved in the near future through appropriate calibrations. Since January 2011, the BIPM publishes in Sect. 41.5 of its circular T values of [UTC–UTC(USNO)_GPS] and [UTC–UTC(SU)_GLONASS], that is, the differences between the true UTC and the predictions broadcast by GPS and GLONASS, respectively; during the 2 year period corresponding to Fig. 41.1, the differences [UTC–UTC(USNO)_GPS] remained within $[-12, 12]$ ns, while the differences [UTC–UTC(SU)_GLONASS] varied within $[-440, -240]$ ns.

At the user level, an accuracy of some nanoseconds on the prediction of UTC can thus presently be obtained only with GPS; Galileo and BeiDou will offer the same capability in the near future. However, the nanosecond accuracy can only be reached if the signal delays in the antenna, cable, and receiver are known; these delays reach the level of hundreds of nanoseconds, so that without any calibration of the receiving chain, GNSS can provide an access to UTC with a submicrosecond accuracy. Calibration aspects will be detailed in Sect. 41.3.2.

The accuracy statement here above should be understood within the way the uncertainties are defined for time dissemination and time transfer. As recommended in the guide to the expression of uncertainty in measurement produced by the working group 1 of the Joint Committee for Guides in Metrology [41.4], a distinction is made between the type A and type B uncertainties. The precision is given by the type A uncertainty $u_A$, which corresponds to the statistical uncertainty, evaluated by taking into account the level of phase noise in the raw data and the magnitude of effects varying over a typical duration below one month [41.5]; the type B uncertainty $u_B$ is the uncertainty of the calibration. The uncertainties $u_A$ and $u_B$ correspond to the variance and bias in a classical decomposition of the mean-square-error. The accuracy of time measurements is then given by the combined uncertainty

$$u = \sqrt{u_A^2 + u_B^2}.$$

### 41.1.2 GNSS Disciplined Oscillators

For all applications requiring precise and stable frequencies, the expensive purchase of an atomic clock can be substituted by the use of a GNSS-disciplined oscillator (GNSSDO in what follows), for which the cost is much less than cesium standards.

As explained in the previous section, GNSS signals allow one to determine continuously the synchronization error between the local receiver clock and the prediction of UTC, with an accuracy of 1 μs or better, and a precision of a tens of nanoseconds. The GNSS receiver can therefore output a 1 pps signal synchronized continuously with one of the best available realizations of UTC. Considering a precision of 10 ns on the timing, it is theoretically possible to reach a frequency stability of $1 \cdot 10^{-13}$ at an averaging time of one day.

The principle of GNSSDOs (Fig. 41.2) is to generate time and frequency signals using a voltage-controlled oscillator (VCO), which can be a high-quality quartz or a rubidium oscillator, and whose frequency is controlled by timing information broadcast by the GNSS satellites and reproduced by the

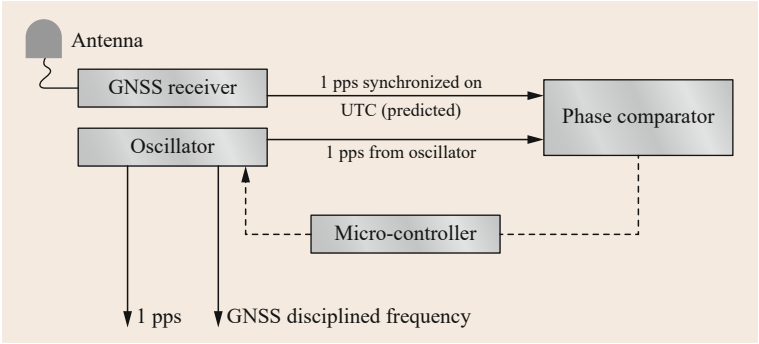

**Fig. 41.2** Schematic representation of the GNSS-disciplined oscillator

GNSS receiver in its 1 pps output. The local oscillator is controlled with a servo loop, in a similar way as a phase-locked loop (PLL, see Chap. 13). In its basic form, the PLL compares the phase of the reference signal given by the GNSS receiver to the phase of the oscillator. The phase detector then outputs the phase difference between the two input signals, and a microcontroller sends the correction to be applied to the oscillator to be aligned with the GNSS received signal. In some cases, the software used by the microcontroller compensates for not only the phase and frequency changes of the local oscillator, but also for the effects of aging, temperature, and other environmental parameters [41.6]. These effects being modeled can still be corrected for in the case of temporary interruption of GNSS signals.

The software also provides the ability to vary its time constant. For example, if a more stable oscillator is used, the software can adapt the servo loop to use a longer time constant and make frequency corrections less often. Indeed, thanks to their permanent synchronization with UTC, GNSS receivers have excellent long-term stability at averaging times greater than several hours. However, their short-term stability is degraded by the noise in GNSS signals, due to multipath, atmospheric perturbations, and uncertainties in orbit and clocks broadcast in the navigation message, conferring a precision of about 30 ns on the 1 pps. On the other hand, a rubidium or a good quality quartz oscillator (like an oven-controlled oscillator) has better short term stability but is susceptible to long-term effects like aging. A GNSSDO aims at using the best of both sources, combining the short-term stability performance of the oscillator with the long-term stability of the GNSS signals to give a reference source with excellent overall stability characteristics. The time constant of the steering is therefore chosen as a function of the stability of the oscillator, compared to the stability of the GNSS-based frequency.

An illustration is provided in Fig. 41.3 which presents the Allan deviation (giving the frequency stability of the signal on different averaging times, as defined in Chap. 5) of two distinct oscillators in comparison with the Allan deviation of the GNSS-based timing signals (solid line). A time constant of about 1 h would be chosen for the illustrated oven-controlled crystal oscillator (OCXO) as for longer averaging times the GNSS-based frequency has a better stability. For the Rubidium oscillator, a time constant of about one day would be preferred to keep the frequency stability of the oscillator for shorter averaging times as it is there better than the stability of the GNSS-based frequency. For long averaging times, the GNSSDO is always based on the GNSS-based frequencies, whatever the oscillator used.

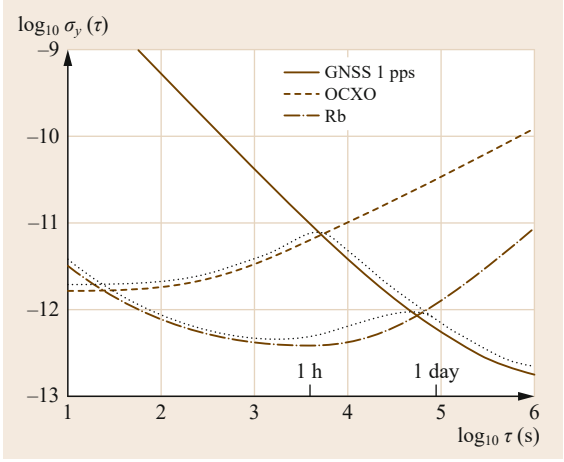

**Fig. 41.3** Frequency stability of the GNSSDO for two distinct types of oscillators. The *solid line* corresponds to the Allan deviation of the GNSS, *dashed lines* to the Allan deviation of the oscillators, and *dotted lines* correspond to the Allan deviation of the frequency delivered by the GNSSDO. The GNSS 1 pps frequency stability is based on a 1 pps precision of about 30 ns

The performances of GNSSDOs are highly variable among the available models, as influenced by the design characteristics, by the oscillator implemented, by

the number of frequencies measured by the receiver (dual-frequency receiver allowing for ionospheric delays correction), etc. However, any GNSSDO that is locked to the satellite signals should be able to provide, when averaging for periods of several days or longer, a frequency accuracy at the level of some parts in $10^{13}$. GNSSDO indeed rely on the GNSS predictions of UTC, and hence provide an accurate frequency (i. e., in agreement with the SI second realized by the UTC), and a long-term stability better than any free running oscillator, including the atomic standards.

GNSSDO are nowadays widely used as primary standards in calibration laboratories. They can theoretically assure the traceability of generated time and frequency to the SI second realized by UTC. Here, traceability of a measurement to the SI unit is defined as maintaining an unbroken chain of calibrations that trace back to the SI unit. GNSSDO serve as self-calibrating standards that should not require adjustment or calibration. The uncertainties on the time and frequencies generated by the GNSSDO can be determined using firstly the uncertainty of the GNSS measurements, and secondly the differences between the predicted UTC and the true UTC, as published in the BIPM Circular T. Additionally, all signal delays in internal circuits and antenna as well as their uncertainties should be determined if the GNSSDO is used as a time reference. However, as the rules for traceability vary from country to country, it is recommended to the users to refer to their national metrology institute.

## 41.2 Remote Clock Comparisons

People are familiar with the saying *if you have one clock you always know what time it is, but if you have more than one, you never know*! But in reality, if you have only one clock, you cannot know anything about its accuracy unless you compare it with a second clock whose you know the accuracy, and similarly for their frequency stability; furthermore if your clock suddenly stops to run, you loose completely any time information. This is the reason why it is always recommended to work with several clocks, to monitor continuously the differences between their readings and an accurate time available somewhere. Atomic clock comparisons are also essential for the needs of time and frequency metrology. First, for the generation of UTC, the only data that can be used for clocks are the differences between two clocks at successive epochs. The ensemble algorithm used to produce UTC, or any other time scale, treats therefore the differences between all the clocks of the ensemble. Second, in order to determine the frequency accuracy and the frequency stability of commercial or experimental clocks, these must be compared with other clocks whose frequency accuracy and/or stability is at least the same as the one of the clock examined. Finally, clock comparisons can be necessary for scientific applications requiring a measurement of a time interval of which the starting and closing points are measured with different clocks. This is, for example, the case for the measurement of the velocity of the neutrinos [41.7] where the clock measuring the departure time and the clock measuring the arrival time are separated by some hundreds of kilometers.

In a local environment, clocks can be compared using a phase or frequency comparator, or a time interval counter, while for remote clocks separated by some to thousands of kilometers other techniques must be envisaged. A prime requisite is that the methods of comparison at a distance do not contaminate the frequency stability of the clocks. For applications requiring only a moderate precision (some hundredths of a second), any clock can be compared to the precise time delivered by some precise time facility via the internet and the network time protocol, an internet-based hierarchical time transfer technique [41.8], or to the timing signals delivered by some radio-frequency emitting station connected to a UTC(k) realization. However, these precisions are often insufficient and the use of satellite systems is necessary; one of them is the GNSS.

### 41.2.1 The GNSS Time Transfer Technique

The technique, called GNSS time transfer, was used since the 1980s for the comparisons of remote frequency standards needed for the realization of UTC [41.9]. Additionally, as a consequence of its reduced cost, the technique is widely used by private companies offering time stamping, or time and frequency calibration. They then continuously monitor their local clock against the realization of UTC maintained by their national metrology institute.

GNSS time transfer is based on the following principle illustrated in Fig. 41.4. The first step is to determine the synchronization error between the local clock and the reference time scale of the GNSS. This is achieved by connecting each clock to a GNSS receiver, in such a way that the synchronization error between the internal receiver clock and the external clock can be continuously measured. From the GNSS signals, each receiver determines

$$\Delta t_{\mathrm{rec},i} = (t_{\mathrm{rec},i} - t_{\mathrm{ref}})$$

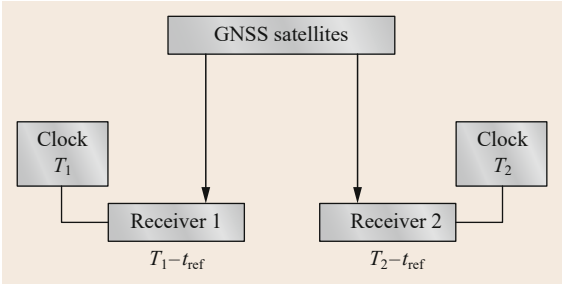

**Fig. 41.4** Schematic principle of GNSS time transfer, that is, remote clock comparison

as explained in Sect. 41.1, and from the external measurement between the receiver and the clock $T$ one gets in each laboratory

$$(T_i - t_{ref}) = (t_{rec,i} - t_{ref}) - (t_{rec,i} - T_i) \; . \tag{41.6}$$

The second step consists in computing the difference between the quantity $(T_i - t_{ref})$ obtained in two stations $(i = 1, 2)$ from simultaneous observations to get $(T_1 - T_2)$, that is, the synchronization error between the two remote clocks. Note that in the present case simultaneous means that the two observation epochs should not differ by more than one microsecond, which can be easily reached with any GNSS receiver.

In what follows, different analysis strategies as well as the instrumental setup and requirements needed to enable a stable and accurate time and frequency transfer are discussed.

### 41.2.2 Time Transfer Standard CGGTTS

As timing information can only be provided by the GNSS code measurements, due to the ambiguities inherent to the carrier-phase data, the most employed time transfer tools are based on code measurements only. Carrier-phase data however provide high precision frequency comparisons, and the use of precise point positioning (Chap. 25) for time transfer is currently widespread (Sect. 41.2.4), and used for the computation of UTC since 2009 [41.10].

The common GNSS generic time transfer standard (CGGTTS) has been developed by the Consultative Committee of Time and Frequency (CCTF) as a common format to facilitate the data exchange for time dissemination and time transfer. The last version V2E [41.11] covers the use of GPS, GLONASS, Galileo, BeiDou, and QZSS and has evolved from an earlier GPS-only standard. CGGTTS files contain, among other associated quantities, the differences between the clock connected to the GNSS receiver and the GNSS reference time scale $(T - t_{ref})$. These differences result from a well-defined analysis procedure of code measurements [41.12] in which the station coordinates are fixed and the satellite position and satellite clock are extracted from the broadcast navigation messages. The computation procedure applies to satellite tracks of 13 min. For each satellite visible during this 13 min period, the corresponding solution $(T - t_{ref})$ is reported in the CGGTTS file. The tracking schedule is distributed by the BIPM as a list of the starting epochs of the tracks. Note that this 13 min duration was decided in the 1980s as it was the time required by a receiver to acquire a full GPS navigation message.

The common-view method was proposed in the 1980s by *Allan* and *Weiss* [41.9] and the associated CCTF format was based on one-channel C/A code receivers. Following the improvements of atomic frequency standards in terms of precision and accuracy, GPS (or more generally GNSS) time and frequency transfer underwent major evolutions both at the algorithmic levels and at the hardware level. A first improvement was found in the use of a multichannel approach [41.13], increasing the number of satellites which reduces correspondingly the noise of clock solutions. For applications requiring the highest precision, as for example the computation of international atomic time (TAI, Chap. 2), the CGGTTS results are improved by adding a correction for satellite orbits and clocks using the rapid IGS products. Also, the ionospheric correction used in the CGGTTS results, based on the broadcast ionospheric model of the constellation, is replaced by a new estimation based on IONosphere map EXchange format (IONEX) maps (Annnex ) delivered by the IGS [41.14]. A further upgrade of the CGGTTS was the use of dual-frequency receivers measuring the GPS P(Y)-codes, enabling to remove the ionosphere delays at the first order, and leading to a factor-of-2 improvement in the precision of the intercontinental time links [41.15]. Note that for short baselines, the increase of noise in the ionosphere-free combination with respect to the single-frequency time transfer solution can be larger than the residual ionospheric errors associated with the Klobuchar model or with the IONEX maps. The same ionospheric delay is indeed suffered by the GNSS signals when they arrive in stations close to each other. However, the timing community is preferring using the ionosphere-free combination so that the CGGTTS files can be used easily whatever the distance of the second clock entering into the comparison may be.

An example of CGGTTS file is shown in Fig. 41.5. The header of the file summarizes the station information, that is, receiver name, station coordinates, and hardware delays (Sect. 41.3.2) used for the com-

putation. The results are then provided, with each line corresponding to one satellite 13 min track. The columns for the time transfer solutions are REFSV and REFSYS, that is, the differences modulo one second between the laboratory clock and the satellite in view (SV) or the system time scale (SYS). They correspond to the midpoint of a linear fit applied to the 13 min results; the standard deviations with respect to this linear term are also provided (columns SRSV and SRSYS).

### 41.2.3 Common View or All-in-View

The initial CGGTTS files were produced by single channel receivers and the time transfer was computed as the differences of the CGGTTS results collected simultaneously from the same satellite by the two stations. The technique received the name of GPS common view (as at that time only GPS was used). All the satellite hardware delays or satellite clock errors are removed by this technique; the remaining errors are mainly due to different atmospheric distributions on the signals received at the remote stations, and the multipath at the stations. This common view (CV in what follows) technique was also used when multichannel receivers entered into the time laboratories. The final time transfer solution for the clocks $T_1$ and $T_2$ is then for each 13 min track of the BIPM schedule, a weighted average of the results obtained with the satellites in common view of both stations

$$(T_1 - T_2)(t) = \frac{1}{N(t)} \sum_{i=1}^{N(t)} w_i \left[ (T_1 - t_{\mathrm{ref}})_i(t) - (T_2 - t_{\mathrm{ref}})_i(t) \right] , \tag{41.7}$$

where $(T_x - t_{\mathrm{ref}})_i(t)$ is the solution found in the CGGTTS file from station $x$ for the satellite $i$ at the epoch $t$, $w_i$ is the weight, generally the $\sin^2(E)$ with $E$ the satellite elevation, and $N(t)$ is the number of satellites simultaneously visible by the two stations. However, the quality of the CV solutions tends to degrade with increasing distance between the stations, since the number of simultaneously observed satellites decreases as the baseline increases.

An alternative to the common-view technique is therefore called the *all-in-view* (AV) approach: a clock solution $(T_x - t_{\mathrm{ref}})(t)$ is computed independently for each station using all visible satellites and the difference is then computed afterward

$$(T_1 - T_2)(t) = \frac{1}{L(t)} \sum_{i=1}^{L(t)} w_{i1}(t)(T_1 - t_{\mathrm{ref}})_i(t) - \frac{1}{M(t)} \sum_{i=1}^{M(t)} w_{i2}(t)(T_2 - t_{\mathrm{ref}})_i(t) , \tag{41.8}$$

where $L(t)$ and $M(t)$ are the total number of observed satellites by stations 1 and 2, respectively, at the epoch $t$ as in (41.7). AV is therefore independent of the distance between the stations. This is the same principle as precise point positioning (Sect. 41.2.4) but using only code measurements and fixing the position to its known value. Of course, the errors from satellite clock or ephemeris estimate do not cancel as they do in the common-view technique. Therefore, the use of precise ephemerides and clocks rather than the broadcast navi-

gation messages is mandatory [41.16]. Using IGS rapid products, the remaining uncertainties due to satellite orbits and clocks average appropriately to well below 100 ps for averaging 1 d and longer [41.17]. These authors also demonstrate the superiority of AV with respect to CV for baselines longer than 2000 km.

The choice between the CV and the AV will therefore rely on the distance between the stations where the clocks are located, and also the availability of precise orbits and clocks. CV will be preferred when only the broadcast ephemerides are available, but this approach should be restricted to short distance clock comparisons.

As the time transfer based on CGGTTS is a code-only analysis, both AV and CV are significantly affected by multipath of the code signals as well as uncertainties of the hardware delays. Depending on the station setup, some important diurnal variations can appear in the time transfer solution, which are not a clock variation but only the signature of the code multipath in one or both stations. An example is provided in Fig. 41.6, where specific patterns appear in the clock solution with a 23 h 56 min periodicity, that is, the needed time to retrieve the same geometrical relationship between the satellite, the receiving antenna, and the nearby reflectors.

To date, all in view time transfer using the ionosphere-free combination of GPS L1/L2 P(Y)-code observations constitutes the state of the art in GNSS time transfer using code measurements only. The statistical uncertainty ($u_A$) is at the level of a few nanoseconds, being limited by the current noise and multipath of the code measurements. The systematic uncertainty ($u_B$) relies on the calibration capabilities described in Sect. 41.3.2.

### 41.2.4 Precise Point Positioning

The noise and multipath of the code measurements in a code-only analysis masks the short-term stability of some atomic clocks, for example, hydrogen masers. A significantly higher stability can be obtained by using the carrier-phase measurements in addition to the code data. This requires a combined analysis of both code and carrier-phase measurements with a consistent modeling of these measurements similar to GNSS data analysis dedicated to precise positioning.

Only processing zero differences (e.g., precise point positioning) or single differences can be used for time transfer because the receiver clock disappears in double differences. Single differences rely on the same principle as the code-only CV approach, but using both code and carrier-phase measurements, while precise point positioning (PPP) relies on the same principle as the AV. As in the choice between CV and AV, PPP is usually preferred to single-difference analysis as independent on the baseline length. The impact of the satellite geometry on the single-difference solution was clearly demonstrated, for example, in [41.18], where differences between single-difference and PPP analyses reach the nanosecond level for an intercontinental baseline.

As explained in Chap. 25, PPP provides, besides the station position (static or kinematic), the tropospheric delay and the receiver clock solution. When used for time and frequency transfer, the station is of course considered as static, while the receiver clock is solved for each observation epoch. The receiver clock solution is, as explained before, $(t_{rec} - t_{ref})$ where $t_{ref}$ is the reference time scale of the satellite clock products used in the PPP processing. The time transfer solution, as explained in Sect. 41.2, is then a difference between the clock solutions obtained for two remote stations.

It is mandatory that both PPP clock solutions have been computed using the same satellite orbit and clock products so that the reference is the same for both. Note that the IGS also provides receiver clock solutions $(t_{rec} - t_{ref})$ for part of the stations in the network. These are computed using zero differences, but the satellite and station clocks are computed at the same time, fixing the tropospheric delays to the values determined from a double difference network processing. As the IGS solution is based on the combination of solutions obtained by different analysis centers, it is usually considered as

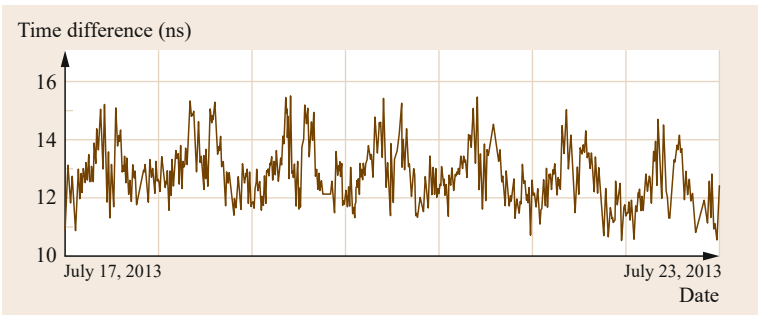

**Fig. 41.6** Example of multipath impact in GNSS time transfer based on CGGTTS: clock comparison between the time laboratory ROA (Spain) and PTB (Germany), computed with the all in view technique based on the ionosphere-free combination of GPS P(Y)-code measurements on the L1 and L2 frequencies

the best solution available for the stations included in the network. The reference time scale of these solutions is the IGS time scale IGST (resp. IGRT) for the final (resp. rapid) products.

In a time transfer solution, the shape of the curve corresponds to the frequency variations between the two clocks (or timescales) compared, while the position of the curve on the *y*-axis corresponds to the time synchronization difference between the two clocks (or timescales). When the solution is computed using a combined analysis of code and carrier-phase measurements, the shape of the curve will be given by the carrier-phase data, while its position on the *y*-axis will be given by the code measurements. The carrier-phase data indeed contain an ambiguity term, which would put the solution on an arbitrary value on the *y*-axis. This ambiguity is determined for each satellite continuous track from the differences between the code and the carrier-phase measurements, and the final solution is then given by the carrier-phase data corrected for their ambiguity term. Thanks to their higher precision, carrier-phase data improve significantly the comparison of remote clock frequencies with respect to a code-only solution.

This improvement is illustrated in Fig. 41.7 for the comparison of two masers located in Brussels (Royal Observatory of Belgium) and Braunschweig (Physikalisch-Technische Bundesanstalt); both AV and PPP solutions are presented as well as their frequency

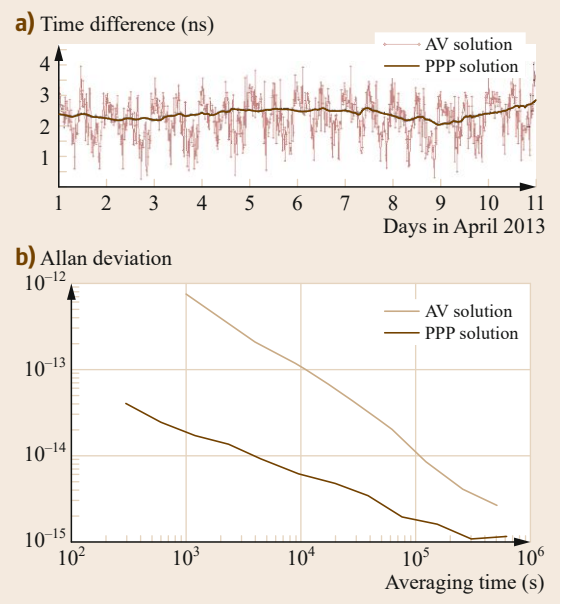

**Fig. 41.7a,b** Comparison of the time transfer solutions between two H-masers located in Brussels, Belgium and Braunschweig, Germany, computed with either AV or PPP **(a)** and associated Allan deviations **(b)**

stabilities highlighted by the Allan deviation. The statistical uncertainty $u_A$ of PPP time transfer is currently below 100 ps for each observation epoch, allowing frequency transfer with an uncertainty approaching $1 \cdot 10^{-15}$ or even better for averaging times of one day [41.19–21]. The systematic uncertainty $u_B$ of PPP time transfer is however the same as for code-only solutions, that is, a few nanoseconds, and relies on the calibration capabilities detailed in Sect. 41.3.2.

In a PPP analysis, the noise of the code measurements is responsible for jumps between successive and independent clock solutions. Indeed, as explained here above, the carrier-phase ambiguities are determined as the average over the continuous satellite track of the differences between the carrier-phase and code pseudoranges (maybe corrected with some bias to assure the integer nature of the ambiguity). As a consequence, the absolute values of the final PPP solution, that is, position of the curve on the *y*-axis, correspond roughly to the average of the code measurements of the data batch analyzed. Due to the noise of the code measurements, the standard error of the mean (SEM) is not zero and one can have jumps between two successive clock solutions. Consider, for example, one day of data sampled at 5 min with four visible satellites at each epoch. For a pseudorange pure white noise with an standard deviation of 30 cm, the standard error of the mean clock solution is then typically about 33 ps. This implies jumps between the successive daily clock solutions, distributed as a white noise with a zero mean and a standard deviation of 47 ps. However, the magnitude of these day-boundary jumps can be significantly larger [41.22]. The standard deviations of the jumps are station dependent, ranging from 150–1000 ps [41.23], well larger than the expected 47 ps. Only stations equipped with H-masers are considered there as for less stable frequency standards the clock instability dominates the day-boundary jumps caused by the pseudorange noise.

The origin of these large day-boundary jumps and of their station-dependent behavior is not yet fully understood, but reflects different station code performances, and reveals the colored signature of the code measurements. Several causes have already been identified, for example, a correlation with external temperature variations, but with opposite sign for different stations [41.22]. A large part of the day-boundary jumps (especially those of large magnitude) was also shown to be associated with pseudorange variations similar to all the satellites [41.24], with magnitudes reaching several nanoseconds, and possibly caused by instrumental delay variations (which can be due to temperature variations), reflections in the cable connectors or some nongeometrical near-field effect.

As an example, Fig. 41.8 presents the PPP clock solution for the IGS station OPMT (Paris) equipped with a H-maser. Based on the use of IGS final products, the solution corresponds to (OPMT-IGST). A same linear term was removed from all the curves in order to facilitate the visibility. The results depicted in Fig. 41.8 correspond to (1) a PPP solution from daily processing, (2) a PPP solution from a unique process of a one month data batch (computed by the BIPM for the computation of UTC), and (gray dots) a code-only solution plotted for each satellite separately. The observed day boundary jumps in curve (1) are because the absolute value of the PPP solution corresponds to the average of the code measurements of the data batch analyzed, while these code measurements suffer from some long-term variations, as seen from the code-only solution (gray dots). For comparison, the PPP solution computed for the complete five day data batch is of course continuous across the day boundaries. Note that the two PPP solutions presented in Fig. 41.8 have been produced by two different software tools, which explains the small differences in the subdiurnal variations.

Several approaches have been addressed in order to reduce or eliminate the daily discontinuities. Correcting the jumps observed in the clock solution when the ambiguities are still float in the solution produces a random walk of the continuous solution [41.20]. Processing multiday data batches [41.25] as proposed in curve (2) of Fig. 41.8, transports of course the problem at the batch boundaries, but in that case the jumps are smaller as the impact of the code noise is reduced thanks to the increased number of observations. A dedicated data filtering method [41.26] was also proposed, as well as processing sliding windows [41.27] but again the problem is mitigated rather than solved.

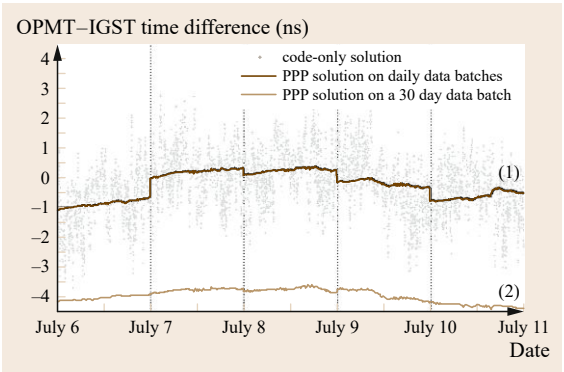

**Fig. 41.8** PPP solutions for the station OPMT (Paris) equipped with a H-maser. Solution *(1)* is based on daily process, while solution *(2)* was obtained from the analysis of a one month data batch. *Gray dots* are the code-only solutions plotted for each satellite separately. In order to improve the visibility, a same linear term was removed from all the curves as well as a 3 ns bias from curve *(2)*

The optimal way to produce independent solutions while ensuring their continuity is to fix the ambiguities to integer values [41.28]. This requires the introduction of some station and satellite biases to absorb the non integer part of the ambiguities. In the results produced by this integer PPP processing, the day boundary discontinuities still exist but are always an integer number of cycles of the narrow-lane combination of the two frequencies used in the ionosphere-free combination; these integer jumps can then be easily canceled out [41.29]. Equivalently, in [41.30] a new parametrization is proposed that separates the pseudorange observation colored noise from the carrier-phase parameters, that is, ambiguities and clock; the continuity is then directly obtained between independent PPP solutions of successive data batches, but requires to arbitrarily fix one initial receiver bias.

All these issues related to the continuity of the PPP solutions at the batch boundaries and to the reduction of the impact of the noisy code measurements find their importance in the wish to improve the performances of GNSS frequency transfer. The time transfer quality however always relies on the code measurements, and the best way to improve these measurements will be to design an antenna setup which reduces the near-field multipath. Using either absorbing material around the antenna or a pillar of at least 2 m height supporting the antenna, have for example, shown convincing results in reducing the magnitude of the day boundary jumps [41.31], or [41.32]. Furthermore, antenna cables with low sensitivity to temperature variations, and a stabilized temperature around the clock and receiver are as well recommended to reduce pseudorange coloured noise.

A last point to be emphasized is the correlation between the clock and the tropospheric zenith path delay (TZD) estimated in the PPP processing. It was, for example, demonstrated that a short sampling rate (shorter or equal to 15 min) in the estimation of the TZD is mandatory to reproduce as much as possible the true troposphere variations and hence to avoid any contamination of the clock solution from unmodeled short-term tropospheric changes [41.33]. The details of the mapping function employed have however no significant impact [41.34].

The ultimate performances of GNSS frequency transfer can be estimated using a pair of stations in a common-clock setup, that is, both connected to a same clock, so that the solution is not influenced by the clock instability. The Allan deviation of such solutions

are presented in Fig. 41.9. The common-clock results were obtained using two separate receiving chains with a distance of 100 m between the antennas. In order to emphasize the impact of the code measurements on the stability of the solutions, Fig. 41.9 presents, for this common-clock setup, one classical PPP solution and one solution obtained using only carrier-phase data. In latter, the single differences of carrier-phase data were used and the ambiguities were determined with respect to zero (the expected clock difference) rather than with respect to the code single differences as is the case in PPP. Therefore, only the noise of the carrier-phase data influences the solution. Note that for nearby stations, processing single differences or PPP provides similar results as PPP because of the geometry of satellites which is exactly the same for both stations. The impact of any error on satellite products has therefore exactly the same impact on the PPP solutions of both stations, and cancels out in the difference of the PPP solutions while in single differences it cancels out at the level of observations. The second curve results from a PPP analysis using the NRCAN PPP software on a multi-day basis [41.25] in order to avoid a contamination of the Allan deviation from the day-to-day discontinuities inherent to daily processing of PPP. The difference between these two curves comes by using code measurements in the PPP case, which degrades the stability at intervals of a few hours, that is, the classical duration of the satellite visibility on which the ambiguities are constant.

The two other curves of Fig. 41.9 present the Allan deviation of the PPP solutions for the links Brussels–Washington (BRUS-USN3, about 6000 km) and Brussels–Paris (BRUX-OPMT, about 300 km). Both provide approximately the same quality. The short-term stability is however lower than what was expected from the common-clock results; the origin of this degraded quality has not yet been identified to date. The H-maser stability curve in the figure shows that H-maser instabilities dominate over periods longer than 3 h, so that the curves (3) and (4) associated with H-maser comparisons cannot provide information about the performance of the technique; only the common-clock setup can be used to this end. The optical clock stability curves show that optical clock comparisons from GNSS will be possible only for averaging times longer than several days.

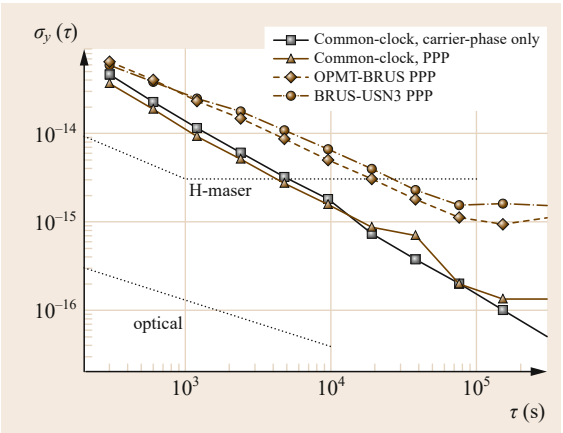

**Fig. 41.9** Allan deviation of the clock solutions estimated with state-of-the-art GNSS frequency transfer compared with the Allan deviation of the most stable atomic clocks to date, that is, the H-masers and optical frequency standards. The clock solutions correspond to two links among stations equipped with H-masers: Brussels–Paris (BRUS-OPMT, 300 km), Brussels–Washington (BRUS-USN3, 6000 km); the 100 m baseline is using the same clock for both stations so that the solution does not depend on the stability of the clock and shows the maximum capabilities of the method

## 41.3 Hardware Architecture and Calibration

The GNSS equipment needed for time and frequency transfer consists of a receiving antenna connected via cable to a dedicated GNSS receiver and some cable link between the receiver and the external clock to be examined. For time transfer, it is also necessary to have access to the 1 pps given by the external clock, and each of the just mentioned components should be calibrated, which means that the hardware delay of each signal in these instruments or cables should be accurately determined. This section describes the characteristics of dedicated GNSS receivers for time/frequency transfer, and the existing methods for calibrating the receiving chain.

### 41.3.1 Time Receivers

Specific GNSS receivers have been developed and commercialized for time transfer. The receiver system consists of an input for an external frequency reference (typically 5 or 10 MHz) to be used in all internal oscillator functions, an input for an external pulsed signal related to the external clock 1 pps, and possibly an in-

ternal time-interval counter. The components may be integrated into a single package or may be separate and connected together by appropriate cables.

Figure 41.10 shows three types of receivers satisfying these requirements. The epoch of the receiver clock can be either:

- Based on the GNSS signals themselves and continuously monitored against the 1 pps signal of the external clock using a time-interval counter (R1 and R2).
- Locked directly to the 1 pps signal from the external clock (R3).

The classical geodetic receiver (R1) can be used for time transfer only if the 1 pps output is related to the internal reference (or receiver clock), and if the relation between the internal reference and the 1 pps output is perfectly known: it must be provided by the manufacturer or measured by the user following a given procedure which is different for each receiver make. The time interval counter (TIC) for R1 and R2 measures the synchronization error between the receiver internal clock and the external clock to be examined. This TIC should measure time intervals (of up to 1 s if required) with a $u_B$ uncertainty approaching 100 ps or better, and a noise level below 100 ps; the TIC measurements should furthermore be reported separately from the GNSS measurements. The main difference between the receiver types R1 and R2 is that the TIC and the computation of the CGGTTS data are inside the receivers R2 while they are external to the classical geodetic receivers R1; for these receivers, the CGGTTS files will be generated using an external software tool that combines the raw measurements available in, for example, Receiver INdependent EXchange format (RINEX (Annex A.1.2) files and the TIC measurements.

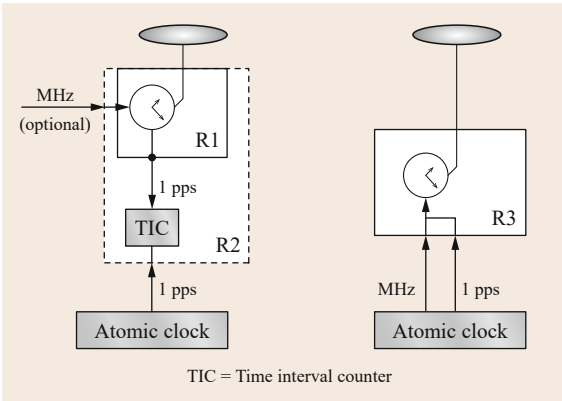

**Fig. 41.10** Different kinds of receiver setups for GNSS time and frequency transfer. R1 and R2 use their own internal clock and compares it with the external clock using a time interval counter, while R3 directly uses the 1 pps of the external clock as internal reference

In order to overcome the possible noise introduced by the TIC, some geodetic + time receivers (R3) directly synchronize their internal clock (modulo one constant bias) on the external clock to be compared. The user must in that case ensure that the 1 pps signal is coherent with the frequency reference and maintained sufficiently close to the GNSS time scale to assure proper operation. The input 1 pps allows the receiver to choose without ambiguity one particular cycle of the input frequency to form its internal time reference. The receiver clock is so locked in phase on some given point of the input frequency following the pulse of the input 1 pps signal. This kind of receiver cancels the need for a time interval counter and hence provides a final clock solution which is less noisy than the solutions obtained with R1 or R2. Furthermore, the CGGTTS results can be obtained directly from raw measurements available in the RINEX files, using a dedicated software tool as proposed, for example, in [41.35]. In receiver type R3, the internal reference is obtained either by locking the internal oscillator on the external frequency, or by using directly the external frequency for the internal reference. If the internal oscillator is locked on the external frequency with an enslavement system, then the system must be described in full details by the manufacturer to allow for accurate calibration (Sect. 41.3.2). This system must furthermore be designed to introduce no noise on the frequency; adding noise would make impossible the study of frequency stabilities of the best frequency standards via GNSS frequency transfer. Furthermore, the way the internal reference clock is obtained from the external 1 pps must also be described by the manufacturer; this is mandatory to have access to the delay between the external clock and the GNSS measurements, and hence to correctly transfer time.

The Consultative Committee for Time and Frequency (CCTF) advocated in its recommendation S5(2001) [41.36] that the manufacturers of receivers used for timing with GNSS implement the technical guidelines for receiver hardware compiled by the CCTF group on GNSS time transfer standards (CGGTTS). These guidelines have been compiled with the aim of achieving a system that can transfer time with an accuracy of 1 ns or better. A detailed review and extension to new systems can be found in [41.37].

### 41.3.2 Hardware Calibration

As already stated, GNSS measurements can be exploited for time transfer only if the electric delay accumulated by the signal between the antenna phase

center and the internal timing reference of the receiver is accurately known, as well as the synchronization error between this internal timing reference and the external clock to be examined. Note that the satellite hardware delay being the same for all the ground observing stations, it is already included in the satellite clock and need not be corrected for in the GNSS analysis dedicated to time transfer. One exception comes however when the code measured by the receiver are not the same as the codes used for the satellite clock determination. This happens, for example, when the receiver measures the GPS L1 C/A code. All the clock products for GPS satellites are indeed based on the ionosphere-free combination of L1/L2 P(Y)-codes. Using the combination of L1 C/A and L2 P(Y) code measurements requires therefore a transformation of the satellite clock products to the same combination, using the satellite differential code biases L1 C/A–L2 P(Y) that are provided, for example, by the IGS (Sects. 19.6.1 and 21.3.1).

The station hardware delays, in contrary, must be determined by calibration, as well as the exact time offset between the receiver internal clock and the external clock. All these delays are represented schematically in Fig. 41.11 for the three types of receivers described earlier.

Hardware delays exist in both code and carrier-phase measurements. However, only the code delays are determined by calibration and corrected for in time transfer computation, since only the code measurements provide the time. When carrier-phase data are used, the phase delays are absorbed in the ambiguities.

The first category of delays consists of the electric delays affecting the GNSS signals, that is, $\delta_A$ the antenna delay, $\delta_{AC}$ the antenna cable delay, and $\delta_R$ the receiver delay, that is, between the antenna cable

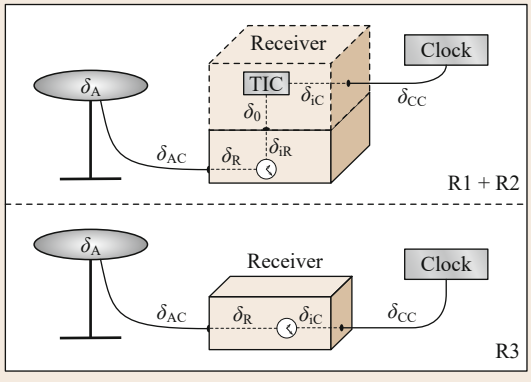

**Fig. 41.11** Hardware delays to be accounted for time transfer and associated with three types of receivers of Fig. 41.10

connector and the internal reference where the measurement is made. These instrumental delays are present in the term errors of (41.4) When extracting them explicitly one gets

$$P = \|\boldsymbol{x}_s - \boldsymbol{x}_r\| + c(\Delta t_{rec} - \Delta t_{sat}) + B(\text{rec}) + \epsilon \,, \quad (41.9)$$

where $B$(rec) is the bias associated with the signal delay accross the antenna, the antenna cable, and the receiver

$$B(\text{rec}) = \delta_A + \delta_{AC} + \delta_R \,. \quad (41.10)$$

This bias should therefore be removed from the code measurements to retrieve the accurate synchronization error $(t_{rec} - t_{ref})$ between the receiver clock and the reference time scale. $B$(rec) should be constant. It is however sensitive to temperature variations, so that a temperature stabilization is recommended in the receiver room, as well as choosing an antenna cable with low sensitivity to temperature variations.

The second category of delays consists of the synchronization error between the internal timing reference and the external clock to be examined. For receivers with an internal or external time interval counter (i. e., R1 and R2), the synchronization error is measured by the TIC. This measurement must however be corrected for:

- The delays in the cables and electronic devices transporting the 1 pps signal from the clock to the TIC, that is, $(\delta_{iC} + \delta_{CC})$ for receivers R1 or $\delta_{CC}$ for receivers R2.
- The delays in the cables and electronic devices transporting the 1 pps signal from the receiver clock to the TIC, that is, $\delta_0$.
- The synchronization error between the internal reference and the 1 pps output of the receiver, that is, $\delta_{iR}$, to be provided by the manufacturer.

When the receiver clock is directly using the frequency and time signals from the external clock (i. e., R3), only the clock cable delay $\delta_{CC}$ should be measured, and added to the bias $\delta_{iR}$ provided by the manufacturer. This second category of delay has to be added from the GNSS solution to go back from the receiver clock to the external clock.

Finally the synchronization error between the clock and the reference of the satellite clock products is for R1 and R2

$$\begin{aligned}(T - t_{ref}) = {} & (t_{rec} - t_{ref})_{PR} \\ & - (\delta_A + \delta_{AC} + \delta_R) \\ & + \text{TIC} + \delta_{CC} + \delta_{iC} - \delta_{iR} - \delta_0 \,, \end{aligned} \quad (41.11)$$

while for the receiver R3 it reads

$$(T - t_{\mathrm{ref}}) = (t_{\mathrm{rec}} - t_{\mathrm{ref}})_{\mathrm{PR}} - (\delta_{\mathrm{A}} + \delta_{\mathrm{AC}} + \delta_{\mathrm{R}}) + (\delta_{\mathrm{CC}} + \delta_{\mathrm{IC}}) \,, \tag{41.12}$$

where $(\ldots)_{\mathrm{PR}}$ denotes the time offset as derived from pseudorange measurements.

The cable delays are independent of the signal frequency, and correspond to the product between the cable length and the group velocity of the signal in the cable given by

$$v_{\mathrm{g}} = \frac{c}{\sqrt{\varepsilon_{\mathrm{r}}}} \,, \tag{41.13}$$

where $v_{\mathrm{g}}$ is the group velocity, $c$ the velocity of light and $\varepsilon_{\mathrm{r}}$ the relative dielectric permittivity (Sect. 6.1). The connectors at both ends of the cable also induce some delays that must be taken into account. The group delay in the cable with its connectors can be measured with an accuracy of some tens of picoseconds using a time interval counter or a vector network analyzer (VNA). The offset $\delta_{\mathrm{IC}}$ can only be determined if either the receiver offers an access to its internal clock via, for example, a 1 pps output synchronized on the internal clock, or the receiver manufacturer provides a detailed explanation of how the internal clock is constructed from the combination of input 1 pps and frequency coming from the external clock, so that it can be reproduced to be measured outside the receiver.

The antenna and receiver delays affecting the GNSS signals ($\delta_{\mathrm{A}}$ and $\delta_{\mathrm{R}}$) are both frequency dependent. Two techniques exist to date for their calibration: the relative technique, using true GNSS signals, and the absolute technique using simulated GNSS signals. Note that the antenna calibration concerned here differs from the one discussed in 17.6.2 of this Handbook, which aims at determining the accurate phase center, while in the present case it determines the electric delay of the signal in the antenna. Neither elevation nor azimuth dependence of this delay is considered to date.

### Absolute Calibration

The principle of the absolute calibration is to use simulated signals in order to determine the electric delay of the receiver or antenna (or the complete receiving chain), and compare the receiver/antenna measurements to the simulated signals. Complete descriptions of the method can be found, for example, in [41.38–40] and references therein. The simulated signal is produced by a GNSS signal generator, and is free of noise or perturbation like atmospheric delays or multipath existing in the case of true GNSS signals. This kind of calibration offers a very high accuracy of 0.4 ns [41.41] while it requires the use of a GNSS simulator and a VNA, as well as an anechoic chamber for the antenna, which are not existing in the major part of the laboratories. Moreover, this method does not allow one to determine the hardware delays of already operational receiving chains, as these may not be interrupted and the antenna is calibrated in nonreal conditions.

### Relative Calibration

Much more simple to be technically implemented is the relative calibration technique, which is consequently used for all operational stations. It consists in a comparison of pseudorange measurements collected by the local receiving chain and a reference receiving chain traveling from laboratory to laboratory [41.42]. For this, both stations should be connected to the same clock and installed in co-location (Fig. 41.12), so that all the perturbations except the multipath are equal. The difference of the pseudoranges measured by the two receiving chains then contain only a difference in antenna position plus the differences between the hardware delays of the two stations. Using the same nomenclature as in Fig. 41.11, this gives for a given satellite $s$ and a given code $c$

$$\begin{aligned} P_{\mathrm{lab}}(c,s) - P_{\mathrm{ref}}(c,s) &= \|\boldsymbol{x}_s - \boldsymbol{x}_{\mathrm{lab}}\| - \|\boldsymbol{x}_s - \boldsymbol{x}_{\mathrm{ref}}\| \\ &\quad + (\delta R + \delta A)_{\mathrm{lab}} - (\delta R + \delta A)_{\mathrm{ref}} \\ &\quad + (\delta_{\mathrm{AC}} - \delta_{\mathrm{CC}} - \delta_{\mathrm{IC}})_{\mathrm{lab}} \\ &\quad - (\delta_{\mathrm{AC}} - \delta_{\mathrm{CC}} - \delta_{\mathrm{IC}})_{\mathrm{ref}} + \epsilon \,, \end{aligned} \tag{41.14}$$

where $\epsilon$ is the combined noise and multipath of the two stations. The terms $(\delta_{\mathrm{AC}} - \delta_{\mathrm{CC}} - \delta_{\mathrm{IC}})$ can be measured and deduced from the receiver manufacturer information for both receivers. The difference of pseudoranges therefore provides the $(\delta R + \delta A)$ of the laboratory receiver chain with respect to the reference chain. If this reference chain has been absolutely calibrated, the relative calibration then gives access to the true hardware

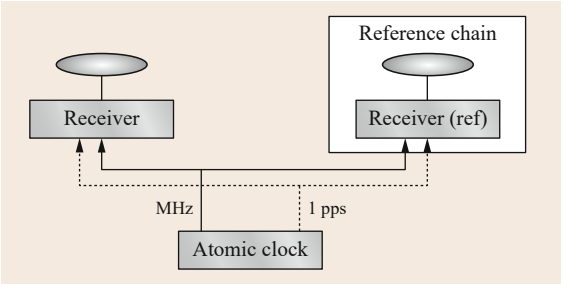

**Fig. 41.12** Setup for relative calibration exercise

delay of the laboratory receiver+antenna. If not, then the relative calibration data can be used to calibrate a time transfer link in which the same reference chain was used for the calibration of both stations. In that case [41.43], the reference station has to be installed in co-location with the two stations of the link, and the calibration exercise provides the quantity $(\delta R+\delta A)_1-(\delta R+\delta A)_2$ which can be directly applied to the time transfer solution $T_1-T_2$. The same strategy can be applied to a network of stations in which all the stations are differentially calibrated with respect to a same reference. Any time link of the network will then be correctly calibrated by applying the computed relative hardware delays $(\delta R+\delta A)$ to each of the stations.

The relative calibration technique just described does not allow separating the hardware delays of the antenna and of the receiver. The isolated effect of receiver and antenna could be determined connecting the two receivers to the same antenna, using a splitter. However, the hardware delays of GNSS signals in the splitter are really difficult to be measured, and the splitter introduces a source of signal reflections, also called cable multipath, possibly inducing interferences [41.44]. Solutions to overcome that problem exist [41.40] but require the use of amplifiers and attenuators of which the levels have to be chosen thoroughly as a function of the antenna and receiver types. It is therefore recommended to use relative calibration only for the determination of the combined receiver plus antenna hardware delays.

The uncertainty budget of the differential calibration technique gives 2.3 ns for each isolated code [41.45], when taking into account the uncertainty on the absolute calibration of the reference chain, on the cable delay measurements, and the noise of the code measurements. In parallel, the uncertainty on the difference between two codes (e.g., L1/L2 P(Y) for GPS) is estimated to 2.0 ns so that the associated uncertainty on the ionosphere-free combination is 3.8 ns. Considering a time transfer between two stations independently calibrated provides a type B uncertainty on the link at the level of 5.4 ns reduced to 5 ns in BIPM circular T. However, this 5 ns uncertainty reflects the long-lasting conservative practice. A significantly reduced uncertainty was found in [41.43] using a traveling receiver. The technique was then refined to reach an uncertainty around 1 ns in [41.46] and [41.47]. Such small $u_B$ value however can be maintained over long times only if periodic re-calibrations are made.

The challenge for relative calibration is furthermore to keep constant the hardware delays of the reference station. The reference equipment is always subject to possible damages or instabilities due to its traveling between stations. The local temperature and humidity conditions in different locations can furthermore be very different from the conditions during the absolute (or relative) calibration of the reference equipment, which can cause some biases in the results [41.48]. While receivers can be installed in temperature-controlled rooms, the antenna and antenna cables can suffer diurnal temperature changes of around 40 °C, as occur in certain parts of the world. Some experiments of measuring the temperature sensitivities of the antennas showed maximum diurnal variations (for diurnal variations of 20 °C) of 40 ps for the carrier-phases [41.49], while up to 2 ns for the code measurements [41.50, 51]. Special attention should therefore be paid to sensitivity to temperature variations for the choice of the antenna and cable of the traveling reference GNSS station, as well as any other GNSS station dedicated to time transfer. The stability of the reference GNSS station should furthermore be regularly verified, by intercomparison with fixed stations. The delays of the most stable GPS common-view time transfer receivers vary typically by a few nanoseconds over years, generally by less than 5 ns peak-to-peak [41.52].

## 41.4 Multi-GNSS Time Transfer

### 41.4.1 General Requirements

The combination of measurements from different GNSS constellations for time transfer requires several specifications. The first one is that the receiver internal reference be the same for all systems. A second requirement is that the receiver must be fully calibrated, that is, the hardware delays must be determined for each signal transmitted by each constellation. Indeed, in some cases the frequency bands used by different systems do not completely overlap, or the power spectrum inside the band is not the same. For example in GLONASS, several carrier frequencies are used in each frequency bands (Chap. 8), yielding complex calibration procedures due to the need to calibrate one delay per carrier frequency.

Finally, a last requirement concerns the reference of the satellite clock products. The receiver clock solution obtained from observations of satellites belonging to constellations A and B are $(t_{rec}-t_{ref,A})$ and $(t_{rec}-t_{ref,B})$, where $t_{ref,A}$ and $t_{ref,B}$ are the reference time scales of the two constellations. In order to get only one combined

receiver clock solution, the user should either know the accurate de-synchronization $(t_{\mathrm{ref,A}} - t_{\mathrm{ref,B}})$ at each observation epoch, or use satellite clock products having the same reference whatever the constellation to which they belong, or introduce $(t_{\mathrm{ref,A}} - t_{\mathrm{ref,B}})$ as unknown and then estimate it along with the other parameters. As $(t_{\mathrm{ref,A}} - t_{\mathrm{ref,B}})$ is generally not available at each observation epoch, only the two other possibilities can be used. The last one however requires the estimation of one additional parameter at each observation epoch which increases the uncertainty of the solution. The optimal option is therefore the second one. Combined products already exist for GPS and GLONASS satellites, they are provided by some analysis centers of the IGS. It is assumed that in the future, such products will also be provided for Galileo and BeiDou. The combination of all these constellations in one global time transfer solution will therefore be possible with the second option. We describe here the case of GLONASS which requires a special treatment due to existence of interfrequency biases, and present some first results on the use of Galileo and BeiDou for time and frequency transfer. Note that QZSS can also be used for regional clock comparisons, while it will play no role in intercontinental time transfer.

### 41.4.2 GPS + GLONASS Combination

The main difference between GLONASS and the other GNSS is the channel access method. While all the GNSS constellations use the code division multiplex access (CDMA) technique in which all the satellites share the same carrier frequencies, GLONASS is based on the frequency division multiple access (FDMA) technique. Each GLONASS satellite transmits consequently on a different frequency in the L1 band as well as in the L2 band.

Due to the frequency-dependent nature of the hardware delays in the receiver and in the antenna, these are different for each GLONASS satellite group transmitting a given pair of frequencies L1, L2, inducing interfrequency biases up to tens of nanosecond in the code measurements and hence in the clock solutions as determined from different satellites. The observation equation (41.9) should therefore be modified for GLONASS satellites as

$$P = \|\boldsymbol{x}_{\mathrm{s}} - \boldsymbol{x}_{\mathrm{r}}\| + c(\Delta t_{\mathrm{rec}} - \Delta t_{\mathrm{sat}}) + B(\mathrm{rec,sat}) + \epsilon \ . \quad (41.15)$$

In this case, the bias $B$(rec,sat) being satellite dependent cannot be absorbed by the receiver clock $\Delta t_{\mathrm{rec}}$. Note that, in principle, bias should be the same for satellites using the same frequency pair, but it is rarely modeled as such, and a satellite-dependent bias is generally preferred.

The satellite clock $\Delta t_{\mathrm{sat}}$, the receiver clock $\Delta t_{\mathrm{rec}}$, and the bias $B$(rec,sat) in equation (41.15) cannot be separated unequivocally. As a consequence, the GLONASS satellite clocks determined from some network analysis are affected by artificial biases. In that computation, it is indeed necessary to fix arbitrarily one bias for a given receiver–satellite pair and then to determine all satellite clocks, receiver clocks and receiver–satellite biases with respect to that fixed parameter. If the fixed bias changes between the treatments of two successive data batches, the biases for all station–satellite pairs will change accordingly. As classically the satellite clock products are computed on a daily basis, their use to determine the clock solution of a single station (in AV or PPP) requires the estimation of daily receiver–satellite biases $B'(\mathrm{rec, sat, day})$ in addition to the clock solution. These biases contain a physical part, corresponding to the station hardware delays for the frequency emitted by the satellite, and which is constant (or nearly constant) over the long-term, plus an artificial bias present in the satellite clock products

$$B'(\mathrm{rec, sat, day}) = B(\mathrm{rec,sat}) + \gamma(\mathrm{sat, day}) \ , \quad (41.16)$$

$B$(rec,sat) corresponds to the terms $(\delta_{\mathrm{A}} + \delta_{\mathrm{AC}} + \delta_{\mathrm{R}})$ in (41.11), that is, the sum of antenna delay, antenna cable delay and receiver delay.

As the biases $\gamma(\mathrm{sat, day})$ are the same for all the GNSS stations, they cancel out in the common view approach (Sect. 41.2.3) and a calibrated GLONASS clock solution can be obtained if $B$(rec,sat) is known for both stations of the link, that is, if the stations have been calibrated for all the GLONASS frequencies.

However, such a calibrated clock solution cannot be obtained with the PPP and AV techniques using only GLONASS measurements due to the unknown biases $\gamma(\mathrm{sat, day})$. The combination of GPS plus GLONASS measurements allows one to solve for that issue. Two approaches are then possible: the first one uses only the GPS calibration results and determines the biases $B'(\mathrm{rec, sat, day})$ as the differences for each satellite and each day, between the noncalibrated GLONASS clock results and the calibrated GPS clock solution.

An application of this technique for the computation of all in view solutions based on CGGTTS results was presented in [41.53], and the corresponding combination of GPS and GLONASS in precise point positioning can be found in [41.54]. However, in both cases the GLONASS measurements are not calibrated which is not convenient from the metrological point of view but is a consequence of the unknown bias present in the satellite clock products. The second possibility is to use

a link approach. The basic idea is that the differences between the estimated $B'(\text{rec}, \text{sat}, \text{day})$ for the two stations of the link reads

$$B'(\text{rec}_1, \text{sat}, \text{day}) - B'(\text{rec}_2, \text{sat}, \text{day}) = B(\text{rec}_1, \text{sat}) - B(\text{rec}_2, \text{sat}) \quad (41.17)$$

that is, does not depend any more on the biases of the satellite clock products, and can be accurately determined by a calibration exercise. The values of $B(\text{rec}_1, \text{sat}) - B(\text{rec}_2, \text{sat})$ can then be used to constrain the determination of $B'(\text{rec}_1, \text{sat}, \text{day})$ and $B'(\text{rec}_2, \text{sat}, \text{day})$. This requires, of course, that the clock solutions (AV or PPP solutions) of the two stations are determined in a same analysis procedure [41.55]. Finally, the clock solutions obtained from the combination of GLONASS and GPS measurements provide a same level of performances than the GPS-only solutions, as shown in the publications cited earlier.

### 41.4.3 Time Transfer with Galileo and BeiDou

As stated in Chap. 9, Galileo is transmitting in three frequency bands (E1, E5, and E6), but only the two former ones are available in the open service. Most dual-frequency receivers measure the unencrypted ranging codes E1 and E5a, and improved-accuracy receivers measure additionally the signal E5b and the wide-band E5 alternative binary offset carrier (AltBOC) signal.

Some first experiments of using the Galileo signals for time transfer were already realized, based on the ionosphere-free combinations of E1 with either E5a, or E5b or E5 AltBOC. The results indicate that the noise of the Galileo measurements is significantly lower than the noise of the ionosphere-free combination of the GPS measurements P(Y)-codes on L1 and L2 at all elevations [41.56]. This comes partly from the smaller coefficients multiplying the code measurements (and hence the noise) in the ionosphere-free combination. These coefficients are indeed smaller for more distant frequencies, as is for (L1, L5) with respect to (L1, L2). The noise of the final solution however depends of the number of visible satellites so that Galileo will compete with GPS only when the full constellation will be deployed.

First steps in BeiDou time transfer have also been started [41.57]. From theoretical point of view, the noise of the ionosphere-free combination should not be so much lower than the present GPS noise, due to the proximity of the frequencies of the open service (B1 and B2), but no rigorous comparison exists to date.

It must however be noted that as GPS, Galileo, and BeiDou are based on the CDMA technique, so that a same total hardware delay affects the code measurements from all the Galileo satellites, and a same corresponding hardware delay affects the code measurements from all the BeiDou satellites. No satellite-dependent hardware delay should be determined as is the case for GLONASS. The combination of GPS with Galileo and/or BeiDou will therefore increase the number of observations without increasing the number of unknowns (except in PPP where additional phase ambiguities will have to be resolved), and an improvement by a factor of $\sqrt{3}$ is expected from the combination of GPS with the full Galileo and BeiDou constellations.

## 41.5 Conclusions

This chapter presented the time and frequency applications offered by the GNSS, as well as their current performances summarized in Table 41.1. Accurate time or time transfer can be realized with an accuracy approaching one nanosecond thanks to most advanced calibration techniques. Due to the noise and multipath of the code pseudoranges, the accurate frequency transfer will be preferably determined with PPP which makes use of the carrier-phase measurements, and which allows comparing atomic clocks at the level of $1 \cdot 10^{-13}$ for short averaging times (some minutes) and approaching $1 \cdot 10^{-16}$ at one day averaging times. These ultimate performances can of course be reached only with appropriate instrumentation.

In the future, GNSS may grow to include more than 100 satellites, mostly in medium Earth orbit, with some in geostationary and inclined elliptical orbits. Using the

**Table 41.1** Summary of the best performances of GNSS timing applications

| Application | Parameter | Performance |
|---|---|---|
| Synchronization on UTC[a] | $u_B$<br>$u_A$ | 20 ns<br>10 ns |
| Frequency steering (GNSSDO)[b] | Stability | $\leq 1 \cdot 10^{-12}$ one day |
| Time transfer with CGGTTS[c] | $u_B$<br>$u_A$ | $< 2$ ns<br>2 ns |
| Time transfer with PPP[c] | $u_B$<br>$u_A$ | $< 2$ ns<br>100 ps |
| Frequency transfer with PPP[b] | Stability | $2 \cdot 10^{-16}$ one day |

[a] Function of the GNSS prediction of UTC and of the receiver calibration
[b] Given by the Allan deviation
[c] Function of the receiver calibration

same kind of signals from different constellations will increase the number of measurements in the averaging procedure, and hence produce a slight improvement in terms of precision [41.58]. Furthermore, each of the GNSSs will be gradually modernized with, for example, new onboard clocks for GPS, or transfer to the CDMA technique for GLONASS which will eliminate the inter-channel biases.

However, the added value of these constellations resides also in the new possibilities they offer thanks to new ranging signals having more complex structure and improved characteristics. We can, for example, expect new timing performances thanks to the precise Galileo E5 AltBOC signal, whose combined noise and multipath is limited to less than 25 cm at all satellite elevations [41.59]. If in the future, GNSSs offer some new signals in the C-band (or Ku band), the ionosphere-free combination with code measurements in the L-band would also mitigate the noise amplification due to the coefficients of the linear combination.

In parallel, some new clock comparison techniques will be offered by the GNSS for fundamental time metrology. BeiDou, for example, will provide, besides the timing services described in this chapter, a two-way time transfer, that is, based on signals that travel both ways between the two ground clocks to be compared via a BeiDou geostationnary satellite equipped with a transponder [41.60]. This technique is already widely used by the time laboratories for their participation to TAI [41.61] but relies presently on commercial satellites. BeiDou will be the first navigation system to propose that alternative to the classical one-way method. The station equipment for that technique will however be completely different from the classical GNSS receiving station, as an emission unit must be considered as well. BeiDou and GLONASS will additionally allow laser time transfer as the satellites are equipped with laser reflectors, offering to compare remote ground clocks with accuracy levels not achievable by radio systems. A first experiment with BeiDou demonstrated a precision of approximately 300 ps on the clock difference and relative frequency stability of $1 \cdot 10^{-14}$ for the comparison between a ground hydrogen maser and satellite rubidium clocks [41.62]. Finally, future generations of the GNSS, still under study, will open in the next decades still new horizons for time and frequency metrology.

# Annex A: Data Formats

Oliver Montenbruck, Ken MacLeod

GNSS formats have developed within government, industry, and academia. Their standardization has facilitated the efficient development of the GNSS industry. Current GNSS formats support metadata such as GNSS station, receiver, antenna and equipment calibration information, GNSS observation and broadcast navigation information and also GNSS products such as precise orbits, clock corrections, atmospheric measurements and station coordinates. RINEX, BINEX and IGS standards have been widely accepted and have become de facto standards. RTCM de jure standards on the other hand have developed within a standards organization and were adopted by industry. The development of new GNSS constellations has lead to the need for new formats and also encouraged a higher level of cooperation and integration between the GNSS standards groups. The most widely used GNSS standards are described in this chapter.

The GNSS community relies on a variety of standards that have been developed by different entities to facilitate an interoperable and efficient exchange of data and products between providers and users.

Even though most manufacturers employ company specific – and sometimes nondisclosed – message formats for communication with their GNSS receivers, a variety of nonvendor-specific formats have been developed by various nonprofit organizations [A.1]:

- RTCM SC-104 standard for Differential GNSS Services of the Radio Technical Commission for Maritime Services (RTCM)
- The GNSS-related parts of the NMEA 0183 interface standard of the National Marine Electronics Association (NMEA)
- The Receiver INdependent EXchange (RINEX) format developed by the International GNSS Service (IGS and RTCM SC-104)
- The BINary Exchange (BINEX) format of the University NAVSTAR consortium (UNAVCO).

A subset of these protocols and formats is typically supported in addition (or alternative) to proprietary data formats by all receivers. However, the various standards coexist with each other and the specific standard(s) supported by a given receiver depends largely on the type of user and application.

Complementary to the aforementioned standards for the exchange of GNSS receiver data, a variety of standards have been developed by the IGS to harmonize the exchange of products and metadata. Examples include:

- The Standard Product 3 (SP3) for orbit and clock information,
- The Clock RINEX format for the exchange of postprocessed satellite and receiver clock offset solutions,
- The IONosphere EXchange format (IONEX),
- The ANTenna Exchange (ANTEX) format for the provision of antenna phase center offsets and variations,
- The SiteLog format for station related information, and
- The Solution INdependent EXchange (SINEX) format for a harmonized exchange of estimated parameter sets.

In view of their primary application within the IGS community, the latter standards are generally more open and flexible than formal standards established by industrial or governmental standardization organizations.

Within the following sections the key features of the various standards are briefly described along with illustrating examples. For a more detailed discussion and concise definitions the readers are referred to the official documentation published by the corresponding organization.

## A.1 Receiver Formats

### A.1.1 NMEA 0183

The National Marine Electronics Association (NMEA) [A.2] is a nonprofit organization that was founded in 1957 by a group of electronic dealers with the goal of strengthening their relationships with electronic manufacturers. NMEA standards include the NMEA 0183 standard (using an ASCII text format) and a modernized version NMEA 2000 (binary). Both standards enable interoperability between marine electronics and support communications as well as data message standards.

The legacy standard (NMEA 0183 [A.3]), which has widely been adopted in GNSS receivers for marine, aeronautical and personal navigation, provides generic specifications of electrical requirements, protocols and message formats for a wide range of devices via a serial interface bus. Such devices may include electronic chart display and information systems, timekeeping equipment, radars, heading sensors, and sounders, LORAN-C (LOng RAnge Navigation) receivers, as well as receivers for global navigation satellite systems.

All NMEA 0183 data are transferred in the form of ASCII text messages via an RS422 (or, alternatively, RS232) serial interface. At a nominal rate of 4800 baud, approximately 600 characters can be transmitted per second, which is generally compatible with the needs of communicating position, speed and auxiliary data of slow moving vessels. Each device sending data is assigned a two letter *talker ID* reflecting the equipment type (Table A.1).

All messages start with a $ sign followed by a five-character string comprising the talker ID (`tt`) and a three character message ID (`mmm`):

```
$ttmmm,d1,d2,...*hh<CR><LF>
```

Following the message header, individual data fields `d1,d2,...` made up of numbers or characters are provided as a comma separated list. The sequence of parameters is specific for each message type. Optional values may be omitted but the separating comma must be provided to enable an unambiguous decoding. The message is terminated by an optional, two-character checksum (introduced by an asterisk) and a set of carriage-return line-feed characters.

An overview of commonly used NMEA 0183 messages for GPS devices is provided in Table A.2. In addition to these, vendor-specific messages are supported by the standard and are in use by various receiver manufactures. These are identified by $P and a three-letter vendor ID instead of the standard message header (e.g., $PUBX and $PASH for uBlox and Ashtech receivers), but otherwise follow the message concept described above.

As an example, the contents of the most widely employed GPS position message ($GPGGA) is illustrated in Fig. A.1. It provides the measured position in terms of geographic longitude and latitude along with the height above sea level but also the difference between ellipsoidal and geoid height assumed used in its computation. Since only the time-of-day is given in the $GPGGA message, a complementary $GPZDA date and time message may need to be output for a unique specification of the current epoch.

Even though common users are mostly interested in position-, velocity- and time-related information, the NMEA 0183 standard also supports a variety of lower-level observation data. This includes a list of visible satellites with information on their line-of-sight direction and received signal strength ($GPGSV) or the range residuals of all satellites used in the navigation solution ($GPGRS). While originally conceived for GPS receivers, the current NMEA 0183 standard also considers other GNSS constellations (GLONASS, Galileo) through dedicated message types and satellite/signal identifiers.

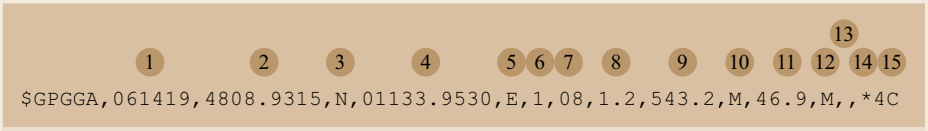
While substantial documentation on the format of the most popular NMEA 0183 GPS messages is available from public Internet sources, users should consider the official standard [A.3] as their primary source of information. It can be obtained directly from the NMEA web site [A.2] at a fee contributed to cover the work of this organization.

**Table A.1** Short list of selected NMEA 0183 talker identifications

| ID | Device |
|---|---|
| EC | Electronic chart display & information system |
| GP | Global Positioning System receiver |
| IN | Integrated navigation system |
| RA | Radar |
| WI | Weather instrument |
| ZQ | Timekeeper (quartz) |

**Table A.2** Common NMEA 0183 GNSS messages

| Msg ID | Description |
|---|---|
| $GPALM | GPS almanac data |
| $GPBOD | Bearing: origin to destination (UTC time, current position, true & magnetic bearing and distance to destination) |
| $GPDTM | Datum reference |
| $GPGGA | Global Positioning System fix data (UTC time, position, quality indicators, use of differential corrections) |
| $GPGLL | Geographic position latitude/longitude |
| $GPGRS | GPS range residuals |
| $GPGSA | GPS DOP and active satellites (positioning mode, fix type, satellites used in fix, PDOP, HDOP and VDOP) |
| $GPGST | GPS pseudorange noise statistics |
| $GPGSV | GPS satellites in view (number satellites in view, satellite number, azimuth and elevation, signal-to-noise ratio) |
| $GPHDT | True heading |
| $GPRMC | Recommended minimum navigation information (UTC time and date, latitude and longitude, speed over ground, status, etc.) |
| $GPVTG | Course over ground and ground speed |
| $GPZDA | Time and date (UTC time, calendar date, local time zone UTC offset) |



| | | |
|---|---|---|
| 1 | UTC time | ($06^{h}14^{m}19.0^{s}$) |
| 2 3 | Geographic latitude and hemisphere | (48°08.9315′ North) |
| 4 5 | Geographic longitude and hemisphere | (11°33.9530′ East) |
| 6 | Quality indicator | (1 = valid GPS navigation fix) |
| 7 | Number of satellites in view | (8) |
| 8 | Horizontal dilution of precision | (1.2) |
| 9 10 | Altitude above mean sea-level (geoid) and unit | (543.2 m) |
| 11 12 | Height of geoid above WGS-84 ellipsoid and unit | (46.9 m) |
| 13 | Age of differential corrections | (not used) |
| 14 | Differential reference station ID | (not used) |
| 15 | Checksum | (4C) |

**Fig. A.1** Example of an NMEA 0813 Global Positioning System Fix Data message ($GPGGA)

### A.1.2 RINEX

The Receiver INdependent EXchange (RINEX) format [A.4, 5] was developed under the leadership of *Werner Gurtner*, Astronomical Institute of Bern (AIUB), in 1989. A first version was defined to support the first large European GPS campaign (EUREF 89), where data from four different receiver types was converted from proprietary formats into RINEX 1. In 1990, RINEX 2 supporting both GPS and GLONASS was developed and released. In subsequent years RINEX 2 was continuously updated to support the needs of the GNSS community. The latest release RINEX 2.11 [A.6] supports GNSS observation data for GPS, GLONASS, Galileo, and SBAS, navigation data for GPS, GLONASS, and SBAS as well as a dedicated format for meteorological data.

Even though RINEX 2.11 is still widely used today within the GNSS community, its inherent limitations have long been recognized and led to the development of a new and fully generic multi-GNSS observation and navigation data format. RINEX 3.x was triggered by the gradual buildup of the Galileo system and the ongoing GPS modernization and offers more flexible and detailed observation signal codes than its predecessor. At the same time RINEX 3.x observation records were modified to enable a more human-readable structure. In RINEX 3 complete observation records (pseudorange, phase, signal-to-noise ratio and loss of lock indicator) are provided for each tracked signal. Originally worked out by W. Gurtner (AIUB) and Lou Estey (UNAVCO), the RINEX 3 standard is now jointly maintained by the IGS RINEX Working Group and the RTCM Special Committee 104 (Sect. A.1.3). RINEX Version 3.03 [A.7] released in 2015 supports observation and navigation data for the GPS, GLONASS, Galileo, BeiDou, QZSS, IRNSS/NavIC, and SBAS constellations.

To support both human and machine reading, all RINEX data files employ printable ASCII text formats with predefined field widths for data and labels. A maximum line width of 80 characters is defined for RINEX 2 but has been given up for RINEX 3.x observation files to better accommodate the large number of individual observations available with new and modernized navigation systems.

The complete documentation of the RINEX standard including past and current versions is available from the data server of the IGS web site [A.8].

*Observation Data.* RINEX 3 observation data files are made up of a variable-length header followed by a series observation record providing the measurements at each epoch. The header is itself made up of a series of individual records with a data section in columns 1–60 and descriptive labels in columns 61–80. It closes with a parameterless `END OF HEADER` line after which the first observation record is given.

As illustrated in Fig. A.2, the header starts with two lines identifying the file type (Observation Data) and format version (3.03) as well as details of its generation. Intermediate header records (shown in red) provide relevant metadata of the station such as a four-letter marker name and a site number, the employed equipment (receiver, firmware, antenna, radome), the approximate coordinates of a surveyed monument marker point, and, finally, the offset of the antenna reference point relative to that marker.

The header continues with a series of `SYS / # / OBS TYPES` records serving as in-

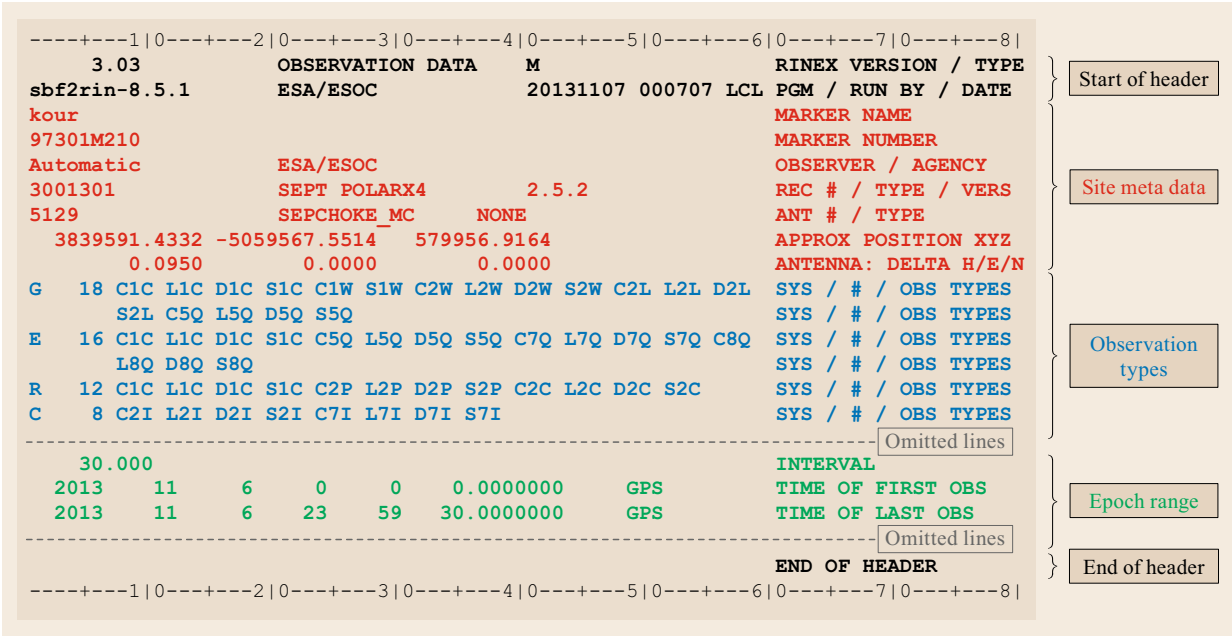


**Fig. A.2** Sample RINEX 3 observation file header from the IGS KOUR station in Kourou, French Guyana. Rulers in the first and last line have been added for illustration only and are not part of the actual file. Colors indicate different groups of header records. Selected records from the original RINEX file have been omitted for brevity

**Table A.3** RINEX 3 satellite system identifiers

| ID | System |
|---|---|
| G | GPS |
| R | GLONASS |
| S | SBAS payload |
| E | Galileo |
| C | BeiDou |
| J | QZSS |
| I | IRNSS/NavIC |

**Table A.4** RINEX 3 observation types and units

| ID | Observation | Units |
|---|---|---|
| C | Pseudorange | m |
| L | Carrier-phase | cy |
| D | Doppler | Hz |
| S | Signal strength ($C/N_0$) | dB-Hz |

dex of the observation types provided later for the satellites of each GNSS constellation. The individual constellations are identified by a single-character identifier in column 1 of these records. Currently supported systems and designations are summarized in Table A.3. Except for GPS (G) and SBAS (S) the satellite system identifiers are derived from the nation (Russia, Europe, China, Japan, India) operating the specific constellation.

The individual observations types for each constellation are described by a three-character observation code. Its first character identifies one of the four types of measurements defined in Table A.4. Even though additional pseudo-observations such as channel number (X) and ionospheric phase delay (I) are formally permitted by the RINEX 3 standard, they are rarely used by the community.

The second and third characters of the observation code indicate the frequency band (single-digit band number) and the specific modulation or tracking mode (single-letter attribute). Since many of the new and modernized signals comprise multiple components (e.g., an in-phase channel with navigation information and a dataless pilot code on the quadrature channel), distinct attributes are defined for the individual components (e.g., I, Q) and the combined tracking of both components (e.g., X). An overview of currently defined RINEX 3 observation codes is provided in Table A.5.

The observation codes listed in the `SYS / # / OBS TYPES` header records define the set of observations provided for satellites of a given constellation. In the Galileo example of Fig. A.2, a full set of four measurements (pseudorange, carrier-phase, Doppler, signal strength) is specified for tracking of the pilot components of the E1 Open Service (*1C), E5a (*5Q), E5b (*7Q) and E5 AltBOC (*8Q) signals.

**Table A.5** RINEX 3 observation codes for carrier-phase observations. Corresponding observation codes with initial letters C, D, and S apply for pseudorange, Doppler and signal strength observations

| System | Band | Code | Description |
|---|---|---|---|
| GPS | L1 | L1C | C/A-code |
| | | L1S, L1L, L1X | L1C (data, pilot, combined) |
| | | L1P | P-code (unencrypted) |
| | | L1W | Semicodeless P(Y) tracking |
| | | L1Y | Y-code (with decryption) |
| | | L1M | M-code |
| | | L1N | codeless |
| | L2 | L2C | C/A-code |
| | | L2D | Semi-codeless P(Y) tracking (L1 C/A+(P2-P1)) |
| | | L2S, L2L, L2X | L2C-code (medium, long, combined) |
| | | L2P | P-code (unencrypted) |
| | | L2W | Semicodeless P(Y) tracking |
| | | L2Y | Y-code (with decryption) |
| | | L2M | M-code |
| | | L2N | codeless |
| | L5 | L5I, L5Q, L5X | L5 (data, pilot, combined) |
| GLONASS | L1 | L1C | C/A-code |
| | | L1P | P-code |
| | L2 | L2C | C/A-code |
| | | L2P | P-code |
| | L3 | L3I, L3Q, L3X | L3 (data, pilot, combined) |
| SBAS | L1 | L1C | C/A-code |
| | L5 | L5I, L5Q, L5X | L5 (data, pilot, combined) |
| Galileo | E1 | L1A | PRS signal |
| | | L1B, L1C, L1X | OS (data, pilot,combined) |
| | | L1Z | PRS + OS(data+pilot) |
| | E5a | L5I, L5Q, L5X | E5a (data, pilot, combined) |
| | E5b | L7I, L7Q, L7X | E5b (data, pilot, combined) |
| | E5 | L8I, L8Q, L8X | E5 AltBOC (data, pilot, combined) |
| BeiDou (BDS-2) | B1 | L2I, L2Q, L2X | B1I(OS), B1Q, combined |
| | B2 | L7I, L7Q, L7X | B2I(OS), B2Q, combined |
| | B3 | L6I, L6Q, L6X | B3I, B3Q, combined |
| QZSS | L1 | L1C | C/A-code |
| | | L1S, L1L, L1X | L1C (data, pilot, combined) |
| | | L1Z | L1-SAIF signal |
| | L2 | L2S, L2L, L2X | L2C-code (medium, long, combined) |
| | L5 | L5I, L5Q, L5X | L5 (data, pilot, combined) |
| | E6 | L6S, L6L, L6X | LEX signal (short, long, combined) |
| IRNSS/NavIC | L5 | L5A | SPS Signal |
| | | L5B, L5C, L5X | RS (data, pilot, combined) |
| | S | L9A | SPS signal |
| | | L9B, L9C, L9X | RS (data, pilot, combined) |

Later, in the observation section of the file, a total of 16 matching measurements will be provided for each Galileo satellite.

A (truncated) example of an observation record corresponding to the header of Fig. A.2 is shown in Fig. A.3. The record starts with an epoch line (marked by a ">" character in column 1) specifying the date and time of the observations (here: 6 Nov 2013 00:00:00.0 GPS time) and the number of tracked satellites (here: 20). Subsequently the observations are provided in a single line for each satellite. The individual satellites are identified in columns 1–3 by the satellite number. This is made up of the satellite system indicator and a two-digit number identifying the transmitted pseudo-random noise (PRN) code or, in case of GLONASS, the slot number of the tracked satellite. Each observation is stored in a fixed field of 14 characters and with three trailing digits after the decimal point. Carrier-phase and pseudorange observations are furthermore complemented by an optional loss-of-lock indicator (0, blank, or 1) and/or a single-digit signal-strength indicator in the two cells adjacent to the actual measurement value.

Although the RINEX format supports the loss-of-lock indicator for each observation type, it is common practice to only indicate it on the phase observations. Likewise, the single-digit signal-strength field is often omitted if the signal strength (in dB-Hz) is explicitly provided as an observation type.

*Hatanaka Compression.* A practical problem associated with the transfer and storage of RINEX observation data is the large file size caused by the use of

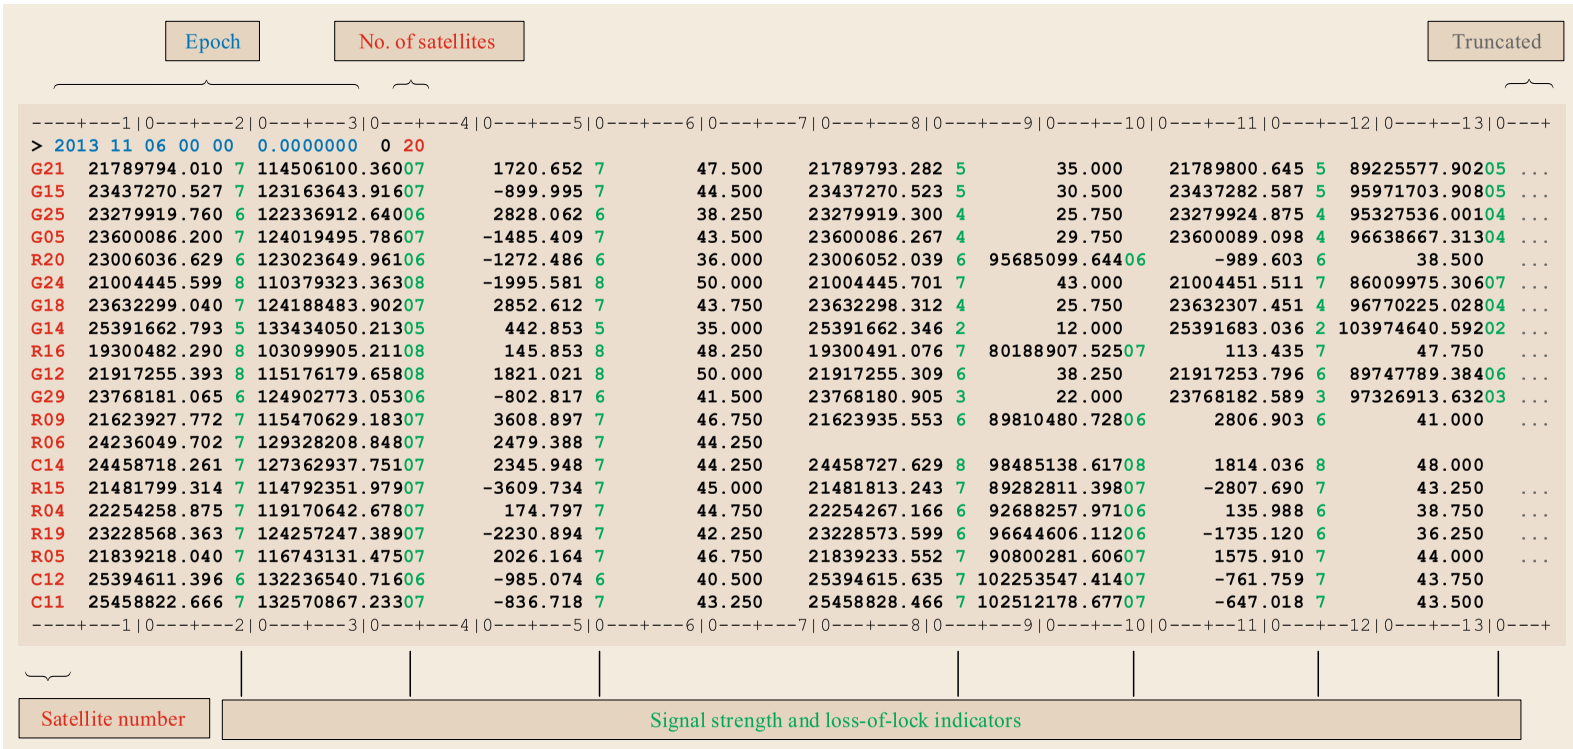

**Fig. A.3** Sample observation record from a RINEX observation file obtained by the IGS KOUR station in Kourou, French Guyana. Rulers in the first and last line have been added for illustration only and are not part of the actual file

an ASCII text format. Considering a 30 s sampling, a multi-GNSS reference station with 40 or more commonly tracked satellites provides daily RINEX 3 observations of about 25 MB and an even higher data volume is obtained with 1 Hz high-rate data. This problem can partly be alleviated through standard compression tools such as compress, zip, and rar, which achieve a compression ratio of 1 : 3 to 1 : 4 for typical RINEX files.

A complementary compression technique [A.9], which retains the ASCII representation but reduces the high level of redundancy in the observation data themselves has been developed by *Yuki Hatanaka* at the Geospatial Information Authority (GSI), Japan. It is based on the observation that a time series of consecutive measurements may better be represented by an initial value and the differences between epochs, since the differences are smaller in size than the absolute values and require a reduced number of digits.

Hatanaka compression retains most of the RINEX file header but replaces the observation records with the differenced data and uses a "&" separator between data fields to minimize the overall amount of white space. The resulting *Compact RINEX* format already achieves a file size reduction by a factor of 3–4. In combination with standard file compression tools, an overall reduction by a factor of approximately eight is achieved compared to the original RINEX file. It should be noted that the Hatanaka compression is lossless and enables a full recovery of the original observations data upon decompression.

*Navigation Data.* As a complement to the observation data format discussed above, the RINEX standard also defines a navigation data format for the exchange of broadcast ephemeris information. These broadcast ephemerides comprise the orbit and clock parameters as well as auxiliary data transmitted by each GNSS satellite for use in real-time navigation. Even though the broadcast ephemerides are generally less accurate than postprocessed ephemeris products, the navigation data files are frequently used for preprocessing of GNSS data (e.g., elevation screening), relative positioning, and as a priori information for precise GNSS orbit and clock determination.

While distinct GPS and GLONASS files were foreseen in early versions, the current RINEX 3 standard supports mixed files with navigation data for all GNSSs. Similar to the observation data format, navigation files are fixed-format text files but are limited to 80 characters per line. The file header follows the same concepts as introduced before and starts with two lines identifying the file type and format version. For the purpose of illustration an annotated format example is given in Fig. A.4.

All header parameters are optional and may comprise different types of ionospheric model parameters and time conversion parameters. These include the eight coefficients $\alpha_0, \ldots, \alpha_3$ and $\beta_0, \ldots, \beta_3$ of the Klobuchar model for GPS and QZSS users or the Klobuchar-style model employed by BeiDou. For Galileo, a set of four parameters $A_0, \ldots, A_3$ is provided that enables ionospheric corrections of single-frequency observations with the NeQuick model. An overview of these models is provided in Chap. 6 and references therein, while detailed information on the application of the broadcast ionospheric parameters is given in the interface specifications of the individual GNSSs [A.10–14].

The remaining header parameters provide the relation of different GNSS timescales among each other and with UTC. These include the number of UTC leapseconds since 1980 (or, equivalently the integer seconds time difference between GPS time and UTC) as well as linear polynomials for the fractional time differences (which typically amount to some tens or at most hundreds of nanoseconds). The individual time correction parameters are identified by a 2 + 2 character code in columns 1–4 of the `TIME SYSTEM CORR` header lines and contain the polynomial coefficients ($A_{f0}$, $A_{f1}$) as well as the corresponding reference epoch (week and seconds of week). While not a mandatory header line, provision of the leapseconds information is strongly recommended since it facilitates the translation between the native time systems of each constellation and enables the processing of the subsequent ephemeris data in a consistent timescale.

Following the header, a series of ephemeris data sets for individual satellites and epochs are given. Following the satellite identification and reference epoch, the various ephemeris parameters are provided in fixed fields of 19 characters. The set of parameters and their total is predefined for each individual constellation (GPS, GLONASS, BeiDou, Galileo, QZSS, IRNSS/NavIC, and SBAS) and reflects the different types of information made available in the various types of navigation messages.

Common to all constellations, the satellite clock offset is specified through a clock reference epoch ($t_{oc}$) and a clock offset polynomial ($a_{f0}$, $a_{f1}$, and, for most systems, $a_{f2}$). For many GNSSs, the clock offset information is complemented by differential code biases (known as timing group delay (TGD), broadcast group delay (BGD) or intersignal correction (ISC) parameters). These enable a consistent processing of the transmitted clock offsets when using single-frequency observations or a different set of signals than the ones used by the control segment to determine the broadcast clock offsets. Clock-related parameters in the format example of Fig. A.4 are highlighted in blue color.

**Fig. A.4** Format example of a multi-GNSS RINEX navigation file (*top*). Layout of Galileo and GLONASS ephemeris records (*bottom*; clock and orbit parameters are highlighted by *blue* and *red color*)

Orbit information parameters provided in the individual broadcast navigation data vary among the different constellations, but fall in either of two basic categories: orbital elements ($\sqrt{a}$, $e$, $i_0$, $\Omega_0$, $\omega_0$, $M_0$) and perturbation coefficients ($di/dt$, $d\Omega/dt$, $C_{rc}$, $C_{rs}$, $C_{ic}$, $C_{ic}$, $C_{uc}$, $C_{us}$) for use with a perturbed Keplerian orbit

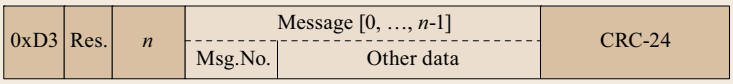

**Fig. A.5** RTCM SC-104 v3.x message protocol. The first field contains the 8 bit preamble (hex value 0xD3)

model or Cartesian state vectors ($x$, $y$, $z$, $\dot{x}$, $\dot{y}$, $\dot{z}$, $\ddot{x}$, $\ddot{y}$, $\ddot{z}$) for numerical integration or polynomial interpolation of the trajectory across short time intervals. Details of the orbit models and the employed parameters are provided in Chap. 3 as well as the interface specifications of the individual constellations [A.10–15]. Broadcast ephemerides with orbital elements are presently used for GPS, QZSS, Galileo, BeiDou, and IRNSS/NavIC while state vectors are provided by the GLONASS and SBAS satellites. The corresponding parameters are highlighted using red color in the format example of Fig. A.4.

Up to version 3.03 the RINEX navigation format supports only legacy navigation data (i. e., one parameter set per constellation), but will be extended for CNAV, CNAV2 and other modernized broadcast ephemeris data sets in subsequent releases.

### A.1.3 RTCM SC-104 DGNSS Data Format

The Radio Technical Commission for Maritime Services (RTCM) was formed as a United States government advisory committee in 1947. Currently, the RTCM is an international nonprofit scientific, professional and educational organization that is supported by its members from all over the world. Membership consists of both corporate and government organizations. RTCM members charter Special Committees (SC) to address in-depth radio communication and radio navigation issues, with the goal of supporting interoperability.

RTCM Special Committee 104 (RTCM-SC104) was chartered to address differential global navigation satellite systems (DGNSSs). Initially, RTCM SC-104 focused on standards and protocols for differential GPS for maritime applications. SC-104's mandate has grown to support not only maritime differential GNSS, but also real-time kinematic and precise GNSS data formats and Network Transport of RTCM using Internet Protocol (NTRIP, [A.16]).

The following paragraphs provide an overview of the RTCM SC-104 standard for DGNSS services based on the latest version 3.3 [A.17]. A full specification is available from the RTCM [A.18] at a service fee, which contributes to covering the work of this organization.

*Message Types and Format.* RTCM SC-104 messages are primarily designed for real-time GNSS applications and use a binary protocol to minimize the overall data volume that needs to be transferred between providers and users. While early versions made use of a message format made up of fixed-length data words with parity protection similar to that of the GPS navigation message, a revised, variable-length message format was introduced for use from version 3.0 onwards. It comprises a header with an 8 bit preamble, 6 bit reserved fields and a 10 bit message length field (Fig. A.5).

Following the header, a data field of up to 1023 bit is provided and the message concludes with a 24 bit cyclic redundancy check (CRC) checksum to ensure integrity of the transmitted data. Except for zero-length filler messages, all messages start with a 12 bit message number that identifies the message type and provides the key to decoding the subsequent message data fields.

RTCM SC-104 v3.x defines various groups of messages for observation data, network RTK corrections, auxiliary and metadata as well as state space correction data (Table A.6). Various multisignal messages provide similar parameters albeit in different combinations and/or resolutions. In this way positioning services of different accuracy may be implemented that make best use of the available communication bandwidth.

*Multisignal Messages.* Early versions of the RTCM SC-104 standard were strongly focused on the GPS and GLONASS systems and their legacy L1/L2 signals. As of version 3.2, the concept of multisignal messages (MSMs, [A.19]) has been introduced, to establish a truly generic framework for observations of all GNSS constellations and all transmitted signals.

The multisignal messages employ a highly efficient packing scheme, which minimizes the overall amount of data that need to be transmitted. For each observed satellite, the pseudorange and carrier-phase observations are decomposed into the sum of a *rough range* and a *fine range*. The rough range at each epoch is common to all observations of the given satellite collected simultaneously on the individual signals. The remaining fine range reflects the differences in ionospheric path delays and systematic GNSS satellite and receiver biases. It is generally confined to less than $\pm 300$ m, which requires considerably fewer data bits for storage than the original value.

Other MSM features include the signal and satellite masks, which serve as an index for the overall set of tracked signals (across all satellites of a constellation) and the subset tracked for a specific satellite. In this way, the presence of modernized signals available for only part of a constellation (e.g., L2C on GPS Block

**Table A.6** RTCM SC-104 v3 message groups

| Groups | Type | Messages |
|---|---|---|
| Experimental messages | | 0–100 |
| Observations | GPS L1, L1/L2 | 1001–1004 |
| | GLONASS L1, L1/L2 | 1009–1012 |
| | Multi Signal Messages for individual GNSSs | 1071–1077 (GPS)<br>1081–1087 (GLONASS)<br>1091–1097 (Galileo)<br>1101–1107 (SBAS)<br>1111–1117 (QZSS)<br>1121–1127 (BeiDou) |
| Site metadata | Station coordinates, receiver and antenna description | 1005–1008, 1032–1033 |
| Network RTK corrections | Auxiliary station data | 1014 |
| | Geometric and ionospheric corrections | 1015–1017, 1037–1039 |
| | Network RTK residuals and FKP gradients | 1030–1031, 1034–1035 |
| Auxiliary information | System parameters | 1013 |
| | Satellite ephemeris | 1019, 1020, 1042, 1044, 1045, 1046 |
| | Text (unicode) | 1029 |
| | GLONASS code/phase biases | 1230 |
| Transformation parameters | | 1021–1027 |
| State Space Representation parameters | Orbit & clock corrections, code biases, URA | 1057–1062 (GPS)<br>1063–1068 (GLONASS) |
| Proprietary messages | | 4001–4095 |

IIR-M and L5 on Block IIF) can be supported without requiring empty or padded data fields for older satellites.

Finally, a total of seven different multisignal messages are defined for each constellation. The individual message types are distinguished by the final digit of the message number and offer different sets of elementary observations (pseudorange, carrier-phase, signal strength, and Doppler) at different levels (compact, full) of range and resolution.

*Network-RTK Messages.* Network-RTK refers to real-time kinematic positioning (RTK) using correction data derived from a network of terrestrial reference stations (Chaps. 26 and 31). Compared to a single reference station, the network-based corrections can be applied in a wider region and the quality of carrier-phase ambiguity resolution becomes less dependent on the base station distance. The RTCM SC-104 standard offers a harmonized framework for transmitting such corrections to the user independent of the underlying network architecture. Both GPS and GLONASS network-RTK services are supported through dedicated messages. Aside from station-related information provided in the auxiliary station data message, *geometric* (nondispersive) and *ionospheric* (dispersive) correction data may be transmitted in distinct or combined messages. Details of the respective messages and the applicable processing conventions are provided in the RTCM SC-104 standard [A.17]. Another class of network-RTK messages comprises the *Network-RTK Residual Error* messages, which are used to implement concepts such as virtual base stations to improve the RTK service for specific users.

*State-Space Representation Messages.* The state-space representation (SSR) represents a new concept for the provision of correction data in real-time kinematic precise point positioning (PPP-RTK) applications. Rather than providing combined corrections in observation space, the SSR approach employs decomposed corrections to remove individual GNSS error sources [A.20]. These include satellite position corrections (in three dimensions) and satellite clock corrections as well as code biases. Different message types are supported for individual or combined orbit and clock corrections. Furthermore, distinct high-rate clock correction messages are available to ensure that satellites with fast changing atomic clocks can be accurately characterized. The SSR concept also foresees the provision of vertical total electron content (VTEC) information for single-frequency users, even though these are not yet part of the RTCM SC-104 standard. The generic nature of the SSR corrections makes them largely independent from the user location and provides the basis for global PPP applications.

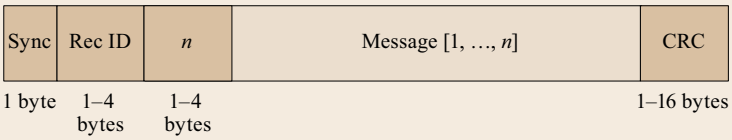

**Fig. A.6** Basic BINEX message protocol

### A.1.4 GNSS BINary Exchange (BINEX) Format

The BINary Exchange (BINEX) format, is a GNSS format standard that supports both research and operational applications. BINEX was developed at UNAVCO under the leadership of *Lou Estey* (UNAVCO) to achieve a better data compression and increased reliability for real-time data streams from permanent GPS monitoring stations [A.21, 22]. Other than common binary formats, BINEX is designed to support both little-endian and big-endian word-orders, which allows use on a wide range of hardware platforms and processors. Also, a wide range of message lengths is supported through checksum and message number fields with a varying number of bytes. The BINEX format supports observation and navigation messages for all current GNSS constellations as well as metadata messages to encapsulate site-specific parameters. BINEX is supported by major GNSS receiver manufacturers (Trimble, Topcon, Javad, Leica, Septentrio) and is continuously extended and refined to meet the needs of new signals and systems. The official documentation of the BINEX format is maintained as a living document on the UNAVCO web site [A.23].

*Record Structure.* BINEX data files are made up of a sequence of consecutive BINEX data records that can be processed independent of each other. Since BINEX files do not contain a file header, multiple BINEX files can easily be concatenated for further processing without the need for special tools. The BINEX standard supports various generic forms of message frames for different applications. These are designed to enable any foreseeable type of GNSS receiver data, auxiliary information as well as final data products.

In their most simple (and widely used) form, each record comprises a header with synchronization byte, record identifier and message length field before the actual message data and concludes with a checksum field (Fig. A.6). The message itself may contain additional fields (subrecord ID, etc.) to further distinguish the actual contents.

Both the record identifier and the message length are stored in an *unsigned BINEX integer* (ubnxi) data word, which occupies between 1–4 byte depending on the size of the encoded value. Likewise, different types of checksum (1 byte XOR checksum, 2 byte CRC-16, or 4 byte CRC-32) are employed depending on the length of the message data field.

**Table A.7** Common BINEX record types

| ID | Sub ID | Contents |
|---|---|---|
| 0x00 | | Site Metadata |
| 0x01 | | GNSS Navigation Information |
| | 0x00 | ● coded (raw bytes) GNSS ephemeris |
| | 0x01 | ● decoded GPS ephemeris |
| | 0x02 | ● decoded GLONASS-FDMA ephemeris |
| | 0x03 | ● decoded SBAS ephemeris |
| | 0x04 | ● decoded Galileo ephemeris |
| | 0x05 | ● decoded Beidou-2/Compass ephemeris |
| | 0x06 | ● decoded QZSS ephemeris |
| | 0x07 | ● decoded IRNSS ephemeris |
| | 0x41–0x47 | ● raw navigation subframe/block/page for individual constellations |
| 0x7d | | Receiver Internal State |
| | 0x00 | ● Temperature and power |
| 0x7e | | Ancilliary Site Data Prototyping |
| | 0x00 | ● Meteorological and local geophysical data |
| 0x7f | | GNSS Observable Prototyping |
| | 0x00 | ● for JPL LEO support network |
| | 0x01 | ● for UCAR COSMIC and GPS/MET |
| | 0x02 | ● for UCAR Suominet |
| | 0x03 | ● for EarthScope |
| | 0x04 | ● for EarthScope |
| | 0x05 | ● Generic multi-GNSS observation data |

*Message Types.* While BINEX is a highly generic protocol intended to support the binary transfer of all types of GNSS-related information, only a limited number of messages are widely used at present. All of these employ a 1 byte record identifier and belong to one of five major categories shown in Table A.7.

For most record types, the message fields start with a 1 byte subrecord ID to further distinguish the data contained within. Even though records 0x7e and 0x7f are formally considered as prototype messages that shall eventually be replaced by 0x03 and 0x02 messages, some of them (such as 0x7f 0x05) represent a de facto standard and have already been adopted by various receiver manufacturers.

In addition to the public messages described in Table A.7, various record identifiers have been assigned to different institutions or companies to enable the implementation of private BINEX messages. These make use of record IDs beyond 0x7f (= 127) that require more than one byte for ubnxi encoding.

## A.2 IGS Product and Metadata Formats

Complementary to the text and binary formats for exchange of receiver-related information (observations, navigation data, metadata, etc.) a wide range of different formats have been developed in the frame of the International GNSS Service (IGS). These enable a consistent exchange of GNSS data products and auxiliary information among users and analysis centers. Most common examples include precise orbit and clock information, atmospheric products, antenna information and site metadata, all of which are described in this section. Current and past versions of the various format specifications are available in electronic form through the IGS web site [A.8].

### A.2.1 SP3 Ephemeris Format

The *Standard Product 3 (SP3)* format defines a widely used standard for the provision of precise orbit and clock data of GNSS satellites. Aside from RINEX observation data, the SP3 orbit and clock information forms the basis of most precise point positioning (PPP) applications. IGS orbit and clock products are consistently made available in SP3 format by the various analysis centers and can be utilized by all common PPP software packages.

SP3 originates from two types of GPS orbit data formats (SP1, SP2) developed by the US National Geodetic Survey (NGS). Other than its predecessors that were limited to orbit-only data, SP3 also incorporates clock data and accuracy information [A.24]. Even though both text and binary versions have originally been defined, only the former has found widespread acceptance and continues to be developed. In its latest version, SP3d, the format supports all GNSS constellations using satellite identifiers consistent with those of the RINEX standard (Sect. A.1.2). To facilitate a joint use for precise orbit information of satellites in low Earth orbit (LEO), a constellation letter "L" has furthermore been introduced for non-GNSS satellites in addition to the designations in Table A.3.

Even though the SP3 format is specifically designed to combine orbit and clock offset information in a fully consistent manner, clock data are often desired at higher rate. In view of their smooth motion, GNSS orbits with periods of 12–24 h can readily be interpolated from known values at a 15 min spacing or more. Clock variations, on the other hand, are governed by stochastic processes and a smaller sampling interval (down to 30 s or less) is required for accurate interpolation. PPP users may therefore prefer to complement SP3 orbit data with separate high-rate clock data (Sect. A.2.2), provided that both products have been generated by a common provider, using fully consistent processes.

*Format Description.* The basic format and contents of an SP3d orbit and clock data file are illustrated in Fig. A.7 based on the comprehensive specification in [A.25]. It comprises a header section with auxiliary information for the proper processing of the subsequent data records. These provide orbit and clock data as well as optional accuracy and event information on an equidistant epoch grid for a previously specified number of satellites and epochs. While the format was originally limited to a line width of 80 characters and a 22-line header, a larger number of header lines has been introduced in SP3d to accommodate more than 85 satellites and extended comments.

The file header comprises various blocks of lines (introduced by #, +, %, and / characters), which provide relevant indices and parameters for the proper interpretation of the subsequent orbit, clock and accuracy data records.

The first header line indicates the format version ("d" for SP3d in column 2) and distinguishes position-only files from files with position and velocity information ("P" or "V" in column 3). Thereafter the calendar date of the initial epoch and the number of data points is provided. Along with the stepsize provided in columns 25–38 of line 2, the epochs of all subsequent orbit and clock data records are fully defined by this header information. Complementary to the specification of the start epoch in line 1, a (redundant) representation in terms of weeks and seconds as well as integer and fractional Modified Julian Day count are given in line 2. Further information in the first header includes an indicator for the employed data (e.g., u+U for undifferenced carrier-phase and code observations), the coordinate system descriptor, the type of orbit product and an acronym of the responsible institution.

Following these initial header lines, a block of five or more lines introduced by a single + character specifies the total number of satellites, the satellite identifiers (constellation letter plus number) and the sequence of satellites for which orbit and clock data are later given in the epochwise SP3 data blocks. The next header block (highlighted in red in Fig. A.7) provides integer-valued orbit accuracy indicators $a$ for each spacecraft, from which the standard deviation $\sigma_{\mathrm{orb}} = 2^a$ mm of the respective orbit errors across all epochs can be obtained.

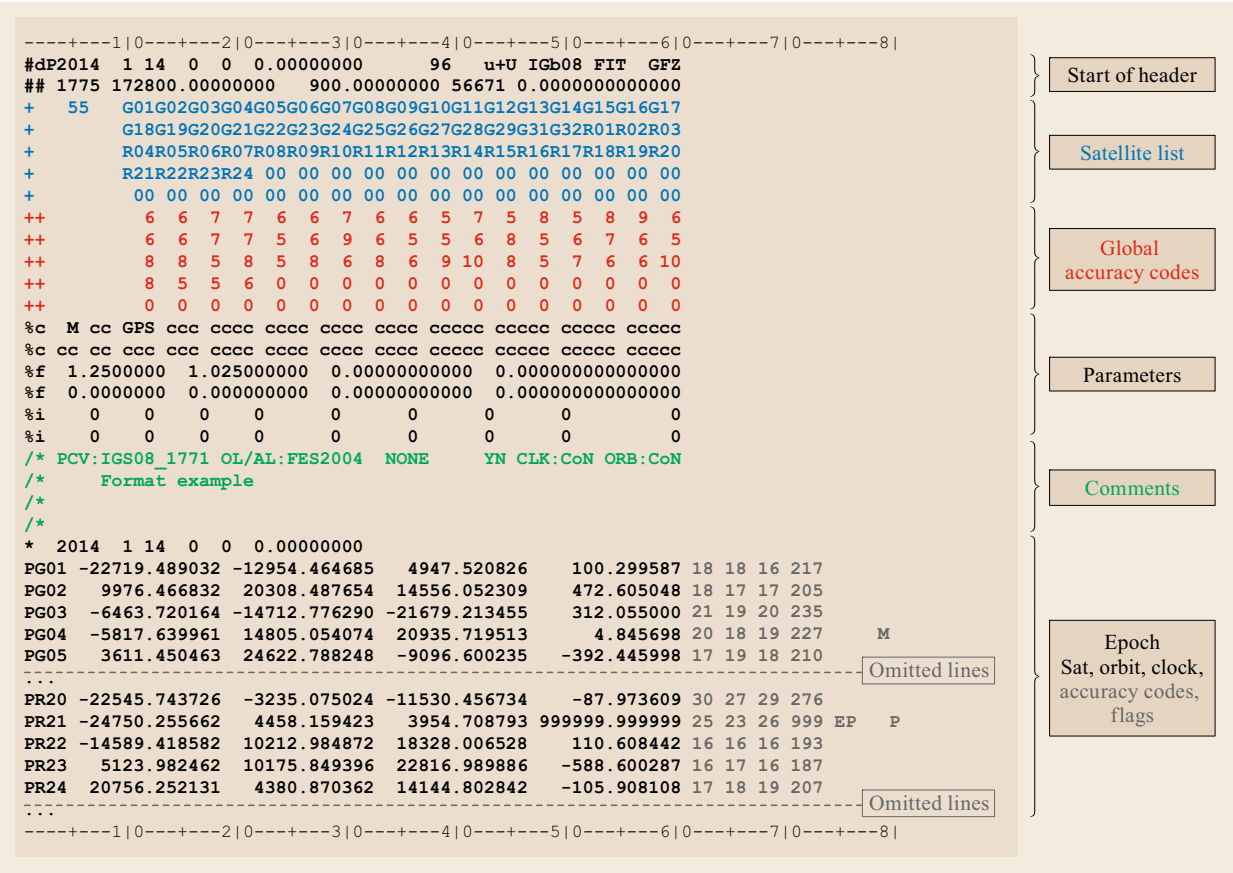

**Fig. A.7** SP3d format example

The header continues with a block of auxiliary parameters, most notably the time system indicator in the first line starting with `%c`. It concludes with a block of four or more comment lines used within the IGS to identify various processing conventions such as antenna offset or tide models.

Each of the subsequent data blocks starts with an epoch header line specifying the epoch date and time, which must be consistent with the sequence of the record and the epoch grid defined in the file header. Thereafter, the position (in units of km) and clock offset (in $\mu$s) are specified for each satellite in lines marked by an initial "`P`" character. For files containing both position and velocity information, each position record is complemented by a subsequent velocity record (indicated by the initial "`V`" character), which provides the spacecraft velocity (in units of 0.1 m/s) and clock rate (in $10^{-4}$ $\mu$s). Unknown or invalid data in both records are indicated by zero values (position and velocity) or 999999.999999 (clock offset and clock rate).

Fig. A.7 also illustrates the use of optional epoch- and componentwise accuracy indicators (columns 62–73) as well as additional flags (columns 75–80 for clock events ("`E`"), orbit maneuvers ("`M`") and predicted orbit or clock data ("`P`"). Similar to the global accuracy indicators described above, these indicators provide the exponent $a$ for computing the standard deviation of the respective value using a relation of the form $\sigma = b^a$. Other than using a fixed base of $b = 2$, the base value can be selected by the provider and is separately specified in the `%f` header line for position and clock data. In this way a better resolution of the accuracy information is achieved. Using epochwise accuracy indicators is optional but enables a better distinction of predicted orbit and clock information from values based on actual observations.

For completeness, we note that the SP3 standard also foresees the use of an optional position and clock correlation record (EP) as well as a corresponding EV record for velocity and clock rate information. These records enable provision of a fully four-dimensional covariance matrix to describe the statistical properties of the respective data. However, neither the position nor the clock correlation records

have found widespread acceptance in official IGS products.

*Interpolation.* Based on its history, SP3 is designed as a tabular ephemeris format, which provides all data at equal intervals. This is a natural choice for orbit information generated by numerical orbit prediction software and facilitates the interpolation of intermediate values. Having said that, some synchronization may be required to ensure that clock data can be made available at the same epochs as the orbit information. Even though the SP3 format supports the joint provision of epochwise position and velocity data, it has been recognized that position-only information is generally sufficient, since velocity can be obtained from these data through differentiation of an interpolating function. Versions with and without complementary velocity (and clock rate) data are therefore supported by the SP3 format. Aside from their reduced size, position-only SP3 files ensure full consistency of the derived position-velocity information and avoid the cumbersome transformation of inertial to Earth-fixed velocity data.

Various forms of interpolators for GNSS ephemeris data have been proposed and studied in the literature [A.26–28], but polynomial interpolation is probably most widely used. A variety of algorithms have been developed for this purpose [A.29], among which the Lagrange method appears best suited when multiple values (such as the $x$-, $y$-, and $z$-coordinates of the position vector) have to be interpolated on the same epoch grid. It is therefore commonly recommended for use with SP3 orbit data [A.24, 30, 31].

Given a set of $n+1$ epochs $t_i$, the elementary $n$th-order Lagrange polynomials

$$l_i(t) = \prod_{j=0, j\neq i}^{n} \frac{(t-t_j)}{(t_i-t_j)} \qquad (i = 0, \ldots, n) \tag{A.1}$$

are first computed. These are designed to vanish at all but one grid point, i. e.,

$$l_i(t_j) = \left\{ \begin{array}{c} 1 \\ 0 \end{array} \right\} \quad \text{for} \quad \left\{ \begin{array}{l} i = j \\ i \neq j \end{array} \right\} . \tag{A.2}$$

With this result the interpolating polynomial of order $n$ can conveniently be expressed as a linear combination

$$\boldsymbol{r}(t) = \sum_{i=0}^{n} \boldsymbol{r}_i l_i(t) , \tag{A.3}$$

where $\boldsymbol{r}_i$ denotes the values of the position vectors at the given grid points. The velocity at time $t$ can likewise be obtained through Lagrange interpolation

$$\boldsymbol{v}(t) = \sum_{i=0}^{n} \boldsymbol{v}_i l_i(t) , \tag{A.4}$$

based on known values $\boldsymbol{v}_i$ at the grid epochs. Alternatively, the interpolating polynomial (A.3) may be differenced to obtain the relation

$$\boldsymbol{v}(t) = \sum_{i=0}^{n} \boldsymbol{r}_i l_i'(t) , \tag{A.5}$$

where

$$l_i'(t) = \sum_{\substack{k=0 \\ k\neq i}}^{n} \frac{1}{(t-t_k)} \cdot \prod_{\substack{j=0 \\ j\neq i}}^{n} \frac{(t-t_j)}{(t_i-t_j)} \tag{A.6}$$

denotes the time derivative of the $n$th-order Lagrange polynomial. It may be noted that the above expressions are also applicable for interpolation of nonequidistant values. However, a constant step size (as implied by the SP3 format) simplifies the computation of the Lagrange polynomials and contributes to an even distribution of interpolation errors.

At the 15 min spacing adopted for most GNSS orbit products, a ninth-order polynomial using an equal number of grid points on both sides of the interpolation epoch offers an interpolation accuracy compatible with the numerical resolution of the SP3 orbit data [A.26]. However, larger interpolation errors may be encountered near the beginning or end of the ephemeris period [A.27]. Also, high-order interpolation must not be applied to clock data, which are not as smooth as the orbit information. Here, linear interpolation or at most cubic interpolation [A.32] is recommended.

*Conventions.* To enable a consistent use of multi-GNSS orbit and clock files, the SP3 standard requires that information for all satellites shall refer to a common time and reference system identified in the file header. Despite this, further specifications by the product provider will typically be required for the proper interpretation of the data.

Within the IGS, GNSS satellite positions provided in the SP3 precise ephemeris products are referred to the spacecraft center-of-mass and a mean-crust-fixed terrestrial coordinate system (which may differ by a few millimeters from a barycentric system due to tidal deformation of the Earth).

Clock data, in contrast, refer to an adopted antenna phase center and a conventional dual-frequency signal combination (L1/L2 P(Y)-code observations for GPS).

**Fig. A.8** RINEX clock format example

Furthermore, the dominant relativistic contribution to the apparent clock caused by the orbital eccentricity has been removed from the provided clock data to better reflect the clock's proper time. As such, a corresponding correction must be added to clock offsets retrieved from the SP3 ephemeris for the proper modeling of GNSS observations (Sect. 19.2).

### A.2.2 Clock RINEX Format

The *RINEX Extensions to Handle Clock Information* [A.33] were introduced in 1998 as a generic framework for the exchange of general clock offset information. Today, the format is primarily used to provide precise GNSS satellite and receiver clock data derived from the analysis of global networks of monitoring stations. Despite its name, the Clock RINEX format has therefore evolved to a GNSS product format rather than a receiver data format. Clock RINEX data are widely used for precision point positioning (PPP) and also to monitor the performance of GNSS satellite clocks and atomic clocks of national time standard laboratories.

The structure and contents of a Clock RINEX file are illustrated in Fig. A.8. In accordance with RINEX observation and navigation data formats (Sect. A.1.2), the clock data file header is made up of a sequence of header lines identified by their labels in columns 61–80. These mandatory or optional header lines provides auxiliary information for the proper interpretation of the actual clock data and are terminated by a `END OF HEADER` line. Key parameters provided within the header comprise a time system indicator, information on the signal or signal combination used in the clock offset determination for each GNSS constellation, information on the application of phase center offsets, phase pattern variations and differential code biases, and the station clock serving as a reference for all clock offsets. Additionally, lists of all stations and satellites used in the clock offset estimation process are provided.

The subsequent data section of the RINEX clock file provides clock offset values for each of these stations and receivers on an epoch-by-epoch basis. The respective lines are marked by a leading "AR" (for analysis data, receivers) and "AS" (for analysis data, satellites) and contain explicit epoch information. The remaining fields specify the number of data items followed by the clock offset and, optionally, its standard deviation. Both values are provided in units of seconds. If desired, clock rate and acceleration as well as their standard deviation may also be given on a continuation line.

A fixed stepsize is not required but it is a common practice among the IGS analysis centers. Depending on the product and provider, step sizes of 5 min and 30 s are most frequently used, but 5 s products are also available for high-precision applications. Linear interpolation of clock data between consecutive epochs is recommended in view of the stochastic nature of typical clock variations.

### A.2.3 SINEX

The Solution INdependent EXchange (SINEX) format [A.34] was originally designed to facilitate the exchange and distribution of station coordinates, velocities and Earth orientation parameters (EOP) between the IGS analysis centers. These parameters are routinely estimated from the processing of the global IGS GNSS network using a wide range of software tools. A common format was therefore required to enable a comparison and combination of the analysis center solutions. SINEX has been used for this purpose from 1995 onwards and received continuous amendments to handle new parameters over the past decades.

The format has also been adopted and extended to meet the needs of Very Long Baseline Interferometry (VLBI), Satellite Laser Ranging (SLR) and Doppler Orbitography and Radiopositioning Integrated by Satellite (DORIS) techniques. The combination of these techniques is used to generate the International Terrestrial Reference Frame (ITRF).

A basic SINEX file contains station coordinate and Earth rotation parameter estimates along with auxiliary information about the site, such as receiver and antenna type, eccentricity and phase center information. In addition, covariance information or normal equations can be stored to facilitate the combination of solutions from different analysis centers and/or geodetic observation systems [A.35].

SINEX employs a fixed-format text representation with a maximum line width of 80 characters. Each file is started with a mandatory `%=SNX` header line and terminated with an `%ENDSNX` footer. In between, various blocks of data may be given in arbitrary order. Each block is identified by a predefiend label and embedded in a frame of *+label ...* - *label* lines. An overview of SINEX data blocks file is given in Table A.8 and a format example is provided in Fig. A.9.

*SINEX Troposphere Format.* The SINEX troposphere format [A.36] extends the SINEX format to capture tropospheric observations and estimates. The format can contain the total and wet zenith path delays, precipitable water vapor, and gradients thereof along with the respective standard deviations. In addition, standard atmospheric measurements such as barometric pressure, temperature, and relative humidity can be provided. GNSS users can use the SINEX troposphere data to correct the range observations to improve the position estimate. Weather reporting and prediction agencies also use the observed and estimated meteorological data contained in the SINEX troposphere file for numerical modeling and climatological archives.

SINEX troposphere files follow the overall conventions of a standard SINEX file format and inherit various of its data blocks, but are identified by a `%=TRO` header line. A list of labels specific to the troposhere format is provided in Table A.9.

*Bias SINEX Format.* Following the example of the SINEX troposphere format, a tailored SINEX version has also been proposed for the exchange of code and phase biases of satellites and GNSS monitoring stations [A.37]. The format is specifically designed to handle differential code biases (DCB), but can also handle carrier-phase and intersystem biases. A list of associated labels for the bias-specific data blocks is provided in Table A.9. SINEX bias files are distinguished from standard SINEX files through the `%=BIA` header line.

### A.2.4 IONEX Format

The IONosphere EXchange (IONEX) format [A.38] has been developed for the exchange of global ionosphere maps (GIMs) derived from the analysis of GNSS observations. Aside from space weather monitoring and ionospheric analyses, these maps enable more accurate and precise single-frequency position estimates than the Klobuchar or NeQuick models (Chap. 6) used for real-time ionospheric correction inside a GNSS receiver.

GIM products in IONEX format are generated by various IGS analysis centers [A.39] and provide estimated vertical total electron content (VTEC) values on an equidistant grid in geo*centric* longitude and latitude at discrete time intervals (Fig. A.10). These are used in combination with a single-layer model (Chaps. 6 and 19) to compute the ionospheric path delays in the processing of pseudorange and phase observations.

| TROP/STA_COORDINATES | (m) | Employed stations and their coordinates |
| TROP/SOLUTION | (m) | Values of estimated parameters at discrete time steps for each site |
| BIAS/DESCRIPTION | (m) | Specification of solution parameters (sampling interval, etc.) |
| BIAS/SOLUTION | (m) | Type of bias (signals, satellite, station), period of applicability, value and standard deviation |

*Format Description.* The IONEX file format follows the RINEX2 template with 80 column records. It contains a file header followed by a TEC map for each epoch. Each TEC map is itself made up of multiple records providing TEC values for a given latitude over the specified longitude grid (Fig. A.11). Optionally,

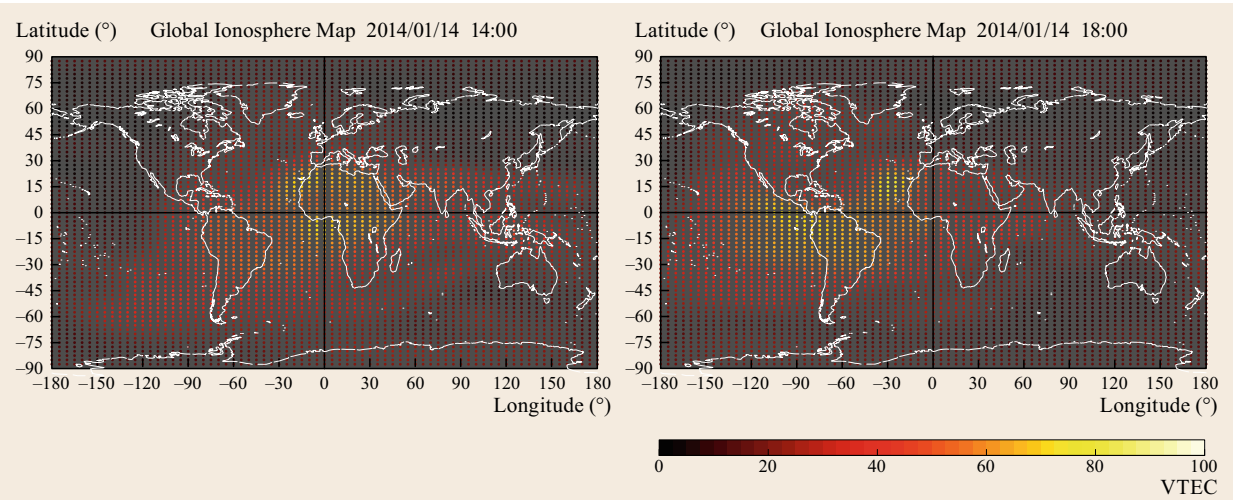

**Fig. A.10** Global ionosphere maps of the IGS CODE analysis center

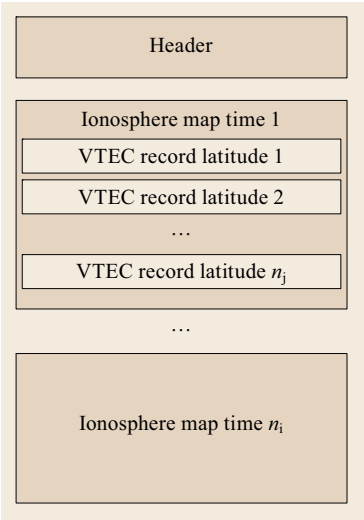

**Fig. A.11** IONEX file structure

the TEC maps may be complemented by RMS TEC maps providing the expected uncertainty of the TEC values.

A truncated example illustrating the basic format of the IONEX header and data records is shown in Fig. A.12. The header primarily specifies the range in time, longitude and latitude as well as the corresponding step sizes for the TEC information given in the various TEC maps. Even though the format is designed to support three-dimensional maps, current products are confined to two-dimensional single-layer representation with a fixed height relative to a specified mean Earth radius. To facilitate interpolation, both 00:00 h and 24:00 h epochs are usually included in the daily IONEX products. Likewise, the longitude grid for global maps includes TEC values for $\lambda = -180°$ and $\lambda = +180°$ despite the resulting redundancy. A second set of header lines provides the set of differential code biases (DCBs) of all satellites and stations incorporated in the generation of the TEC maps. Since ionospheric path delays are retrieved from differences of observations made at two different frequencies (Chap. 39) such biases have a direct impact on the estimated ionospheric activity. Provision of the biases in the file header ensures full transparency and consistency, even though the values are not actually required, to use TEC maps in single-frequency positioning applications.

Each TEC map is made up of a series of consecutive records providing the TEC values over the full set of longitude grid points at a specified latitude. Using a predefined scale of typically 0.1 TECU, all values can be represented through integer numbers with at most five digits. Individual TEC maps are embedded in a `START OF TEC MAP` and `END OF TEC MAP` frame and marked by their sequence number. Furthermore, the calender date and time of the respective epoch are provided to ease their identification.

*Interpolation.* The global ionosphere maps provide the values $\mathrm{VTEC}_{i,j,k}$ of the vertical total electron contents at discrete times $t_i$, geocentric latitudes $\varphi'_j$, and longitudes $\lambda_k$ (Fig. A.10). Application of the single-layer model requires interpolation of these values for a given time $t$ and location $(\lambda, \varphi')$ of the ionospheric pierce point (i. e., the point at which the signal path intersects the thin shell used to represent the ionosphere; see Chap. 19, Fig. 19.1).

Code biases

End of header

TEC records

End of file

**Fig. A.12** IONEX file format example. Rulers at the start and end have been added for information only and are not part of the actual format

For interpolation to the given location a bilinear interpolation

$$\begin{aligned}\mathrm{VTEC}_i(\lambda,\varphi') = {} & (1-p)(1-q)\mathrm{VTEC}_{i,j,k} \\ & + (p)(1-q)\mathrm{VTEC}_{i,j+1,k} \\ & + (1-p)(q)\mathrm{VTEC}_{i,j,k+1} \\ & + (p)(q)\mathrm{VTEC}_{i,j+1,k+1}\end{aligned} \tag{A.7}$$

with coefficients

$$\begin{aligned}p &= (\varphi'-\varphi'_j)/(\varphi'_{j+1}-\varphi'_j) \\ q &= (\lambda-\lambda_k)/(\lambda_{k+1}-\lambda_k)\end{aligned} \tag{A.8}$$

is applied across the intervals $\varphi'_j \le \varphi' < \varphi'_{j+1}$ and $\lambda_k \le \lambda < \lambda_{k+1}$, limited by the surrounding grid points.

For interpolation in time, a linear interpolation

$$\begin{aligned}\mathrm{VTEC}(t,\lambda,\varphi') = {} & (1-\tau)\mathrm{VTEC}_i(\lambda,\varphi') \\ & + \tau\mathrm{VTEC}_{i+1}(\lambda,\varphi')\end{aligned} \tag{A.9}$$

with $\tau = (t-t_i)/(t_{i+1}-t_i)$ can subsequently be employed across the time interval $t_i \le t < t_{i+1}$. Improved results may, however be obtained, by taking into account that ionospheric activity varies mostly with local time rather than UTC. This results in an apparent westwards shift of the average electron density distribution at a rate of $\omega = 15\,^\circ/\mathrm{h}$, which is illustrated in Fig. A.10. A modified relation

$$\begin{aligned}\mathrm{VTEC}(t,\lambda,\varphi') = {} & (1-\tau)\mathrm{VTEC}_i(\lambda,\varphi') \\ & + \tau\mathrm{VTEC}_{i+1}(\lambda-\omega(t_{i+1}-t_i),\varphi')\end{aligned} \tag{A.10}$$

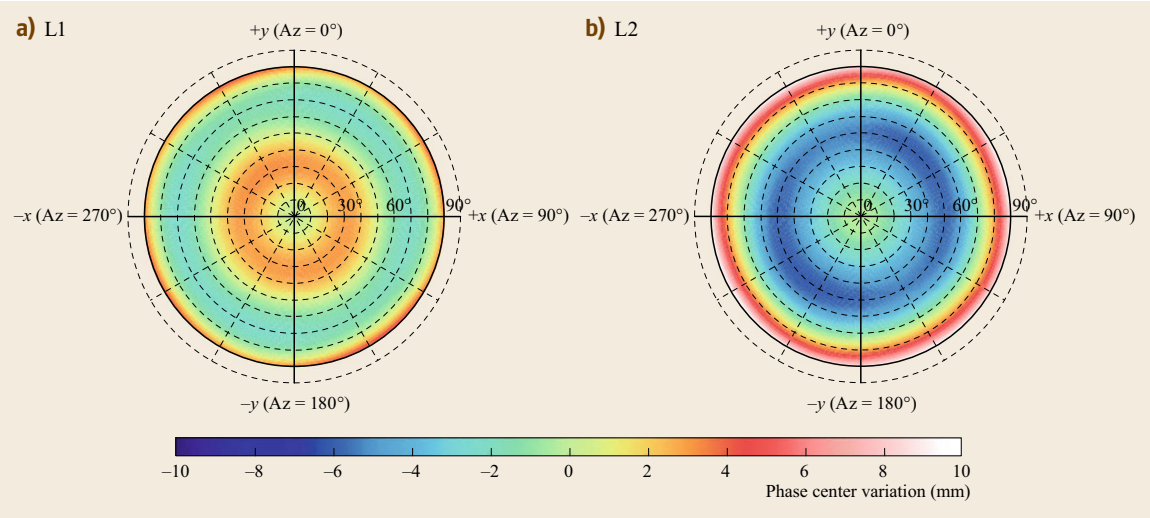

**Fig. A.13** Azimuth and boresight angle-dependent phase center variation of Leica AR25.R4 antenna as provided in the igs08.atx antenna calibration file for GPS L1 **(a)** and L2 **(b)** signals. Image courtesy of A. Hauschild

is therefore recommended by [A.38] for interpolation of IONEX TEC maps in time. Here, the second map is shifted in longitude with respect to the first one to compensate for Earth rotation between the respective epochs.

### A.2.5 ANTEX

The ANTenna EXchange (ANTEX) format [A.40] was developed to facilitate the documentation and distribution of phase center offsets (PCOs) and phase center variations (PCVs) for GNSS receiver and satellite antennas (Fig. A.13). These corrections are used in GNSS precise point positioning applications as well as GNSS satellite orbit and clock determination for high-accuracy modeling of carrier-phase observations (Chap. 19).

Except for PCV data that require an extended line width, ANTEX files employ a line format with parameters in columns 1–60 and descriptive labels in columns 61–80. Following a brief header, a series of data records with information for individual antennas are provided (Fig. A.14). Each record is itself made up of an antenna-specific header and several sets of PCO/PCV data for distinct constellations and frequency bands.

A truncated format example illustrating the basic structure of the ANTEX file and the data blocks is provided in Fig. A.15. Different colors are used to highlight the header of individual antenna records (blue) as well as PCO/PCV data for the GPS L1 (red) and L2 (green) frequency. For GNSS satellite antennas, the antenna type (associated with the block type of a GPS satellite), the three-character RINEX satellite identifier (constellation letter and PRN or slot number), the space vehicle number and the international (COSPAR) satellite number are specified in the first record header line. Next, the grid of azimuth and boresight angle values for the provision of phase center variations is specified. In addition, a validity period is specified that reflects the timespan during which the space vehicle was assigned the given satellite identifier. For GNSS receiver antennas, the antenna and radome name are identified along with the method used for calibration of the phase pattern. Since 2005, absolute antenna phase patterns are exclusively used within the IGS [A.41]. These may be based on either robot calibrations or anechoic chamber measurements.

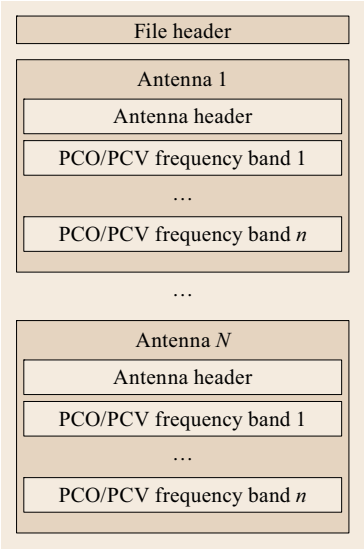

**Fig. A.14** Basic structure of ANTEX antenna data files

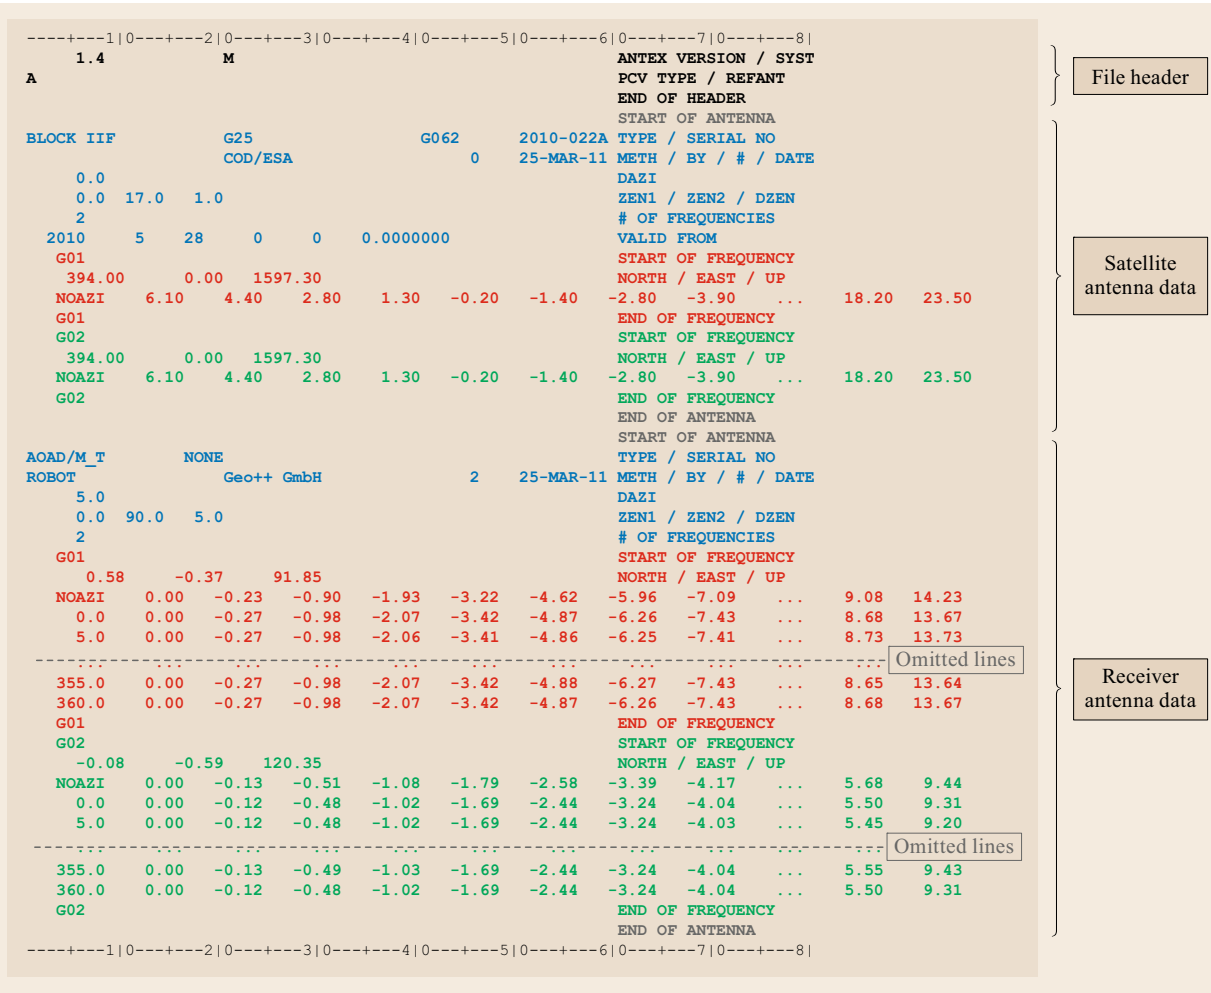

**Fig. A.15** ANTEX file format example. Rulers at the start and end have been added for information only and are not part of the actual format. Ellipses denote characters or lines that have been deleted to fit the available print space

Antenna information for a specific frequency band is embedded in a `START OF FREQUENCY` ... `END OF FREQUENCY` block identified by the RINEX constellation letter and frequency band number. The offset of the antenna phase center is first provided, thereafter the phase center variations are given. Receiver antenna phase center offsets are defined with respect to the antenna reference point (ARP) and a coordinate system aligned with the nominal North, East, and Up directions. GNSS satellite phase center offsets are defined with respect to the satellites center-of-mass and body-fixed $x$-, $y$- and $z$-coordinates. Phase center variations referring to the same reference system are provided in the form of an averaged boresight angle-dependent pattern (marked by the `NOAZI` keyword) as well as an optional azimuth and boresight angle-dependent pattern. For GNSS satellites only the first form is presently provided in the standard IGS ANTEX product, although various efforts have already been made to derive two-dimensional PCV maps for all GPS and GLONASS satellites. For a given boresight direction, the PCV maps can be interpolated using either linear (for one-dimensional PCVs) or bilinear interpolation (for two-dimensional PCVs).

### A.2.6 Site Log Format

Building and maintaining a GNSS station or network of stations requires a standardized station information archive that describes the station including location, equipment, responsible agency and contact information. To meet these needs, the IGS has established a dedicated site log format. Site logs are stored as text files with an 80-character width and made up of 14 numbered sections described in Table A.10. Indi-

```
    KZN2 Site Information Form
    International GNSS Service

0.  Form
    Prepared by (full name)   : Renat Zagretdinov
    Date Prepared             : 2012-02-24
    Report Type               : NEW

1.  Site Identification of the GNSS Monument
    Site Name                 : KAZAN
    Four Character ID         : KZN2
    Monument Inscription      : KFU GNSS STATION
    IERS DOMES Number         : 12374M001
    CDP Number                : NONE
    Monument Description      : PILLAR
      Height of the Monument  : 13(m)
      Monument Foundation     : CONCRETE BLOCK
      Foundation Depth        : 2(m)
    Marker Description        : (CHISELLED CROSS/DIVOT/BRASS NAIL/etc)
    Date Installed            : 2010-10-01
    Geologic Characteristic   : CLAY and SAND
    ...

2.  Site Location Information
    City or Town              : KAZAN
    State or Province         : TATARSTAN
    Country                   : Russian Federation
    Tectonic Plate            : Eurasian
    Approximate Position (ITRF)
      X coordinate (m)        : 2352345.7
      Y coordinate(m)         : 2717466.1
      Z coordinate(m)         : 5251458.5
      Latitude (N is +)       : +554726.82
      Longitude (E is +)      : +0490709.28
      Elevation (m,ellips.)   : 94.6

**Fig. A.16** Site log format example (truncated sections are indicated by ellipses)

**Table A.10** Sitelog file contents

| No. | Section | Contents |
|---|---|---|
| 0 | Form | Lists the author, preparation date, type (new or update), link to previous site log and list of changes |
| 1 | Site identification | Site name, four-character ID, monument inscription, IERS domes number, CDP number; monument description, height (m) and foundation (type and depth); marker description and date installed, geological characteristics of foundation (soil, rock) |
| 2 | Site location | City or town, state, country, tectonic plate, approximate Cartesian and and geographic coordinates |
| 3 | GNSS receiver | Receiver type, GNSS systems supported, serial number, firmware version, elevation cutoff angle, date (installed and removed). Repeated for each change |
| 4 | GNSS antenna | Antenna type, serial number, antenna reference point (ARP), marker-to-antenna ARP offset, antenna alignment w.r.t true north, radome type and serial number, antenna cable type and length, date (installed and removed). Repeated for each change |
| 5 | Surveyed local ties | Tied marker: name, usage (SLR, VLBI, control), CDP number, domes number, differential components (ITRS) (m) : dx, dy and dz, accuracy, survey method, date and additional information as required. Repeated for each additional tie and campaign |
| 6 | Frequency standard | Type (internal, external and type), input frequency, effective dates beginning and end. Repeated for each change |
| 7 | Collocation information | List of instrumentation present an the site: type (DORIS, SLR, VLBI, etc.), status, effective dates (start and end) and notes |
| 8 | Meteorological instrumentation | Humidity sensor: manufacturer, serial number, sampling interval, accuracy, aspiration, height difference to antenna, calibration date and start and end date. Corresponding information for pressure sensor, temperature sensor, water vapor radiometer and other meteorological sensors |
| 9 | Local conditions | Radio interference, multipath sources, signal obstruction |
| 10 | Local episodic effects | Date, event (tree clearing, construction, etc.) |
| 11 | On site contact | Agency, abbreviation, address, primary contact: name, telephone, fax and email, repeated for secondary contact and additional information |
| 12 | Responsible agency | Same content as in site contact section |
| 13 | More information | Primary and secondary data center, URL for station information, availability of site map, diagram, horizon mask, detailed monument description and pictures, antenna graphics and additional information |

vidual parameters within each section are identified by predefined labels with colons in column 31 separating the labels and parameters. When equipment or site conditions change the relevant block is updated. In this way, site logs provide users with a complete record of all the changes that have taken place. A truncated format example of a site log file is shown in Fig. A.16.

# Annex B: GNSS Parameters

Oliver Montenbruck, Michael Meurer, Peter Steigenberger

This chapter summarizes important GNSS-related parameters. Next to general physical constants, key parameters of the GNSS constellations and the various GNSS signals are provided.

## B.1 Physical Constants

Physical constants and parameters of relevance for the generation and processing of GNSS observations are provided in Table B.1.

## B.2 Orbital Parameters

Table B.2 summarizes the orbital parameters of current global and regional navigation satellite systems.

## B.3 Signals

The spectra of current and planned GNSS navigation signals are illustrated in Fig. B.1. Key parameters of the individual signals are compiled in Table B.3.

Signal bandwidths (BW) given in the table refer to the location of the first minimum outside the main lobe(s). The actual spectral usage depends on the filtering and may cover a larger frequency range, particularly when sharing a frequency band with other wideband signals. GNSS signals are commonly described as

$$S = s_{\mathrm{I}} \cos(2\pi f t) \pm s_{\mathrm{Q}} \sin(2\pi f t)\,, \tag{B.1}$$

where the *cos*-component of the signal is designated as the *in-phase* component (I), while the *sin*-signal is termed the *quadrature* component (Q) [B.11]. Depending on the choice of sign in the above equation, the instantaneous phase of the Q-channel is either behind (plus-sign) or ahead (minus-sign) of the I-channel. To distinguish both options, we use the notations

$$S = s_{\mathrm{I}^+} \cos(2\pi f t) + s_{\mathrm{Q}^+} \sin(2\pi f t) \tag{B.2}$$

and

$$S = s_{\mathrm{I}^-} \cos(2\pi f t) - s_{\mathrm{Q}^-} \sin(2\pi f t)\,, \tag{B.3}$$

for the specification of the channel (Ch), where the superscript of the I- and Q-symbols indicates the employed signal description. In the absence of a superscript, the association of signals to the I- and Q-channel and/or the concise phase relation is not traceable from public information. However, signals designated as $I$ and $Q$, respectively, are known to be modulated in phase-quadrature with respect to each other.

**Table B.1** Physical constants and parameters

| Quantity | Description | Value | Unit | References and remarks |
|---|---|---|---|---|
| **Time** | | | | |
| TT–TAI | Time offset TT and TAI | 32.184 | s | IAU 1991 [B.1] |

**Table B.2** Representative orbital parameters (period, semi-major axis $a$, height above the Earth $h$, eccentricity $e$, and inclination $i$) of global and regional navigation satellite system satellites. A period of $n/m$ revolutions (rev) per sidereal day ($\mathrm{d_{sid}}$) results in a ground-track repeat track after $m$ inertial rotations of the Earth (approximately $m \times 23^{\mathrm{h}}56^{\mathrm{m}}$)

| System | Period (rev/$\mathrm{d_{sid}}$) | Period (h) | $a$ (km) | $h$ (km) | $e$ | $i$ (°) |
|---|---|---|---|---|---|---|
| GLONASS | 17/8 | $11^{\mathrm{h}}16^{\mathrm{m}}$ | 25 510 | 19 130 | 0.0 | 64.8 |
| GPS | 2/1 | $11^{\mathrm{h}}58^{\mathrm{m}}$ | 26 560 | 20 180 | 0.0 | 55 |
| BeiDou (MEO) | 13/7 | $12^{\mathrm{h}}53^{\mathrm{m}}$ | 27 910 | 21 530 | 0.0 | 55 |
| Galileo | 17/10 | $14^{\mathrm{h}}05^{\mathrm{m}}$ | 29 600 | 23 220 | 0.0 | 56 |
| QZSS (IGSO) | 1/1 | $23^{\mathrm{h}}56^{\mathrm{m}}$ | 42 160 | 35 790 | 0.1 | 43 |
| BeiDou (IGSO) | 1/1 | $23^{\mathrm{h}}56^{\mathrm{m}}$ | 42 160 | 35 790 | 0.0 | 55 |
| IRNSS (IGSO) | 1/1 | $23^{\mathrm{h}}56^{\mathrm{m}}$ | 42 160 | 35 790 | 0.0 | 29 |
| BeiDou/IRNSS/QZSS (GEO), SBAS | 1/1 | $23^{\mathrm{h}}56^{\mathrm{m}}$ | 42 160 | 35 790 | 0.0 | $\leq 2$ |

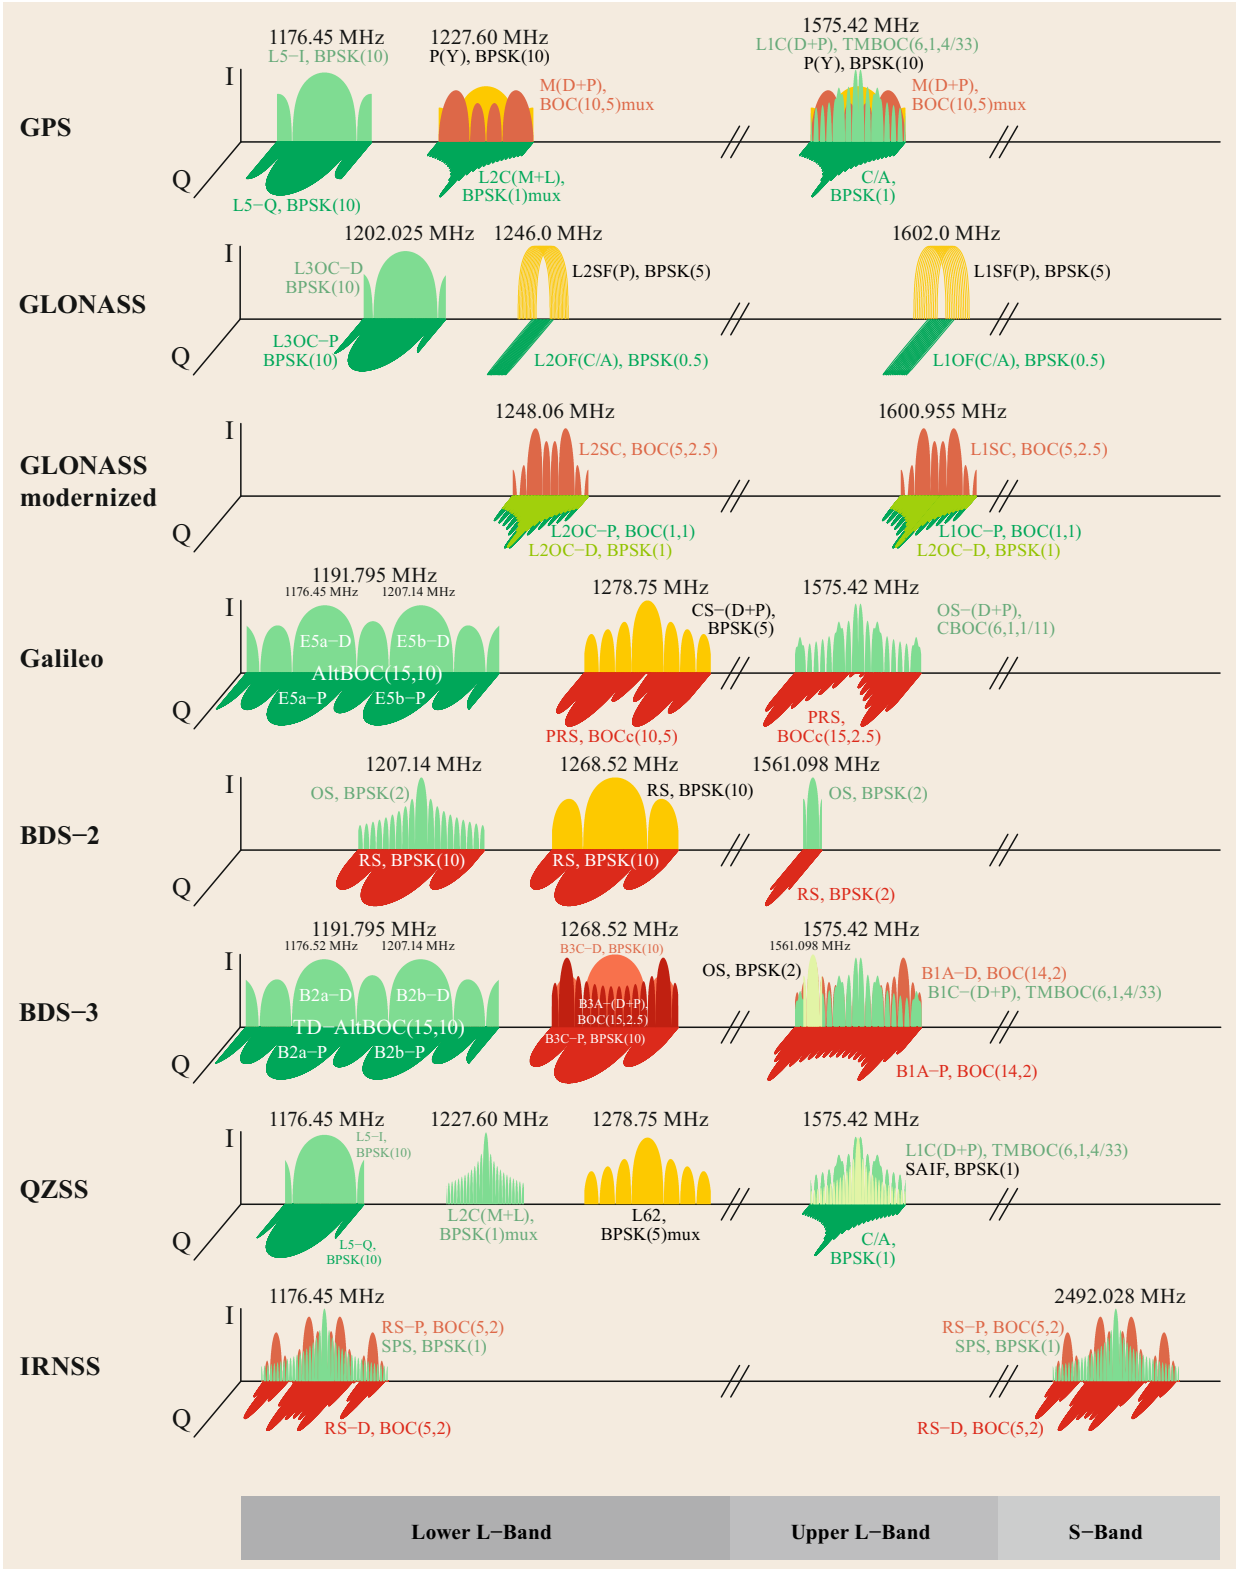

**Fig. B.1** GNSS signals overview. Colors indicate open signals (*shades of green*), authorized signals (*shades of red*), and signals that can be tracked with restrictions (*yellow*)

**Table B.3** GNSS signals overview. The specified bandwidth (BW) refers to the location of the first minimum outside the main lobe(s) of the signal and is generally smaller than the actual transmission bandwidth and onboard bandpass filtering. Question marks indicate missing or undefined information

| Sys | Band | Signal | Frequency (MHz) | BW (MHz) | Ch | Modulation | Rate (MHz) | Code prim./second. (chips) | Type | Data (bps/sps) | Power (min. rcvd.) (dBW) | References |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| GPS | L1 | P(Y) | 1575.42 | ±10 | $I^+$ | BPSK(10) | 10.23 | $6.9 \cdot 10^{12}$ | M-seq. | 50/50 | −161.5 | [B.2, 12] |
| | | C/A | | ±1 | $Q^+$ | BPSK(1) | 1.023 | 1023 | Gold | 50/50 | −158.5 | [B.2, 12] |
| | | L1C-D | | ±2 | $I^+$ | TMBOC(6,1,4/33) | 1.023 | 10 230 | Weil | 50/100 | −163.0 | [B.13] |
| | | L1C-P | | ±2 | $I^+$ | TMBOC(6,1,4/33) | 1.023 | 10 230/1800 | Weil | – | −158.25 | [B.13] |
| | | M-D | | ±15 | $I^+$ | BOC(10,5) mux | 5.115 | n/a | n/a | ≤100/200 | −158.0 | [B.11, 14, 15] |
| | | M-P | | ±15 | $I^+$ | BOC(10,5) mux | 5.115 | n/a | n/a | n/a | −158.0 | [B.11, 14, 15] |
| | L2 | P(Y) | 1227.60 | ±10 | $I^+$ | BPSK(10) | 10.23 | $6.9 \cdot 10^{12}$ | M-seq. | 50/50 | −164.5[a], −161.5[b,c,d] | [B.2, 12] |
| | | L2 CM | | ±1 | $Q^{+e}$ | BPSK(1) mux | 0.5115 | 10 230 | M-seq. | 25/50 | −163.0[b,c], −161.5[d] | [B.2, 12] |
| | | L2 CL | | ±1 | $Q^{+e}$ | BPSK(1) mux | 0.5115 | 767 250 | M-seq. | – | −163.0[b,c], −161.5[d] | [B.2, 12] |

B.39 Signal Specification for SBAS L1/L5, ED-134, Draft v.3, May 2008 (The European Organisation for Civil Aviation Equipment, Paris 2008)

# About the Authors

**Zuheir Altamimi**

Institut National de l'Information
Géographique et Forestière (IGN)
Université Paris Diderot (LAREG)
Paris, France
*zuheir.altamimi@ign.fr*

Chapter F.36

Zuheir Altamimi is Research Director at the Institut National de l'Information Géographique et Forestière (IGN), France. His research focuses are space geodesy and theory and realization of terrestrial reference systems. He is Head of the IGN Terrestrial Reference Systems Research group and the International Terrestrial System (ITRS) Center. He received his PhD in Space Geodesy from Paris Observatory and his habilitation from Paris University VI.

**Felix Antreich**

Federal University of Ceará (UFC)
Dept. of Teleinformatics Engineering
Fortaleza, Brazil
*antreich@ieee.org*

Chapter A.4

Felix Antreich received a Doktor-Ingenieur (PhD) in Electrical Engineering from Munich University of Technology (TUM), Germany, in 2011. Since July 2003, he has been an Associate Researcher with the Department of Navigation, Institute of Communications and Navigation of the German Aerospace Center (DLR), Oberpfaffenhofen, Germany. His research interests include sensor array signal processing for global navigation satellite systems (GNSS) and wireless communications, estimation theory, and signal design for synchronization and GNSS.

**Ron Beard**

US Naval Research Laboratory
Advanced Space PNT Branch
Washington, USA
*ronald.beard@verizon.net*

Chapter A.5

Ronald Beard is the former Head of the NRL Advanced Space PNT Branch. In the 1970s, he was the project scientist in the NRL GPS Program Office that developed Navigation Technology Satellites 1 and 2, which operated the first atomic clocks in space. He became the Program Manager of the NRL GPS Clock Development program in 1984 and Precise Time and Time Interval (PTTI) technology for military navigation and communication systems.

**Alexey Bolkunov**

Federal Space Agency (Roscosmos)
PNT Information and Analysis Center
Korolyov, Russian Federation
*alexei.bolkunov@glonass-iac.ru*

Chapter B.8

Alexey Bolkunov is a Senior Research Associate of the PNT Information and Analysis Center of the Central Scientific Research Institute for Machine Building, Federal Space Agency (Roscosmos), Russia, which he joined as a graduate of Moscow Aviation Institute (National Research University) in 2007. He received his PhD in 2011 from the same institute. Alexey Bolkunov's research interests include GNSS performance and PNT legal and regulatory framework studies.

**Michael S. Braasch**

Ohio University
School of Electrical Engineering &
Computer Science
Athens, USA
*braaschm@ohio.edu*

Chapter C.15

Michael S. Braasch holds the Thomas Professorship in the Ohio University School of Electrical Engineering and Computer Science and is Principal Investigator with the Ohio University Avionics Engineering Center (AEC). One focus of his research has been the characterization and mitigation of the effects of multipath in GNSS. Other areas of research include GNSS software-defined receiver development, novel general aviation cockpit displays and unmanned aerial vehicle sense-and-avoid systems.

**Thomas Burger**

European Space Agency (ESA)
Galileo Project Office
Noordwijk, The Netherlands
*thomas.burger@esa.int*

Chapter B.9

Thomas Burger is Principal Signal Engineer within the Galileo Project Office at the European Space Agency in Noordwijk (The Netherlands). He received his PhD in Engineering Sciences from the Technical University of Darmstadt, Germany. He has been working on space systems, focussed on space-based navigation applications and systems, synthetic aperture radar and microwave instruments, and signal processing for precision applications.

**Estel Cardellach**

Institute of Space Sciences
ICE (IEEC-CSIC)
Cerdanyola del Valles, Spain
*estel@ice.csic.es*

Chapter G.40

Estel Cardellach received a PhD from UPC, Barcelona, Spain (2002). She works on scientific applications of the Global Navigation Satellite Systems (GNSS) for remote sensing of the Earth, including reflectometry and radio-occultations. She enjoyed postdoctoral positions at Jet Propulsion Laboratory and Harvard Smithsonian Center for Astrophysics. Currently she works at the Institute of Space Sciences (ICE-CSIC/IEEC), Spain.

**James T. Curran**

European Space Agency (ESA)
Noordwijk, The Netherlands
*jamestcurran@ieee.org*

Chapter C.18

James T. Curran received a Bachelor degree in Electrical Engineering and a Doctorate in Telecommunications, from University College Cork, Ireland. Since then he has worked as a researcher at various institutions, including the PLAN Group at the University of Calgary and at the Joint Research Centre of the European Commission, Italy. Although focusing on radio-navigation, his research interests also include signal processing, information theory, cryptography and software defined radio.

**Pascale Defraigne**

Royal Observatory of Belgium
Brussels, Belgium
*p.defraigne@oma.be*

Chapter G.41

Pascale Defraigne received her PhD in Physics from the Université Catholique de Louvain (UCL), Belgium (1995). She was Assistant at the Royal Observatory of Belgium in the field of GNSS Time and Frequency transfer and is now Head of the Time Laboratory. She participated in the development of the European Navigation System Galileo and chairs the working group on GNSS Time Transfer of the Consultative Committee of Time and Frequency.

**Bernd Eissfeller**

Universität der Bundeswehr München
Inst. of Space Technology and Space Applications
Neubiberg, Germany
*bernd.eissfeller@unibw.de*

Chapter C.13

Bernd Eissfeller received his PhD in Inertial Geodesy (1989) and his Habilitation (venia legendi) in Navigation and Physical Geodesy (1996). He is Full Professor of Navigation at the Institute of Space Technology and Space Applications at the University of the Bundeswehr (Federal Armed Forces/UFAF), Munich. His current research interests are in the field of Galileo system optimization, GNSS receiver design, GNSS/INS multi-sensor hybridization and deep-space geodesy.

**Gunnar Elgered**

Chalmers University of Technology
Dept. of Earth and Space Sciences
Onsala, Sweden
*gunnar.elgered@chalmers.se*

Chapter G.38

Gunnar Elgered received the MSEE (1977) and PhD (1983) degrees from Chalmers University of Technology, Gothenburg, Sweden. He is Professor of Electrical Measurements and Head of the department. His research area is space geodesy, using radio telescopes and global navigational satellite systems (GNSS). More recently, his focus has been on the use of GNSS data for climate research and evaluation of climate models.

**Marco Falcone**

European Space Agency (ESA)
Galileo Project Office
Noordwijk, The Netherlands
*marco.falcone@esa.int*

Chapter B.9

Marco Falcone is the System Manager in the Galileo Project Office at the European Space Agency in Noordwijk (The Netherlands). He received his Master's in Computer Science from the University of Pisa, Italy (1987) and a Master's in Space Systems Engineering from the University of Delft, The Netherlands (1999). He has 28 years' work experience in system engineering mainly applied to large space systems.

**Richard Farnworth**

Eurocontrol Experimental Centre
Centre du Bois des Bordes – BP15
Bretigny sur Orge, France
*richard.farnworth@eurocontrol.int*

Chapter E.30

Richard Farnworth is the Deputy Head of the Navigation and CNS Research Unit within the Eurocontrol Directorate of Air Traffic Management. He supports the deployment of performance-based navigation and contributes to several projects addressing approaches with vertical guidance. He began his career with Eurocontrol at its Experimental Centre in 1996, where he was employed as an expert in satellite navigation looking at how to use GNSS in aviation.

**Jay A. Farrell**

University of California, Riverside
Dept. of Electrical and Computer Engineering
Riverside, USA
*farrell@ece.ucr.edu*

Chapter E.28

Jay A. Farrell earned BS degrees from Iowa State University, and MS and PhD degrees in Electrical Engineering from the University of Notre Dame. He has worked at Draper Lab and is a Professor and two time Chair of the Department of Electrical and Computer Engineering at the University of California, Riverside. His research interests relate to control, state estimation, sensor fusion, and planning for autonomous vehicle applications.

**Jeff Freymueller**

University of Alaska
Geophysical Institute
Fairbanks, USA
*jfreymueller@alaska.edu*

Chapter F.37

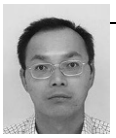
Jeff Freymueller received his PhD in Geology in 1991 from the University of South Carolina. After a postdoctoral fellowship at Stanford University, he has been on the faculty at the University of Alaska Fairbanks since 1995. Throughout his career he has worked on the application of space geodesy to the study of deformation of the Earth, including studies in tectonics, earthquakes and the earthquake cycle, volcanism, and changes in cryospheric loads.

**A.S. Ganeshan**

Indian Space Research Organization (ISRO)
ISRO Satellite Centre (ISAC)
Bangalore, India
*asganeshan53@gmail.com*

Chapter B.11

A.S. Ganeshan is the former Programme Director of Satellite Navigation Program and Group Director, Space Navigation Group at the ISRO Satellite Centre, Bangalore. He also served as Executive Head of the realization of the certified GAGAN system over India. He originated the concept of regional navigation satellite system (IRNSS) and has played a key role in the realization of the same. He is currently associated with Airports Authority of India as Advisor on GAGAN related matters.



**Steven Gao**

University of Kent
School of Engineering and Digital Arts
Canterbury, Kent, UK

Chapter C.17

Steven Gao is Professor and Chair of RF and Microwave Engineering at the University of Kent, UK. His research covers satellite antennas, smart antennas, phased arrays, GNSS antennas, RF/microwave/millimetre-wave/THz circuits, satellite communication, radars (synthetic aperture radar, UWB radars) and small satellites. He has published over 200 papers and 2 books.

**Gabriele Giorgi**

Technical University of Munich
Inst. for Communications and Navigation
Munich, Germany
*gabriele.giorgi@tum.de*

Chapter E.27

Gabriele Giorgi is a lecturer and researcher at the Institute for Communications and Navigation, Technical University of Munich, Germany. He obtained a PhD following his work on global navigation satellite system (GNSS) for aerospace applications at the Delft Institute of Earth Observation and Space Systems (DEOS), Delft University of Technology (The Netherlands). His current research focuses on reliable GNSS positioning for aeronautics applications.

**Richard Gross**

California Institute of Technology
Jet Propulsion Laboratory
Pasadena, USA
*richard.s.gross@jpl.nasa.gov*

Chapter F.36

Richard Gross has over 30 years' experience in space geodesy. His research interests include Earth rotation, time variable gravity and, most recently, terrestrial reference frame determination. He has published over 60 peer-reviewed articles on these topics and has worked at the Jet Propulsion Laboratory, California Institute of Technology since 1988, where he is a Senior Research Scientist and, since 2006, the Supervisor of the Geodynamics and Space Geodesy Group.

**Jörg Hahn**

European Space Agency (ESA)
Galileo Project Office
Noordwijk, The Netherlands
*joerg.hahn@esa.int*

Chapter B.9

Jörg Hahn is Head of the Galileo System Procurement Service in the Galileo Project Office at the European Space Agency in Noordwijk. He received his PhD in Engineering Sciences from the University of Federal Armed Forces Munich-Neubiberg, Germany (1999). He has 22 years' work experience in system engineering, mainly with timing, satellite navigation, and large space systems.

**André Hauschild**

German Aerospace Center (DLR)
German Space Operations Center
Wessling, Germany
*andre.hauschild@dlr.de*

Chapters D.19, D.20

André Hauschild is a researcher in the GNSS Technology and Navigation Group at DLR's German Space Operations Center (GSOC). He received his PhD from the Technical University Munich, Germany, in 2010. His field of work focuses on real-time clock offset estimation for GNSS satellites for precise positioning, multi-GNSS processing using modernized and new satellite navigation systems, as well as space-borne GNSS applications.

**Grant Hausler**

Geoscience Australia
Symonston, Australia
*grant.hausler@ga.gov.au*

Chapter F.33

Grant Hausler is Coordinator for the National Positioning Infrastructure at Geoscience Australia. He holds a Bachelor of Geomatic Engineering and a PhD from the University of Melbourne. Grant provides Secretariat to the Australian Government Positioning, Navigation and Timing Working Group and the National Positioning Infrastructure Advisory Board, and represents Geoscience Australia on the Attorney General's Space Community of Interest.

**Christopher J. Hegarty**

The MITRE Coporation
Bedford, USA
*chegarty@mitre.org*

Chapter B.7

Christopher J. Hegarty is the Director for CNS Engineering & Spectrum with The MITRE Corporation, where he has worked mainly on aviation applications of GNSS since 1992. He received BS and MS degrees in Electrical Engineering from WPI and a DSc degree in EE from GWU. He is currently the Chair of the Program Management Committee of RTCA, Inc., and co-chairs RTCA Special Committee 159 (GNSS).

**Thomas Hobiger**

Chalmers University of Technology
Onsala Space Observatory
Onsala, Sweden
*thomas.hobiger@chalmers.se*

Chapter A.6

Thomas Hobiger is Associate Professor for Space Geodesy. He received the MSc and PhD degrees in Geodesy and Geophysics from the Vienna University of Technology, Austria (2002, 2005). He spent 8 years at a Japanese research institute, before moving to Chalmers in 2014. He plays an active role in the development of next-generation space-geodetic systems (in particular VLBI and GNSS) and processing tools for such techniques.

**Urs Hugentobler**

Technical University of Munich
Satellite Geodesy
Munich, Germany
*urs.hugentobler@bv.tum.de*

Chapter A.3

Urs Hugentobler has been Professor for Satellite Geodesy at the Technical University Munich, Germany and Head of the Research Facility Satellite Geodesy since 2006. He obtained his PhD in Astronomy from the University of Bern, Switzerland, in 1998. His research activities include precise positioning applications using GNSS, precise orbit determination and modeling, and clock modeling, using the new GNSS satellite systems.

**Todd Humphreys**

The University of Texas at Austin
Aerospace Engineering and Engineering Mechanics,
W.R. Woolrich Laboratories, C0600
Austin, USA
*todd.humphreys@mail.utexas.edu*

Chapter C.16

Todd Humphreys (BS, MS, Electrical Engineering, Utah State University; PhD, Aerospace Engineering, Cornell University) is Associate Professor in the Department of Aerospace Engineering and Engineering Mechanics at the University of Texas at Austin, where he directs the UT Radionavigation Laboratory. He specializes in the application of optimal detection and estimation techniques to problems in satellite navigation, autonomous systems, and signal processing.

**Norbert Jakowski**

German Aerospace Center (DLR)
Institute of Communications and Navigation
Neustrelitz, Germany
*norbert.jakowski@dlr.de*

Chapters A.6, G.39

Norbert Jakowski received his PhD in Solid State Physics in 1974 from the University of Rostock. Since 1974 he has been working in the Institute of Space Research and since 1991 at the German Aerospace Center (DLR) at their branch in Neustrelitz. His research activities include monitoring, modeling and predicting ionospheric processes related to space weather events and studying their impact on radio wave propagation, in particular on GNSS applications.

**Christopher Jekeli**

Ohio State University
School of Earth Sciences
Columbus, USA
*jekeli.1@osu.edu*

Chapter A.2

Christopher Jekeli received his PhD degree in Geodetic Science from the Ohio State University in 1981. He was employed by the U.S. Air Force Geophysical Laboratory as geodesist (1981–1993), joined the faculty of the Department of Geodetic Science, and the School of Earth Sciences, at the Ohio State University (2005). His principal research interests are geodesy and the Earth's gravity field, its modeling and measurement for geodetic and geophysical applications.

**Gary Johnston**

Geoscience Australia
Symonston, Australia
*gary.johnston@ga.gov.au*

Chapter F.33

Gary Johnston leads the Geodesy and Seismic Monitoring Group at Geoscience Australia. He is the Chair of the International GNSS Service (IGS) Governing Board and the Chair of the UN Global Geospatial Information Management (UN GGIM) working group on the Global Geodetic Reference Frame (GGRF).

**Allison Kealy**

University of Melbourne
Dept. of Infrastructure Engineering
Parkville, Australia
*akealy@unimelb.edu.au*

Chapter E.29

Dr Allison Kealy is an Associate Professor in the Department of Infrastructure Engineering at The University of Melbourne Australia. She holds a PhD in GPS and Geodesy from the University of Newcastle upon Tyne, UK. Allison's research interests include sensor fusion, Kalman filtering, high precision satellite positioning, GNSS quality control, wireless sensor networks and location based services.

**Satoshi Kogure**

National Space Policy Secretariat,
Cabinet Office
QZSS Strategy Office
Tokyo, Japan
*satoshi.kogure.e7f@cao.go.jp*

Chapter B.11

Satoshi Kogure is the former Mission Manager for QZSS in the Satellite Navigation Unit, JAXA. He received an MS from Nagoya University in 1993 and joined the Japanese National Space Agency. He started system design work for the Japanese navigation satellite system QZSS in 2001 and led its technical validation and demonstration after the first satellite launch in 2010. Since 2016, he coordinates the QZS programme within the Japanese Cabinet Office.

**Jan Kouba**

Natural Resources Canada
Canadian Geodetic Survey
Ottawa, Canada
*kouba@rogers.com*

Chapter E.25

Jan Kouba obtained his Doctorate of Science from the Czech Academy of Sciences in 1994. He has been working in satellite geodesy since 1970. He has held several research positions at the Geological Survey of Canada and the Geodetic Survey Division (GSD) of the Natural Resources Canada (NRCan). During 1994–1998 he led the Canadian Active Control Technology/IGS (International GPS Service) Analysis Team at GSD and served as the first Analysis Center Coordinator of IGS.

**François Lahaye**

Natural Resources Canada
Canadian Geodetic Survey
Ottawa, Canada
*francois.lahaye@canada.ca*

Chapter E.25

François Lahaye leads the Geodetic Space-based Technology team at the Canadian Geodetic Survey of Natural Resources Canada. He holds an MSc in geodetic sciences from Laval University, Canada.

**Richard B. Langley**

University of New Brunswick
Dept. of Geodesy & Geomatics Engineering
Fredericton, Canada
*lang@unb.ca*

Chapter A.1

Richard B. Langley is Professor in the Department of Geodesy and Geomatics Engineering at the University of New Brunswick in Fredericton, Canada, where he has been teaching and conducting research since 1981. He holds a PhD in Experimental Space Science from York University, Toronto. His general area of expertise is precision applications of GNSS and he has been active in the development of GNSS error models since the early 1980s.

**Ken MacLeod**

Natural Resources Canada
Canadian Geodetic Survey
Ottawa, Canada
*ken.macleod@canada.ca*

Annex A

Ken MacLeod received a Bachelor of Science degree from the University of Toronto in 1985. He joined the Canadian Geodetic survey in 1987 and since 1995 he has worked on the development of GNSS augmentation systems. He is currently the IGS/RTCM SC104 RINEX working group chairman.

**Moazam Maqsood**

Institute of Space Technology
Dept. of Electrical Engineering
Islamabad, Pakistan
*moazam.maqsood@ist.edu.pk*

Chapter C.17

Moazam Maqsood received his Communication Systems Engineering degree from the Institute of Space Technology (IST), Islamabad, Pakistan in 2006, and MS and PhD degrees from the University of Surrey, UK, in 2009 and 2013. He is currently serving as Assistant Professor in the Electrical Engineering Department at IST. His research interests include use of synthetic aperture radars (SAR) for public safety applications.

**Michael Meurer**

German Aerospace Center (DLR)
Institute of Communications and Navigation
Wessling, Germany
*michael.meurer@dlr.de*

Chapter A.4; Annex B

Dr Michael Meurer is Head of the Department of Navigation of the German Aerospace Center (DLR), Institute of Communications and Navigation, and the Coordinating Director of the DLR Center of Excellence for Satellite Navigation. He is also Professor of Electrical Engineering and Director of the Chair of Navigation at RWTH Aachen. His current research interests include GNSS signals, GNSS receivers, interference and spoofing mitigation, and navigation for safety-critical applications.

**Oliver Montenbruck** Chaps. A.1, A.2, A.3, B.8, B.10, B.11, C.17, E.32; Annexes A, B For biographical profile, please see the section "About the Editors".

**Terry Moore**

University of Nottingham
Nottingham Geospatial Institute
Nottingham, UK
*terry.moore@nottingham.ac.uk*

Chapter E.29

Professor Terry Moore is Director of the Nottingham Geospatial Institute (NGI) at the University of Nottingham. He holds a BSc degree in Civil Engineering and a PhD degree in Space Geodesy, both from the University of Nottingham. He is a Fellow, and a Member of Council, of both the Institute of Navigation and of the Royal Institute of Navigation.

**Dennis Odijk**

Fugro Intersite B.V.
Leidschendam, The Netherlands
*d.odijk@fugro.com*

Chapters D.21, E.26

Dennis Odijk received his PhD degree in Geodetic Engineering from Delft University of Technology, the Netherlands (2002). From 2009 to 2016 he was a Research Fellow at the GNSS Research Centre at Curtin University in Perth, Australia, where he focused on RTK and integer ambiguity resolution enabled PPP. At present Dennis is working as Senior Geodesist with Fugro Intersite in the Netherlands, where he contributes to Fugro's GNSS positioning algorithms.

**Thomas Pany**

Universität der Bundeswehr München
Inst. of Space Technology and Space Applications
Neubiberg, Germany
*thomas.pany@unibw.de*

Chapter C.14

Prof. Thomas Pany is with the Universität der Bundeswehr München where teaches navigation. He obtained a PhD from the Graz University of Technology. His research focuses on GNSS signals, GNSS receiver design and integration with other sensors. Previously he worked for IFEN GmbH and is the architect of the world's most powerful GNSS software receiver.

**Mark G. Petovello**

University of Calgary
Geomatics Engineering
Calgary, Canada
*mark.petovello@ucalgary.ca*

Chapter C.18

Mark G. Petovello received his BSc and PhD degrees in Geomatics Engineering at the University of Calgary in 1998 and 2003, respectively. He is currently a Professor at the same university with research interests in satellite-based navigation, inertial navigation, and multi-sensor integration. He has written and licensed several navigation-related software packages and is actively involved in the navigation community.

**Sam Pullen**

Stanford University
Dept. of Aeronautics and Astronautics
Stanford, USA
*spullen@stanford.edu*

Chapter E.31

Sam Pullen is Technical Manager of the Ground Based Augmentation System (GBAS) research effort within the GNSS Laboratory at Stanford University, where he received his PhD in Aeronautics and Astronautics in 1996. He has supported FAA and other service providers in developing system concepts, technical requirements, integrity algorithms, and performance models for GBAS, SBAS, and other GNSS applications. He has performed GNSS system design, applications, and risk assessment through his consultancy.

**Sergey Revnivykh**

RESHETNEV's Information Satellite Systems Coporation
GLONASS Evolution Department
Moscow, Russian Federation
*revnivykh@iss-reshetnev.ru*

Chapter B.8

Sergey Revnivykh is Deputy Head of the GLONASS Directorate and Director of the GLONASS Evolution Department of Reshetnev's Information Satellite Systems Corporation. Since 2001 he has been actively involved in the GLONASS Federal Program development, management, and implementation. Since 2005 he has been a co-chair of the Working Group on GNSS Compatibility and Interoperability of the International Committee on GNSS. He received his PhD from Moscow Aviation Institute (2006).

**Anna Riddell**

Geoscience Australia
Symonston, Australia
*anna.riddell@ga.gov.au*

Chapter F.33

As a graduate of the University of Tasmania, Anna started her career in geodesy at Geoscience Australia, where she is currently the Primary Operator of the robotic GNSS antenna calibration facility. Other research activities include GNSS analysis for the production of the Asia Pacific Reference Frame (APREF) and providing legal traceability for the verification of position within Australia.

**Antonio Rius**

Institute of Space Sciences
ICE (IEEC-CSIC)
Cerdanyola del Valles, Spain
*rius@ice.csic.es*

Chapter G.40

Antonio Rius received a PhD degree from Barcelona University, Spain, in 1974. From 1975 to 1985, he was a member of the technical staff at NASA's Deep Space Communications Complex, Madrid, Spain, where he was responsible for radio astronomical activities. Since 1986, he has been with the Spanish Research Council and the Institut d'Estudis Espacials de Catalunya.

**Chris Rizos**

The University of New South Wales
School of Civil & Environmental Engineering
Kensington, Australia
*c.rizos@unsw.edu.au*

Chapter F.35

Chris Rizos is Professor of Geodesy and Navigation, School of Civil and Environmental Engineering, University of New South Wales, Australia. Chris is immediate Past President of the International Association of Geodesy (IAG), a member of the Governing Board of the International GNSS Service (IGS), and co-chair of the Multi-GNSS Asia Steering Committee. Chris has been researching the technology and applications of GPS and other navigation/positioning systems since 1985.

**Ken Senior**

US Naval Research Laboratory
Advanced Space PNT Branch
Washington, USA
*ken.senior@nrl.navy.mil*

Chapter A.5

Kenneth L. Senior received his PhD in Applied Mathematics from Bowling Green State University, in 1997. He joined the Naval Research Laboratory as a scientist in 2001 and currently heads the Advanced Space Positioning Navigation and Timing Branch of the Naval Research Laboratory. His research interests include precision time and frequency transfer, timescales, and the analysis of precision clocks.

**Alexander Serdyukov (deceased)**

Chapter B.8

**Tim Springer**

PosiTim UG
Seeheim-Jugenheim, Germany
*tim.springer@positim.com*

Chapter F.34

Tim Springer studied Aerospace Engineering at the Technical University of Delft, and worked at the Astronomical Institute of the University of Bern, where he received his PhD in Physics in 1999. He started the company PosiTim, which offers services and solutions for high accuracy GNSS marked based on the ESA/ESOC software NAPEOS. He has been working at the Navigation Support Office of ESA/ESOC in Darmstadt since 2004.

**Peter Steigenberger**

German Aerospace Center (DLR)
German Space Operations Center
Wessling, Germany
*peter.steigenberger@dlr.de*

Chapter F.34; Annex B

Peter Steigenberger received his Master's and PhD degrees in Geodesy from the Technical University of Munich (TUM) in 2002 and 2009, respectively. Currently, he is Scientific Staff Member at DLR's German Space Operations Center (GSOC). His research interests focus on GNSS data analysis, in particular precise orbit and clock determination of GNSS satellites and the evolving navigation systems Galileo, BeiDou, and QZSS.

**Jing Tang**

China National Administration of GNSS and Applications
Beijing, China
*blazingtangjing@163.com*

Chapter B.10

Jing Tang is an engineer at China National Administration of GNSS and Applications (CNAGA). She received her BA in English from Henan University of Science and Technology in 1996. Since 2007, she has been closely involved in the bilateral frequency coordination between BeiDou and other GNSSs. She has been an active participant of the Internal Committee of GNSS (ICG) meetings since 2008. She has coauthored several papers about the Beidou Satellite Navigation System.

**Pierre Tétreault**

Natural Resources Canada
Canadian Geodetic Survey
Ottawa, Canada
*pierre.tetreault@canada.ca*

Chapter E.25

Pierre Tétreault is a member of the Space Based Technology team of the Canadian Geodetic Survey at Natural Resources Canada. His work is focused on GNSS based end-user applications for reference frame access. He received an MSc with specialization in geodesy from the University of Toronto in 1987.

**Peter J.G. Teunissen** Chapters A.1, D.22, D.23, D.24 For biographical profile, please see the section "About the Editors".

**Sandra Verhagen**

Delft University of Technology
Faculty of Civil Engineering and Geosciences
Delft, The Netherlands
*a.a.verhagen@tudelft.nl*

Chapter D.22

Sandra Verhagen is Assistant Professor at Delft University of Technology. She received her PhD in Geodesy from the same university. She is Theme Leader of Sensing from Space of the Delft Space Institute, and was the president of Commission 4 Positioning and Applications of the International Association of Geodesy (2007–2011). Her research interests are mathematical geodesy and positioning, with a focus on algorithm development for very precise and reliable positioning with GNSS.

**Todd Walter**

Stanford University, GPS Lab
Stanford, USA
*twalter@stanford.edu*

Chapter B.12

Todd Walter is a Senior Research Engineer in the Department of Aeronautics and Astronautics at Stanford University. He received his PhD in Applied Physics from Stanford University in 1993. His research focuses on implementing high-integrity air navigation systems. He is active in international standards bodies coordinating the use of global navigation satellite systems to implement these systems. He is a Fellow of ION and has also served as its President.

**Lambert Wanninger**

Technical University Dresden
Geodetic Institute
Dresden, Germany
*lambert.wanninger@tu-dresden.de*

Chapter E.26

Lambert Wanninger is Professor of Geodesy at the Technical University of Dresden (TU Dresden). He holds a Dr.-Ing. degree in Geodesy from the University of Hannover, Germany, and a Habilitation degree in Geodesy from TU Dresden. He has been involved in research on precise GNSS positioning since 1990.

**Jan P. Weiss**

University Corporation for Atmospheric Research
COSMIC Program
Boulder, USA
*weissj@ucar.edu*

Chapter F.34

Jan P. Weiss is Manager of the COSMIC Data Analysis and Archive Center at the University Corporation for Atmospheric Research in Boulder, CO. His research focuses on precise orbit and clock determination, and geodetic applications of GNSS. At JPL, he worked as an analyst and developer for the JPL IGS Analysis Center, GIPSY-OASIS software, NASA Global Differential GNSS System, and next generation GPS control segment navigation software.

**Jan Wendel**

Airbus DS GmbH
Navigation and Apps. Programmes
Taufkirchen, Germany
*jan.wendel@airbus.com*

Chapter E.28

Jan Wendel received the Dipl.-Ing. and Dr.-Ing. degrees in Electrical Engineering from the University of Karlsruhe in 1998 and 2003, respectively. From 2003 until 2006 he was Assistant Professor at the University of Karlsruhe, where he is currently a private lecturer. In 2006, he joined MBDA in Munich. In 2009, he joined EADS Astrium GmbH in Munich, Germany, now Airbus DS GmbH, where he is involved in various activities related to satellite navigation.

**Jens Wickert**

GFZ German Research Centre for Geosciences
Dept. of Geodesy
Potsdam, Germany
*wickert@gfz-potsdam.de*

Chapter G.38

Jens Wickert graduated in physics from TU Dresden and received his PhD from Karl-Franzens-University Graz, in 2002. Since 1999 he has been with the German Research Centre for Geosciences (GFZ) and is responsible for GNSS remote sensing research. He was Principal Investigator of the pioneering GPS Radio Occultation experiment aboard the German CHAMP satellite and holds a joint professorship on GNSS Remote Sensing, Navigation and Positioning of GFZ and Technische Universität Berlin since 2016.

**Jong-Hoon Won**

Inha University
Faculty of Electrical Engineering
Incheon, Korea
*jh.won@inha.ac.kr*

Chapters C.13, C.14

Jong-Hoon Won studied control engineering at Ajou University, Suwon, South Korea (PhD). He joined the Institute of Space Technology and Space Applications (formerly the Institute of Geodesy and Navigation), University of Federal Armed Forces (UFAF) Munich, Germany in 2005. Currently, he is Assistant Professor of Electrical Engineering at Inha University, South Korea. His current research interests are in the field of GNSS signals, receivers, navigation, and target tracking systems.

**Yuanxi Yang**

China National Administration of GNSS and Applications
Beijing, China
*yuanxi_yang@163.com*

Chapter B.10

Yuanxi Yang is Professor of Geodesy and Navigation at both Xian Research Institute of Surveying and Mapping and China National Administration of GNSS and Applications (CNAGA). He received his PhD in Geodesy from the Institute of Geodesy and Geophysics of the Chinese Academy of Science. His main research field includes geodetic data processing, navigation, and geodetic coordinate system, etc.

# Detailed Contents

**List of Abbreviations** ..... XXVII

## Part A Principles of GNSS

1 **Introduction to GNSS**
*Richard B. Langley, Peter J.G. Teunissen, Oliver Montenbruck* ..... 3
1.1 Early Satellite Navigation ..... 3
1.2 Concept of GNSS Positioning ..... 5
1.2.1 Ranging Measurements ..... 5
1.2.2 Range-Based Positioning ..... 6
1.2.3 Pseudorange Positioning ..... 7
1.2.4 Precision of Position Solutions ..... 8
1.2.5 GNSS Observation Equations ..... 10
1.3 Modeling the Observations ..... 10
1.3.1 Satellite Orbit and Clock Information ..... 10
1.3.2 Atmospheric Propagation Delay ..... 11
1.4 Positioning Modes ..... 13
1.4.1 Precise Point Positioning ..... 13
1.4.2 Code Differential Positioning ..... 14
1.4.3 Differential Carrier Phase ..... 14
1.5 Current and Developing GNSSs ..... 16
1.5.1 Global Navigation Satellite Systems ..... 16
1.5.2 Regional Navigation Satellite Systems ..... 18
1.5.3 Satellite-Based Augmentation Systems ..... 19
1.6 GNSS for Science and Society at Large ..... 19
**References** ..... 22

2 **Time and Reference Systems**
*Christopher Jekeli, Oliver Montenbruck* ..... 25
2.1 Time ..... 25
2.1.1 Dynamic Time ..... 26
2.1.2 Atomic Time Scales ..... 27
2.1.3 Sidereal and Universal Time, Earth Rotation ..... 27
2.1.4 GNSS System Times ..... 30
2.2 Spatial Reference Systems ..... 31
2.2.1 Coordinate Systems ..... 31
2.2.2 Reference Systems and Frames ..... 34
2.3 Terrestrial Reference System ..... 34
2.3.1 Traditional Geodetic Datums ..... 34
2.3.2 Global Reference System ..... 36
2.3.3 Terrestrial Reference Systems for GNSS Users ..... 39
2.3.4 Frame Transformations ..... 40
2.3.5 Earth Tides ..... 42
2.4 Celestial Reference System ..... 44
2.5 Transformations Between ICRF and ITRF ..... 46

2.5.1 Orientation of the Earth in Space ..... 46
2.5.2 New Conventions ..... 50
2.5.3 Polar Motion ..... 52
2.5.4 Transformations ..... 54
2.6 Perspectives ..... 55
**References** ..... 56

3 **Satellite Orbits and Attitude**
*Urs Hugentobler, Oliver Montenbruck* ..... 59
3.1 Keplerian Motion ..... 59
3.1.1 Basic Properties ..... 59
3.1.2 Keplerian Orbit Model ..... 61
3.1.3 Ground Track and Visibility ..... 63
3.2 Orbit Perturbations ..... 66
3.2.1 Orbit Representation ..... 66
3.2.2 Perturbing Accelerations ..... 67
3.2.3 Perturbations at GNSS Satellite Altitude ..... 71
3.2.4 Radiation Pressure ..... 72
3.2.5 Long-Term Evolution ..... 74
3.2.6 Orbit Accuracy ..... 77
3.3 Broadcast Orbit Models ..... 79
3.3.1 Almanac Models ..... 80
3.3.2 Keplerian Ephemeris Models ..... 81
3.3.3 Cartesian Ephemeris Model ..... 83
3.3.4 Broadcast Ephemeris Generation and Performance ..... 83
3.4 Attitude ..... 85
**References** ..... 87

4 **Signals and Modulation**
*Michael Meurer, Felix Antreich* ..... 91
4.1 Radiofrequency Signals ..... 91
4.1.1 Maxwell's Theory of Electromagnetic Waves and Electromagnetic Foundation ..... 91
4.1.2 Modulation and Complex Baseband Representation of Signals ..... 93
4.1.3 Frequency Bands and Polarization ..... 96
4.2 Spread Spectrum Technique and Pseudo Random Codes ..... 97
4.2.1 Spread Spectrum Signals for Ranging ..... 97
4.2.2 Pseudo-Random Binary Sequences ..... 99
4.2.3 Correlation and Time-Delay Estimation ..... 102
4.3 Modulation Schemes ..... 107
4.3.1 Binary Phase Shift Keying ..... 107
4.3.2 Binary Offset Carrier Modulation and Derivatives ..... 109
4.4 Signal Multiplexing ..... 113
4.4.1 Interplex ..... 114
4.4.2 AltBOC ..... 116
4.5 Navigation Data and Data-Free Channels ..... 117
**References** ..... 118

5 **Clocks**
*Ron Beard, Ken Senior* ..... 121
5.1 Frequency and Time Stability ..... 122
5.1.1 Concepts ..... 123
5.1.2 Characterization of Clock Stability ..... 123
5.2 Clock Technologies ..... 127
5.2.1 Quartz Crystal Oscillators ..... 127
5.2.2 Conventional Atomic Standards ..... 128
5.2.3 Timescale Atomic Standards ..... 135
5.2.4 Small Atomic Clock Technology ..... 136
5.2.5 Developing Clock Technologies ..... 137
5.3 Space-Qualified Atomic Standards ..... 138
5.3.1 Space Rubidium Atomic Clocks ..... 139
5.3.2 Space-Qualified Cesium Beam Clocks ..... 140
5.3.3 Space-Qualified Hydrogen Maser Clocks ..... 141
5.3.4 Space Linear Ion Trap System (LITS) ..... 142
5.3.5 Satellite Onboard Timing Subsystems ..... 142
5.3.6 On-Orbit Performance of Space Atomic Clocks ..... 144
5.4 Relativistic Effects on Clocks ..... 148
5.4.1 Relativistic Terms ..... 148
5.4.2 Coordinate Timescales ..... 150
5.4.3 Geocentric Coordinate Systems ..... 150
5.4.4 Propagation of Signals ..... 153
5.4.5 Relativistic Offset for GNSS Satellite Clocks ..... 154
5.5 International Timescales ..... 155
5.5.1 International Atomic Time (TAI) ..... 155
5.5.2 Coordinated Universal Time (UTC) ..... 157
5.6 GNSS Timescales ..... 158
**References** ..... 160

6 **Atmospheric Signal Propagation**
*Thomas Hobiger, Norbert Jakowski* ..... 165
6.1 Electromagnetic Wave Propagation ..... 165
6.1.1 Maxwell Equations ..... 166
6.1.2 Electromagnetic Wave Propagation in the Troposphere ..... 166
6.1.3 Electromagnetic Wave Propagation in the Ionosphere ..... 167
6.2 Troposphere ..... 168
6.2.1 Characteristics of the Troposphere ..... 168
6.2.2 Tropospheric Refraction ..... 170
6.2.3 Empirical Models of the Troposphere ..... 172
6.2.4 Troposphere Delay Estimation ..... 174
6.3 Ionospheric Effects on GNSS Signal Propagation ..... 177
6.3.1 The Ionosphere ..... 177
6.3.2 Refraction of Transionospheric Radio Waves ..... 179
6.3.3 Diffraction and Scattering of GNSS Signals ..... 183
6.3.4 Ionospheric Models ..... 184
6.3.5 Measurement-Based Ionosphere Correction ..... 189
**References** ..... 190

## Part B Satellite Navigation Systems

7 **The Global Positioning System (GPS)**
*Christopher J. Hegarty* ..... 197
7.1 Space Segment ..... 197
7.1.1 Constellation Design and Management ..... 197
7.1.2 GPS Satellites ..... 199
7.2 Control Segment ..... 203
7.2.1 Overview ..... 203
7.2.2 Evolution of Capabilities ..... 204
7.2.3 Operations ..... 204
7.3 Navigation Signals ..... 205
7.3.1 Legacy ..... 205
7.3.2 Modernized Signals ..... 206
7.3.3 Power Levels ..... 209
7.4 Navigation Data and Algorithms ..... 210
7.4.1 Legacy Navigation (LNAV) Data Overview ..... 210
7.4.2 LNAV Error Detection Encoding ..... 211
7.4.3 LNAV Data Content and Related Algorithms ..... 211
7.4.4 Civil Navigation (CNAV) and Civil Navigation-2 (CNAV-2) Data ..... 215
7.5 Time System and Geodesy ..... 216
7.6 Services and Performance ..... 216
**References** ..... 217

8 **GLONASS**
*Sergey Revnivykh, Alexey Bolkunov, Alexander Serdyukov Oliver Montenbruck* ..... 219
8.1 Overview ..... 219
8.1.1 History and Evolution ..... 219
8.1.2 Constellation ..... 220
8.1.3 GLONASS Geodesy Reference PZ-90 ..... 221
8.1.4 GLONASS Time ..... 223
8.2 Navigation Signals and Services ..... 225
8.2.1 GLONASS Services ..... 225
8.2.2 FDMA Signals ..... 226
8.2.3 CDMA Signals ..... 229
8.3 Satellites ..... 232
8.3.1 GLONASS I/II ..... 233
8.3.2 GLONASS-M ..... 235
8.3.3 GLONASS-K ..... 236
8.4 Launch Vehicles ..... 237
8.5 Ground Segment ..... 238
8.6 GLONASS Open Service Performance ..... 241
**References** ..... 243

9 **Galileo**
*Marco Falcone, Jörg Hahn, Thomas Burger* ..... 247
9.1 Constellation ..... 248
9.2 Signals and Services ..... 250
9.2.1 Signal Components and Modulations ..... 251

9.2.2 Navigation Message and Services ..... 256
9.2.3 Ranging Performance ..... 258
9.2.4 Timing Accuracy ..... 263
9.3 Spacecraft ..... 265
9.3.1 Satellite Platform ..... 266
9.3.2 Satellite Payload Description ..... 266
9.3.3 Launch Vehicles ..... 268
9.4 Ground Segment ..... 269
9.5 Summary ..... 270
**References** ..... 271

10 **Chinese Navigation Satellite Systems**
*Yuanxi Yang, Jing Tang, Oliver Montenbruck* ..... 273
10.1 BeiDou Navigation Satellite Demonstration System (BDS-1) ..... 275
10.1.1 System Architecture and Basic Characteristics ..... 275
10.1.2 Navigation Principle ..... 277
10.1.3 Orbit Determination ..... 278
10.1.4 Timing ..... 278
10.2 BeiDou (Regional) Navigation Satellite System (BDS-2) ..... 279
10.2.1 Constellation ..... 279
10.2.2 Signals and Services ..... 281
10.2.3 Navigation Message ..... 283
10.2.4 Space Segment ..... 286
10.2.5 Operational Control System ..... 288
10.2.6 BeiDou Satellite-Based Augmentation System ..... 289
10.2.7 Coordinate Reference System ..... 290
10.2.8 Time System ..... 291
10.3 Performance of BDS-2 ..... 293
10.3.1 Service Region ..... 293
10.3.2 Performance of Satellite Clocks ..... 293
10.3.3 Positioning Performance ..... 295
10.3.4 Application Examples ..... 297
10.4 BeiDou (Global) Navigation Satellite System ..... 297
10.5 Brief Introduction of CAPS ..... 298
10.5.1 CAPS Concept and System Architecture ..... 298
10.5.2 Positioning Principle of CAPS ..... 300
10.5.3 Trial CAPS System ..... 301
**References** ..... 301

11 **Regional Systems**
*Satoshi Kogure, A.S. Ganeshan, Oliver Montenbruck* ..... 305
11.1 Concept of Regional Navigation Satellite Systems ..... 306
11.2 Quasi-Zenith Satellite System ..... 306
11.2.1 Overview ..... 306
11.2.2 Constellation ..... 307
11.2.3 Signals and Services ..... 308
11.2.4 Spacecraft ..... 313
11.2.5 Control Segment ..... 317
11.2.6 Operations Concept ..... 319
11.2.7 Current Performance ..... 320

11.3 Indian Regional Navigation Satellite System (IRNSS/NavIC) ..... 321
11.3.1 Constellation ..... 322
11.3.2 Signal and Data Structure ..... 322
11.3.3 Spacecraft ..... 327
11.3.4 Ground Segment ..... 330
11.3.5 System Performance ..... 333
**References** ..... 334

12 **Satellite Based Augmentation Systems**
*Todd Walter* ..... 339
12.1 Aircraft Guidance ..... 340
12.1.1 Aviation Requirements ..... 340
12.1.2 Traditional Navigational Aids ..... 341
12.1.3 Receiver Autonomous Integrity Monitoring (RAIM) ..... 341
12.1.4 Satellite-Based Augmentation Systems (SBAS) ..... 342
12.2 GPS Error Sources ..... 343
12.2.1 Satellite Clock and Ephemeris ..... 344
12.2.2 Ionosphere ..... 344
12.2.3 Troposphere ..... 344
12.2.4 Multipath ..... 345
12.2.5 Other Error Sources ..... 345
12.3 SBAS Architecture ..... 345
12.3.1 Reference Stations ..... 345
12.3.2 Master Stations ..... 346
12.3.3 Ground Uplink Stations and Geostationary Satellites ..... 347
12.3.4 Operational Control Centers ..... 349
12.4 SBAS Integrity ..... 349
12.4.1 Integrity Certification ..... 349
12.4.2 Threat Models ..... 350
12.4.3 Overbounding ..... 350
12.5 SBAS User Algorithms ..... 351
12.5.1 Message Structure ..... 351
12.5.2 Message Application ..... 352
12.5.3 Protection Levels ..... 353
12.6 Operational and Planned SBAS Systems ..... 353
12.6.1 Wide Area Augmentation System (WAAS) ..... 353
12.6.2 Multifunction Satellite Augmentation System (MSAS) ..... 356
12.6.3 European Geostationary Navigation Overlay Service (EGNOS) ..... 356
12.6.4 GPS Aided GEO Augmented Navigation (GAGAN) ..... 356
12.6.5 System of Differential Corrections and Monitoring (SDCM) 358
12.6.6 BeiDou Satellite-Based Augmentation System (BDSBAS) .. 358
12.6.7 Korean Augmentation Satellite System (KASS) ..... 358
12.7 Evolution of SBAS ..... 358
12.7.1 Multiple Frequencies ..... 358
12.7.2 Multiple Constellations ..... 359
**References** ..... 360

## Part C GNSS Receivers and Antennas

13 **Receiver Architecture**
*Bernd Eissfeller, Jong-Hoon Won* ..... 365
13.1 Background and History ..... 366
13.1.1 Analog Versus Digital Receivers ..... 366
13.1.2 Early Military Developments ..... 367
13.1.3 Early Civil Developments ..... 368
13.1.4 Early Receiver Developments for Other Satellite Navigation Systems ..... 369
13.1.5 Early BeiDou Receiver Developments ..... 371
13.2 Receiver Building Blocks ..... 372
13.2.1 Antenna ..... 373
13.2.2 RF Front End ..... 376
13.2.3 Analog-to-Digital Conversion ..... 380
13.2.4 Oscillators ..... 383
13.2.5 Chip Technologies ..... 386
13.2.6 Implementation Issues ..... 390
13.3 Multifrequency and Multisystem Receivers ..... 391
13.3.1 Civil Receivers for GPS Modernization ..... 391
13.3.2 Galileo Receivers ..... 394
13.3.3 GLONASS Receivers ..... 394
13.3.4 BeiDou/Compass Receivers ..... 395
13.3.5 Military GPS Receivers ..... 395
13.4 Technology Trends ..... 396
13.4.1 Civil Low-End Trends ..... 396
13.4.2 Civil High-End Trends ..... 396
13.4.3 Trends in Military and/or Governmental Receivers ..... 397
13.5 Receiver Types ..... 397
13.5.1 Navigation Receivers Handheld ..... 397
13.5.2 Navigation Receivers Non-Handheld ..... 397
13.5.3 Engines, OEM Modules, Chips, and Dies ..... 398
13.5.4 Time Transfer Receivers ..... 398
13.5.5 Geodetic Receivers ..... 398
13.5.6 Space Receivers ..... 398
13.5.7 Attitude Determination Receivers ..... 398
**References** ..... 399

14 **Signal Processing**
*Jong-Hoon Won, Thomas Pany* ..... 401
14.1 Overview and Scope ..... 402
14.2 Received Signal Model ..... 403
14.2.1 Generic GNSS Signal ..... 403
14.2.2 Signal Model at RF and IF ..... 404
14.2.3 Correlator Model ..... 404
14.3 Signal Search and Acquisition ..... 406
14.3.1 Test Statistics ..... 406
14.3.2 Acquisition Module Architecture ..... 408
14.3.3 Coherent Integration Methods ..... 409
14.3.4 Search Space ..... 410

14.3.5 Acquisition Performance ..... 411
14.3.6 Handling Data Bits and Secondary Codes ..... 412
14.4 Signal Tracking ..... 413
14.4.1 Architecture ..... 413
14.4.2 Tracking Loop Model ..... 414
14.4.3 Correlators ..... 415
14.4.4 Discriminators ..... 415
14.4.5 Loop Filters ..... 417
14.4.6 NCO and Code/Carrier Generator ..... 419
14.4.7 Aiding ..... 421
14.4.8 Switching Rule ..... 421
14.4.9 BOC Tracking ..... 422
14.4.10 Tracking Performance ..... 422
14.5 Time Synchronization and Data Demodulation ..... 424
14.5.1 Bit/Symbol Synchronization ..... 425
14.5.2 Data Bit/Symbol Demodulation ..... 426
14.5.3 Frame Synchronization ..... 427
14.5.4 Bit Error Correction ..... 427
14.5.5 Data Extraction ..... 428
14.6 GNSS Measurements ..... 428
14.6.1 Code Pseudorange ..... 428
14.6.2 Carrier Phase ..... 431
14.6.3 Doppler ..... 433
14.6.4 Signal Power ..... 434
14.7 Advanced Topics ..... 434
14.7.1 Tracking of GPS P(Y) ..... 434
14.7.2 Generic Data/Pilot Multiplexing Approach ..... 435
14.7.3 Combined Processing of Data and Pilot Signals ..... 436
14.7.4 Combined Processing of Code and Carrier ..... 436
14.7.5 Carrier Tracking Kalman Filter ..... 437
14.7.6 Vector Tracking ..... 438
**References** ..... 440

15 **Multipath**
*Michael S. Braasch* ..... 443
15.1 The Impact of Multipath ..... 444
15.2 Characterizing the Multipath Environment ..... 444
15.3 Multipath Signal Models ..... 448
15.4 Pseudorange and Carrier-Phase Error ..... 450
15.5 Multipath Error Envelopes ..... 450
15.6 Temporal Error Variation, Bias Characteristics and Fast Fading Considerations ..... 453
15.7 Multipath Mitigation ..... 455
15.7.1 Multipath Mitigation via Antenna Placement ..... 455
15.7.2 Antenna Type ..... 456
15.7.3 Receiver Type ..... 457
15.7.4 Measurement Processing ..... 458
15.8 Multipath Measurement ..... 459
15.8.1 Isolation of Pseudorange Multipath ..... 460
15.8.2 Short-Delay Multipath ..... 461

15.8.3 Multipath Repeatability ..... 462
15.8.4 Measurement of Carrier-Phase Multipath ..... 463
15.9 A Note About Multipath Impact on Doppler Measurements ..... 466
15.10 Conclusions ..... 466
**References** ..... 466

16 **Interference**
*Todd Humphreys* ..... 469
16.1 Analysis Technique for Statistically Independent Interference ..... 471
16.1.1 Received Signal Model ..... 471
16.1.2 Thermal-Noise-Equivalent Approximation ..... 471
16.1.3 Limits of Applicability ..... 473
16.1.4 Overview of Interference Effects on Carrier Phase Tracking 474
16.2 Canonical Interference Models ..... 476
16.2.1 Wideband Interference ..... 476
16.2.2 Narrowband Interference ..... 476
16.2.3 Matched-Spectrum Interference ..... 478
16.3 Quantization Effects ..... 479
16.3.1 One-Bit Quantization ..... 479
16.3.2 Multibit Quantization ..... 479
16.4 Specific Interference Waveforms and Sources ..... 481
16.4.1 Solar Radio Bursts ..... 481
16.4.2 Scintillation ..... 482
16.4.3 Unintentional Interference ..... 484
16.4.4 Intentional Interference ..... 485
16.5 Spoofing ..... 485
16.5.1 Generalized Model for Security-Enhanced GNSS Signals .. 486
16.5.2 Attacks Against Security-Enhanced GNSS Signals ..... 486
16.6 Interference Detection ..... 491
16.6.1 $C/N_0$ Monitoring ..... 491
16.6.2 Received Power Monitoring ..... 491
16.6.3 Augmented Received Power Monitoring ..... 493
16.6.4 Spectral Analysis ..... 494
16.6.5 Cryptographic Spoofing Detection ..... 495
16.6.6 Antenna-Based Techniques ..... 497
16.6.7 Innovations-Based Techniques ..... 497
16.7 Interference Mitigation ..... 498
16.7.1 Spectrally or Temporally Sparse Interference ..... 498
16.7.2 Spectrally and Temporally Dense Interference ..... 499
16.7.3 Antenna-Based Techniques ..... 500
**References** ..... 501

17 **Antennas**
*Moazam Maqsood, Steven Gao, Oliver Montenbruck* ..... 505
17.1 GNSS Antenna Characteristics ..... 506
17.1.1 Center Frequency ..... 507
17.1.2 Bandwidth ..... 507
17.1.3 Radiation Pattern ..... 507
17.1.4 Antenna Gain ..... 507
17.1.5 3 dB Beam Width ..... 507

17.1.6 Polarization ..... 508
17.1.7 Axial Ratio ..... 508
17.1.8 Impedance Matching and Return Loss ..... 508
17.1.9 Front-to-Back and Multipath Ratio ..... 509
17.1.10 Phase-Center Stability ..... 509
17.2 Basic GNSS Antenna Types ..... 509
17.2.1 Microstrip Patch Antenna ..... 509
17.2.2 Helix Antenna ..... 510
17.2.3 Quadrifilar Helix Antenna ..... 511
17.2.4 Spiral Antenna ..... 512
17.2.5 Wide-Band Bow-Tie Turnstile Antenna ..... 513
17.2.6 Wide-Band Pinwheel Antenna ..... 513
17.3 Application-Specific GNSS Antennas ..... 513
17.3.1 Hand-Held Terminals ..... 513
17.3.2 Surveying and Geodesy ..... 514
17.3.3 Aviation ..... 515
17.3.4 Space Applications ..... 516
17.3.5 Antijamming Antennas ..... 517
17.3.6 GNSS Remote Sensing ..... 518
17.4 Multipath Mitigation ..... 519
17.4.1 Metallic Reflector Ground Plane ..... 520
17.4.2 Choke-Ring Ground Plane ..... 520
17.4.3 Noncutoff Corrugated Ground Plane ..... 521
17.4.4 Convex Impedance Ground Plane ..... 521
17.4.5 3-D Choke-Ring Ground Plane ..... 521
17.4.6 Cross Plate Reflector Ground Plane ..... 522
17.4.7 Electromagnetic Band Gap (EBG) Substrate ..... 522
17.5 Antennas for GNSS Satellites ..... 523
17.5.1 Concentric Helix Antenna Arrays ..... 523
17.5.2 Patch Antenna Arrays ..... 524
17.5.3 Reflector-Backed Monofilar Antenna ..... 526
17.6 Antenna Measurement and Calibration ..... 527
17.6.1 Basic Antenna Testing ..... 527
17.6.2 Phase-Center Calibration ..... 528
**References** ..... 531

18 **Simulators and Test Equipment**
*Mark G. Petovello, James T. Curran* ..... 535
18.1 Background ..... 537
18.1.1 Received RF Signal ..... 537
18.1.2 GNSS Receivers ..... 540
18.1.3 GNSS Simulators ..... 540
18.1.4 Record and Playback Systems ..... 542
18.1.5 Details ..... 543
18.2 RF-Level Simulators ..... 543
18.2.1 Implementation ..... 544
18.2.2 Important Considerations ..... 544
18.3 IF-Level Simulators ..... 546
18.3.1 Implementation ..... 547
18.3.2 Important Considerations ..... 548

18.4 Record and Playback Systems ..... 549
18.4.1 Implementation ..... 550
18.4.2 Important Considerations ..... 550
18.5 Measurement-Level Simulators ..... 552
18.5.1 Implementation ..... 553
18.5.2 Important Considerations ..... 553
18.6 Combining Live and Simulated Data ..... 554
18.6.1 Implementation ..... 555
18.6.2 Important Considerations ..... 555
18.7 Other Considerations ..... 556
18.7.1 GNSS Systems Supported ..... 556
18.7.2 Interference and Spoofing ..... 556
18.7.3 Other Data ..... 556
18.7.4 Configurability ..... 556
18.7.5 Expandability ..... 556
18.8 Summary ..... 557
**References** ..... 557

## Part D GNSS Algorithms and Models

19 **Basic Observation Equations**
*André Hauschild* ..... 561
19.1 Observation Equations ..... 561
19.1.1 Pseudorange Measurements ..... 561
19.1.2 Carrier-Phase Measurements ..... 563
19.1.3 Doppler Measurements ..... 563
19.2 Relativistic Effects ..... 564
19.3 Atmospheric Signal Delays ..... 565
19.3.1 Ionosphere ..... 566
19.3.2 Troposphere ..... 568
19.4 Carrier-Phase Wind-Up ..... 569
19.4.1 Wind-Up Effect for Radio Waves ..... 569
19.4.2 GNSS Satellite Attitude Modeling ..... 570
19.5 Antenna Phase-Center Offset and Variations ..... 572
19.5.1 Overview ..... 573
19.5.2 Calibration Techniques ..... 574
19.5.3 Examples for Phase-Center Variations ..... 575
19.6 Signal Biases ..... 576
19.6.1 Pseudorange Biases ..... 576
19.6.2 Carrier-Phase Biases ..... 578
19.7 Receiver Noise and Multipath ..... 578
19.7.1 Receiver Noise ..... 578
19.7.2 Multipath Errors ..... 579
**References** ..... 579

20 **Combinations of Observations**
*André Hauschild* ..... 583
20.1 Fundamental Equations ..... 583
20.2 Combinations of Single-Satellite and Single-Receiver Observations 586
20.2.1 Narrow- and Wide-Lane Combinations ..... 586

20.2.2 Ionosphere Combination ..... 589
20.2.3 Ionosphere-Free Combination ..... 590
20.2.4 Multipath Combination ..... 591
20.3 Combinations of Multisatellite and Multireceiver Observations ..... 594
20.3.1 Between-Receiver Single Difference ..... 594
20.3.2 Between-Satellite Single Difference ..... 596
20.3.3 Double Difference ..... 596
20.3.4 Triple Difference ..... 598
20.3.5 Single and Double Difference on Zero-Baselines ..... 599
20.4 Pseudorange Filtering ..... 601
**References** ..... 603

21 **Positioning Model**
*Dennis Odijk* ..... 605
21.1 Nonlinear Observation Equations ..... 606
21.1.1 Single-GNSS Observation Equations ..... 606
21.1.2 Multi-GNSS Observation Equations ..... 607
21.2 Linearization of the Observation Equations ..... 609
21.2.1 Linearizing the Receiver–Satellite Range ..... 609
21.2.2 Linearized Observation Equations ..... 612
21.3 Point Positioning Models ..... 612
21.3.1 Computation of the Satellite Clocks and Hardware Code (Group) Delays ..... 613
21.3.2 Some Remarks on the TGDs/DCBs ..... 615
21.3.3 Computation/Estimation of the Atmospheric Errors ..... 615
21.3.4 Single-Constellation SPP Model ..... 615
21.3.5 Multiconstellation SPP Model ..... 617
21.3.6 Precision and DOP ..... 618
21.3.7 PPP Model ..... 619
21.4 Relative Positioning Models ..... 623
21.4.1 Principle of DGNSS and (PPP-)RTK ..... 623
21.4.2 Impact of Orbit Errors ..... 625
21.4.3 Ionosphere-Fixed/Weighted/Float Models ..... 625
21.4.4 Undifferenced Relative Positioning Models ..... 625
21.4.5 PPP-RTK Models ..... 627
21.4.6 Link Between PPP-RTK and PPP ..... 630
21.5 Differenced Positioning Models ..... 631
21.5.1 Single Differencing ..... 631
21.5.2 Double and Triple Differencing ..... 632
21.5.3 Redundancy of the Differenced Models ..... 633
21.6 The Positioning Concepts Related ..... 633
21.6.1 Global Positioning: SPP/PPP ..... 633
21.6.2 Regional Positioning: Network DGNSS/RTK ..... 634
21.6.3 Local Positioning: Single-Baseline DGNSS/RTK ..... 634
21.6.4 Global/Regional Positioning: PPP-RTK ..... 634
21.6.5 Accuracy of the Positioning Concepts ..... 635
**References** ..... 635

22 **Least-Squares Estimation and Kalman Filtering**
*Sandra Verhagen, Peter J.G. Teunissen* ..... 639
22.1 Linear Least-Squares Estimation ..... 639
22.1.1 Least-Squares Principle ..... 639
22.1.2 Weighted Least-Squares ..... 640
22.1.3 Computation of LS Solution ..... 640
22.1.4 Statistical Properties ..... 641
22.2 Optimal Estimation ..... 641
22.2.1 Best Linear Unbiased Estimation ..... 641
22.2.2 Maximum Likelihood Estimation ..... 642
22.2.3 Confidence Regions ..... 642
22.3 Special Forms of Least Squares ..... 644
22.3.1 Recursive Estimation ..... 644
22.3.2 Estimation with Partitioned Parameter Vector ..... 646
22.3.3 Block Estimation ..... 647
22.3.4 Constrained Least-Squares ..... 647
22.3.5 Rank-Defect Least Squares ..... 647
22.3.6 Non-Linear Least-Squares ..... 648
22.4 Prediction and Filtering ..... 650
22.4.1 Prediction Problem ..... 650
22.4.2 Minimum Mean Squared Error Prediction ..... 651
22.4.3 Properties of MMSE Prediction ..... 653
22.5 Kalman Filtering ..... 653
22.5.1 Model Assumptions ..... 653
22.5.2 The Kalman Filter Recursion ..... 654
22.5.3 Kalman Filter Information Form ..... 655
22.5.4 Extended Kalman Filter ..... 656
22.5.5 Smoothing ..... 657
**References** ..... 659

23 **Carrier Phase Integer Ambiguity Resolution**
*Peter J.G. Teunissen* ..... 661
23.1 GNSS Ambiguity Resolution ..... 662
23.1.1 The GNSS Model ..... 662
23.1.2 Ambiguity Resolution Steps ..... 662
23.1.3 Ambiguity Resolution Quality ..... 663
23.2 Rounding and Bootstrapping ..... 666
23.2.1 Integer Rounding ..... 666
23.2.2 Vectorial Rounding ..... 666
23.2.3 Integer Bootstrapping ..... 667
23.2.4 Bootstrapped Success Rate ..... 668
23.3 Linear Combinations ..... 669
23.3.1 Z-transformations ..... 669
23.3.2 (Extra) Widelaning ..... 669
23.3.3 Decorrelating Transformation ..... 670
23.3.4 Numerical Example ..... 672
23.4 Integer Least-Squares ..... 673
23.4.1 Mixed Integer Least-Squares ..... 673
23.4.2 The ILS Computation ..... 674
23.4.3 Least-Squares Success Rate ..... 676

23.5 Partial Ambiguity Resolution ..... 677
23.6 When to Accept the Integer Solution? ..... 678
23.6.1 Model- and Data-Driven Rules ..... 678
23.6.2 Four Ambiguity Resolution Steps ..... 679
23.6.3 Quality of Accepted Integer Solution ..... 679
23.6.4 Fixed Failure-Rate Ratio Test ..... 680
23.6.5 Optimal Integer Ambiguity Test ..... 681
**References** ..... 683

24 **Batch and Recursive Model Validation**
*Peter J.G. Teunissen* ..... 687
24.1 Modeling and Validation ..... 687
24.2 Batch Model Validation ..... 689
24.2.1 Null versus Alternative Hypothesis ..... 689
24.2.2 Unbiased versus Biased Solution ..... 689
24.2.3 Effect of the Influential Bias ..... 690
24.3 Testing for a Bias ..... 692
24.3.1 The Most Powerful Test Statistic ..... 692
24.3.2 Alternative Expressions for Test Statistic $T_q$ ..... 695
24.3.3 Test Statistic $T_q$ Expressed in LS Residuals ..... 696
24.3.4 Optimality of the $w$-Test Statistic ..... 697
24.3.5 The Minimal Detectable Bias ..... 697
24.3.6 Hazardous Missed Detection ..... 700
24.4 Testing Procedure ..... 705
24.4.1 Detection, Identification and Adaptation ..... 705
24.4.2 Data Snooping ..... 706
24.4.3 Unknowns in the Stochastic Model ..... 709
24.5 Recursive Model Validation ..... 710
24.5.1 Model and Filter ..... 710
24.5.2 Models and UMPI Test Statistic ..... 711
24.5.3 Local and Global Testing ..... 711
24.5.4 Recursive Detection ..... 712
24.5.5 Recursive Identification ..... 713
24.5.6 Recursive Adaptation: General Case ..... 714
24.5.7 Recursive Adaptation: Special GNSS Case ..... 715
**References** ..... 717

**Part E Positioning and Navigation**

25 **Precise Point Positioning**
*Jan Kouba, François Lahaye, Pierre Tétreault* ..... 723
25.1 PPP Concept ..... 724
25.1.1 Observation Equations ..... 724
25.1.2 Adjustment and Quality Control ..... 725
25.2 Precise Positioning Correction Models ..... 726
25.2.1 Atmospheric Propagation Delays ..... 728
25.2.2 Antenna Effects ..... 730
25.2.3 Site Displacement Effects ..... 732
25.2.4 Differential Code Biases ..... 733
25.2.5 Compatibility and Conventions ..... 734

25.3 Specific Processing Aspects ..... 735
25.3.1 Single-Frequency Positioning ..... 735
25.3.2 GLONASS PPP Considerations ..... 736
25.3.3 New Signals and Constellations ..... 737
25.3.4 Phase Ambiguity Fixing in PPP ..... 739
25.4 Implementations ..... 741
25.4.1 Post-Processed Solutions ..... 741
25.4.2 Real-Time Solutions ..... 742
25.4.3 PPP Positioning Services ..... 742
25.5 Examples ..... 743
25.5.1 Static PPP Solutions ..... 743
25.5.2 Kinematic PPP Solutions ..... 743
25.5.3 Tropospheric Zenith Path Delay ..... 745
25.5.4 Station Clock Solutions ..... 745
25.6 Discussion ..... 746
**References** ..... 747

26 **Differential Positioning**
*Dennis Odijk, Lambert Wanninger* ..... 753
26.1 Differential GNSS: Concepts ..... 753
26.1.1 Differential GNSS Observation Equations ..... 753
26.1.2 Differential GNSS Biases ..... 754
26.2 Differential Navigation Services ..... 760
26.2.1 DGNSS Implementations ..... 760
26.2.2 DGNSS Services ..... 761
26.2.3 Data Communication: RTCM Message ..... 762
26.2.4 Latency of DGNSS Corrections ..... 762
26.3 Real-Time Kinematic Positioning ..... 763
26.3.1 Double-Differenced Positioning Model ..... 763
26.3.2 Carrier-Phase-Based Positioning Methods ..... 764
26.3.3 GLONASS RTK Positioning ..... 766
26.3.4 Multi-GNSS RTK Positioning ..... 768
26.3.5 RTK Positioning Examples ..... 770
26.4 Network RTK ..... 774
26.4.1 From RTK to Network RTK ..... 774
26.4.2 Data Processing Methods for Network RTK ..... 774
26.4.3 Network RTK Correction Models ..... 776
26.4.4 Refined Virtual Reference Stations ..... 777
26.4.5 From Network RTK to PPP-RTK ..... 778
**References** ..... 778

27 **Attitude Determination**
*Gabriele Giorgi* ..... 781
27.1 Six Degrees of Freedom ..... 781
27.2 Attitude Parameterization ..... 784
27.2.1 The Space of Rotations ..... 784
27.2.2 Parameterization of the Rotation Matrix ..... 784
27.3 Attitude Estimation from Baseline Observations ..... 787
27.3.1 Estimation of the Orthonormal Matrix of Rotations ..... 787
27.3.2 Orthogonal Procrustes Problem ..... 788

27.3.3 Weighted Orthogonal Procrustes Problem ..... 789
27.3.4 Attitude Estimation with Fully Populated Weight Matrix.. 789
27.3.5 On the Precision of Attitude Estimation ..... 790
27.4 The GNSS Attitude Model ..... 790
27.4.1 Potential Model Errors and Misspecification ..... 791
27.4.2 Resolution of the GNSS Attitude Model ..... 792
27.4.3 The GNSS Ambiguity and Attitude Estimation ..... 793
27.4.4 The Quality of Ambiguity and Attitude Estimations..... 795
27.5 Applications ..... 798
27.5.1 Space Operations ..... 798
27.5.2 Aeronautics Applications ..... 800
27.5.3 Marine Navigation ..... 802
27.5.4 Land Applications ..... 803
27.6 An Overview of GNSS/INS Sensor Fusion for Attitude Determination 804
**References** ..... 806

28 **GNSS/INS Integration**
*Jay A. Farrell, Jan Wendel* ..... 811
28.1 State Estimation Objectives ..... 812
28.2 Inertial Navigation ..... 813
28.2.1 Problem Statement ..... 813
28.2.2 Sensor Models ..... 813
28.2.3 INS Computations ..... 813
28.2.4 INS Error State ..... 814
28.2.5 Performance Characterization ..... 814
28.3 Inertial Sensors ..... 815
28.3.1 Gyroscopes ..... 815
28.3.2 Accelerometers ..... 816
28.3.3 Inertial Sensor Errors ..... 816
28.4 Strapdown Inertial Navigation ..... 818
28.4.1 Coordinate Systems ..... 818
28.4.2 Attitude Calculations ..... 819
28.4.3 Velocity Calculations ..... 821
28.4.4 Position Calculations ..... 821
28.5 Analysis of Error Effects ..... 822
28.5.1 Short-Term Effects ..... 822
28.5.2 Long-Term Effects ..... 823
28.6 Aided Navigation ..... 824
28.7 State Estimation ..... 824
28.8 GNSS and Aided INS ..... 825
28.8.1 Loose (Position Domain) Coupling ..... 825
28.8.2 Tight (Observable Domain) Coupling ..... 826
28.8.3 Ultra-Tight or Deep Coupling ..... 826
28.8.4 Illustrative Comparison ..... 828
28.9 Detailed Example ..... 828
28.9.1 System Model ..... 828
28.9.2 Measurement Models ..... 831
28.10 Alternative Estimation Methods ..... 835
28.10.1 Standalone GNSS ..... 835
28.10.2 Advanced Bayesian Estimation ..... 837

28.11 Looking Forward ..... 838
**References** ..... 839

29 **Land and Maritime Applications**
*Allison Kealy, Terry Moore* ..... 841
29.1 Land-Based Applications of GNSS ..... 842
29.1.1 Personal Devices ..... 843
29.1.2 Location-Based Services ..... 845
29.1.3 Positioning Technologies and Techniques for PN and LBS ..... 846
29.1.4 Intelligent Transport Systems ..... 853
29.2 Rail Applications ..... 856
29.2.1 Signaling and Train Control ..... 857
29.2.2 Freight and Fleet Management ..... 862
29.2.3 Passenger Information Systems ..... 863
29.3 Maritime Applications ..... 863
29.3.1 GNSS Performance Requirements for Maritime Applications ..... 864
29.3.2 Maritime Navigation ..... 867
29.3.3 eLoran ..... 869
29.3.4 Automatic Identification System ..... 869
29.3.5 Shipping Container Tracking ..... 872
29.4 Outlook ..... 873
**References** ..... 873

30 **Aviation Applications**
*Richard Farnworth* ..... 877
30.1 Overview ..... 878
30.1.1 Conventional Navigation ..... 878
30.1.2 Area Navigation – RNAV ..... 879
30.1.3 The Arrival of GNSS ..... 880
30.2 Standardising GNSS for Aviation ..... 881
30.2.1 Aircraft Based Augmentation Systems ..... 882
30.2.2 Satellite Based Augmentation Systems ..... 882
30.2.3 Ground Based Augmentation Systems ..... 883
30.3 Evolution of the Flight Deck ..... 884
30.3.1 The Navigation Data Chain ..... 885
30.3.2 General Aviation ..... 885
30.3.3 Helicopters ..... 885
30.4 From the RNP Concept to PBN ..... 886
30.4.1 Performance Based Navigation (PBN) ..... 886
30.4.2 Navigation Specifications ..... 886
30.5 GNSS Performance Requirements ..... 888
30.5.1 Description of the Relevant Parameters ..... 888
30.5.2 GNSS Integrity Concepts ..... 890
30.6 Linking the PBN Requirements and the GNSS Requirements ..... 891
30.6.1 Phases of Flight ..... 891
30.6.2 RNAV Approaches ..... 893
30.6.3 RNP AR APCH ..... 895
30.7 Flight Planning and NOTAMs ..... 897

30.8 Regulation and Certification ..... 897
30.8.1 Airworthiness Certification ..... 897
30.8.2 Operational Approvals ..... 898
30.9 Military Aviation Applications ..... 898
30.10 Other Aviation Applications of GNSS ..... 899
30.10.1 Surveillance (ADS-B) ..... 899
30.10.2 Datalink ..... 899
30.11 Future Evolution ..... 900
30.11.1 GNSS Vulnerability and Alternative-PNT ..... 900
30.11.2 Rationalisation of the Navigation Infrastructure ..... 900
30.11.3 Multi-Constellation ..... 901
**References** ..... 901

31 **Ground Based Augmentation Systems**
*Sam Pullen* ..... 905
31.1 Components ..... 906
31.2 An Overview of Local Area Approaches ..... 907
31.2.1 Pseudorange Corrections ..... 907
31.2.2 Carrier-Phase Corrections ..... 908
31.2.3 Reference Station Distribution ..... 908
31.2.4 Broadcast Techniques ..... 908
31.3 Ground-Based Augmentation Systems ..... 909
31.3.1 Overview and Requirements ..... 909
31.3.2 Generation of Differential Corrections ..... 910
31.3.3 Fault Monitoring ..... 911
31.3.4 User Processing and Integrity Verification ..... 917
31.3.5 Additional Threats: RF Interference and Ionosphere ..... 921
31.3.6 Equipment and Siting Considerations ..... 925
31.3.7 Typical GBAS Errors and Protection Levels ..... 926
31.3.8 Existing GBAS Ground Systems and Airborne Equipment ..... 928
31.4 Augmentation via Ranging Signals Pseudolites ..... 928
31.4.1 Origins and Use in Local-Area DGNSS ..... 928
31.4.2 New-Generation Pseudolite Systems for Commercial Applications ..... 929
31.5 Outlook ..... 930
**References** ..... 930

32 **Space Applications**
*Oliver Montenbruck* ..... 933
32.1 Flying High ..... 933
32.1.1 GNSS Tracking in Space ..... 934
32.1.2 Spaceborne GPS Receivers ..... 936
32.2 Spacecraft Navigation ..... 938
32.2.1 Trajectory Models ..... 939
32.2.2 Real-Time Navigation ..... 942
32.2.3 Precise Orbit Determination ..... 946
32.3 Formation Flying and Rendezvous ..... 951
32.3.1 Differential Observations and Models ..... 952
32.3.2 Estimation Concepts ..... 954
32.3.3 Ambiguity Resolution ..... 955
32.3.4 Flight Demonstrations ..... 955

32.4 Other Applications ..... 957
32.4.1 Attitude Determination ..... 957
32.4.2 Ballistic Missions ..... 958
32.4.3 GNSS Radio Science ..... 959
**References** ..... 959

## Part F Surveying, Geodesy and Geodynamics

### 33 The International GNSS Service
*Gary Johnston, Anna Riddell, Grant Hausler* ..... 967
33.1 Mission and Organization ..... 967
33.1.1 Mission ..... 967
33.1.2 Structure ..... 968
33.2 Components ..... 969
33.2.1 IGS Governing Board and Executive Committee ..... 969
33.2.2 IGS Central Bureau ..... 969
33.2.3 IGS Network ..... 970
33.2.4 Analysis Centers ..... 970
33.2.5 Data Centers (DCs) ..... 970
33.2.6 Working Groups ..... 971
33.3 IGS Products ..... 972
33.3.1 Orbits and Clocks ..... 972
33.3.2 Earth Orientation and Site Coordinates ..... 973
33.3.3 Atmospheric Parameters ..... 974
33.3.4 Biases ..... 975
33.4 Pilot Projects and Experiments ..... 976
33.4.1 Real-Time ..... 976
33.4.2 Multi-GNSS ..... 978
33.5 Outlook ..... 981
**References** ..... 981

### 34 Orbit and Clock Product Generation
*Jan P. Weiss, Peter Steigenberger, Tim Springer* ..... 983
34.1 Global Tracking Network ..... 984
34.2 Models ..... 985
34.2.1 Reference Frame Transformation ..... 985
34.2.2 Site Displacement Effects ..... 985
34.2.3 Tropospheric Delay ..... 988
34.2.4 Ionospheric Delay ..... 988
34.2.5 Relativistic Effects ..... 989
34.2.6 Antenna Phase Center Calibrations ..... 989
34.2.7 Phase Wind-Up ..... 989
34.2.8 GNSS Transmitter Models and Information ..... 990
34.2.9 Models in Downstream Applications ..... 991
34.3 POD Process ..... 992
34.4 Estimation Strategies ..... 993
34.4.1 Estimators ..... 993
34.4.2 Parameterization ..... 994
34.4.3 Ground Stations ..... 995
34.4.4 GNSS Orbits ..... 995

34.4.5 Clock Offsets ..... 996
34.4.6 Earth Orientation ..... 996
34.4.7 Phase Ambiguity Resolution ..... 996
34.4.8 Multi-GNSS Processing ..... 997
34.4.9 Terrestrial Reference Frame ..... 998
34.4.10 Sample Parameterizations ..... 998
34.4.11 Reducing Computation Cost ..... 999
34.5 Software ..... 1000
34.6 Products ..... 1001
34.6.1 IGS Orbit and Clock Combination ..... 1002
34.6.2 Formats and Transmission ..... 1004
34.6.3 Using Products ..... 1005
34.7 Outlook ..... 1005
**References** ..... 1006

35 **Surveying**
*Chris Rizos* ..... 1011
35.1 Precise Positioning Techniques ..... 1013
35.1.1 Static Positioning ..... 1014
35.1.2 Rapid-Static Positioning ..... 1016
35.1.3 Kinematic Positioning ..... 1017
35.1.4 Real-Time Differential GNSS Positioning ..... 1019
35.1.5 Precise Point Positioning ..... 1021
35.2 Geodetic and Land Surveying ..... 1023
35.2.1 Geodetic Survey Applications ..... 1023
35.2.2 Land Surveying Operations ..... 1024
35.2.3 Land Surveying and Mapping Applications ..... 1027
35.3 Engineering Surveying ..... 1029
35.3.1 Engineering Surveying Real-Time Operations ..... 1029
35.3.2 Engineering Surveying Applications ..... 1030
35.3.3 Project Execution and Related Issues ..... 1032
35.4 Hydrographic Surveying ..... 1033
35.4.1 Hydrographic Surveying Applications ..... 1033
35.4.2 Operational Issues ..... 1035
**References** ..... 1035

36 **Geodesy**
*Zuheir Altamimi, Richard Gross* ..... 1039
36.1 GNSS and IAG's Global Geodetic Observing System ..... 1039
36.1.1 The International Association of Geodesy ..... 1040
36.1.2 The Global Geodetic Observing System ..... 1041
36.2 Global and Regional Reference Frames ..... 1044
36.2.1 Reference Frame Representations for the Deformable Earth ..... 1044
36.2.2 Global Terrestrial Reference Frames ..... 1047
36.2.3 GNSS-Based Reference Frames and Their Relationship with the ITRF ..... 1050
36.2.4 General Guidelines for GNSS-Based Reference Frame Implementation ..... 1052
36.2.5 GNSS, Reference Frame and Sea Level Monitoring ..... 1053

36.3 Earth Rotation, Polar Motion, and Nutation ..... 1054
36.3.1 Theory of the Earth's Rotation ..... 1055
36.3.2 Length-of-Day ..... 1055
36.3.3 Polar Motion ..... 1056
36.3.4 Nutation ..... 1058
**References** ..... 1059

37 **Geodynamics**

# Glossary of Defining Terms

## A

**Accuracy**
A measure for the closeness of a measured or estimated quantity to the quantity's true value.

**Acquisition**
The process carried out by a GNSS receiver to identify which GNSS signals are present in the received signal and to determine an approximate code delay and Doppler shift of those signals.

**Aircraft Based Augmentation System (ABAS)**
A GNSS augmentation system that augments and/or integrates the information obtained from the other GNSS elements with information available on board the aircraft.

**Airport Pseudolite (APL)**
A ► *pseudolite* located within the boundary of an airport designed to augment the positioning geometry of aircraft approaching or traveling near that airport.

**Albedo**
A measure for the reflectivity of a body. Earth albedo is a source of indirect radiation pressure acting on a satellite (► *Earth Radiation Pressure*).

**Alert**
A timely warning that a system may no longer be operating as previously described and that it could now be providing misleading information.

**Alert Limit**
A maximum tolerable positioning error for an operation to safely proceed. An alert limit has an associated ► *integrity* risk probability and a maximum time before the user must be notified when the alert limit cannot be assured to that integrity risk level.

**Allan Deviation (ADEV)**
The square-root of the ► *Allan Variance*.

**Allan Variance (AVAR)**
A measure of clock stability named after the physicist David W. Allan. It describes the variance of the average clock frequency over different time scales not taking into account constant frequency errors.

**Almanac**
A set of coarse orbit parameters for an entire GNSS constellation that is transmitted as part of the ► *navigation message* by each satellite of the constellation. The almanac facilitates rapid acquisition of all visible satellites.

**Alternative BOC (AltBOC)**
A modulation scheme combining two quadrature phase shift key signals in adjacent frequency bands, into a combined wideband signal with superior ► *noise* and ► *multipath* properties. AltBOC modulation was first employed for the Galileo E5a/E5b signal.

**Ambiguity Dilution of Precision (ADOP)**
A scalar measure in cycles that captures the intrinsic precision of the estimated float ambiguity vector. The ADOP is invariant for ambiguity re-parameterizing ► *Z-transformations* and facilitates easy-to-compute approximations of the ambiguity success rate.

**Ambiguity**
The initial unknown offset in a carrier phase observation when a GNSS receiver first locks onto a GNSS signal. It is the sum of the initial phase and the integer ambiguity. The ambiguity value remains constant as long as the receiver remains locked on the signal.

**Ambiguity Fixed Solution**
An integer ambiguity resolved GNSS parameter solution. The precision of the ambiguity fixed solution is never poorer than that of the ► *ambiguity float solution*.

**Ambiguity Float Solution**
A GNSS parameter solution for which the ambiguities are not resolved as integers. The precision of the ambiguity float solution is never better than that of the ► *ambiguity fixed solution*.

**Ambiguity Resolution**
► *Integer ambiguity resolution*

**Ambiguity Success Rate**
The probability of correct ► *integer ambiguity* estimation.

**Anechoic Chamber**
A room or cabinet, the interior of which is non-reflective, absorbing radio-frequency signals originating from within the chamber. In many cases it is often desirable that it also contains these signals and isolates the interior from externally originating signals. Typically used when it is necessary to model an infinite, reflector free space, when conducting a broadcast test, or in cases where the test must be isolated from external interference, or when the test involves the broadcast of signals in protected or restricted bands.

**Antenna**
A hardware unit that converts electrical energy to electromagnetic waves or vice versa.

**Antenna Gain Pattern**
A direction-dependent measure of the antenna's efficiency to convert electrical power into radio waves (transmit antenna) or vice versa (receiving antenna).

**Antenna Phase Center**
The point in the antenna radiation pattern where all the field emanates from or converges to.

**Antenna Reference Point**
A well defined and easily accessible mechanical point of the antenna to which the electrical ► *antenna*

*phase center* can be referred and which can itself be referred to the marker of a geodetic monument.

**Antenna Thrust**
The recoil force due to transmission of GNSS microwave signals which causes a non-gravitational acceleration of the satellite.

**ANTEX**
The antenna exchange format is used by the IGS to distribute a consistent set of absolute ► *antenna phase center* corrections for both GNSS receivers and satellites. Includes both ► *phase center offsets* and ► *phase center variations*.

**Anti-spoofing (A/S)**
The use of signal encryption for the military ► *P-code* of the ► *Global Positioning System* to avoid the generation and transmission of spoofed signals by an enemy (► *spoofing*).

**Apogee**
The most distant point of a satellite orbit from the Earth.

**Apogee Kick Motor**
An onboard rocket that is used to place a satellite in its final orbit from a highly elliptical transfer orbit.

**Approach Procedure with Vertical guidance (APV)**
An instrument approach procedure with both lateral and vertical guidance supporting operations with a performance that is between non-precision and precision approach.

**Area Correction Parameters**
► *Flächenkorrekturparameter*

**Area Navigation (RNAV)**
RNAV is a method of navigation which permits the operation of an aircraft on any desired flight path. It allows its position to be continuously determined wherever it is rather than only along tracks between individual ground-based navigation aids.

**Ascending Node**
The point on an orbit at which a satellite crosses the Equator from south to north.

**Astronomical Unit**
A unit of length that is used to specify distances within the Solar System. One astronomical unit (AU) is approximately equal to the mean distance between the Earth and the Sun, and amounts to roughly 149.6 Mio. km.

**Atmosphere**
The shells of gases that surround the Earth. The atmosphere affects the motion of satellites in low Earth orbit (► *drag*) and the radio propagation of electromagnetic waves such as radio navigation signals (► *troposphere*, ► *ionosphere*).

**Atomic Clock**
A device using the frequency of an electronic transition of atoms to generate a timescale. Atomic clocks are the most stable time and frequency standards known.

**Atomic Fountain**
A signal generator/frequency standard based on the laser cooling of atoms in a magneto-optical trap and once cooled to near absolute zero conditions, they are launched upwards in the gravity field in a *fountain* arrangement. In this manner the atoms pass through an interrogation region that stimulates a hyperfine transition of the atom's ground state.

**Atomic Frequency Standard**
A signal generator based on the interrogation of the change in a particular energy state of a specific atom contained in a controlled environment.

**Atomic Time Scale**
A time scale based on atomic or molecular resonance phenomena. Elapsed time is measured by counting cycles of a frequency locked to an atomic or molecular transition. Atomic time scales differ from the earlier astronomical time scales, which define the second based on the rotation of the Earth on its axis. ► *Coordinated Universal Time* (UTC) is an atomic time scale, since it defines the second based on the transitions of the cesium atom.

**Attitude**
The orientation of a rigid body in space with respect to a given reference frame. The attitude can be expressed in various forms of ► *attitude parameters*.

**Attitude Parameters**
The set of variables used to parameterize the orientation of a rigid body in space. Their number ranges from three (e.g., ► *Euler angles*) to nine (e.g., ► *direction cosines*).

**Automatic Dependent Surveillance (ADS)**
A surveillance technique where each aircraft automatically broadcasts its own position periodically via data-link.

**Automatic Direction Finding (ADF)**
an electronic aid to navigation that identifies the relative bearing of an aircraft from a radio beacon transmitting in the medium or long-frequency bandwidth, such as a ► *Non Directional Beacon* or commercial radio broadcast station.

**Availability**
The probability that a user is able to determine its position with the specified accuracy and is able to monitor the integrity of its determined position at the initiation of the intended operation.

**Azimuth**
One of the coordinates in the ► *horizontal system*. Azimuth is the angle, measured positive towards the east, between north and the projection on the horizon of the direction in which an object is observed.

## B

**Bandwidth**
The range of frequencies that pass through a system without (significant) attenuation.

**Barycentric System**
A coordinate system whose center (origin) is at the average center-of-mass of the solar system.

**Baseband**
The frequency range used by conventional transmitters or receivers for performing pre/post-processing of the desired information.

**Baseband Signal**
A signal with a near-zero frequency and low bandwidth, such as the GNSS spreading code and data modulated onto the carrier signal. Also termed the envelope signal.

**Baseline**
The separation between two points in 2-D or 3-D space. For ► *differential positioning* the baseline refers to the 3-D vector between two GNSS receivers, one set up on a ► *base station*, the other at a point (or in space) whose coordinate is to be determined relative to the ► *base station*. Baseline length is a scalar quantity, being the inter-receiver distance expressed in length units.

**Base Station**
► *Reference station*

**BeiDou**
A regional and global navigation satellite system implemented by China. The name refers to the constellation (Big Dipper or Plough) used to find the north direction in stellar navigation.

**BeiDou Satellite-based Augmentation System (BDSBAS)**
A ► *satellite-based augmentation system (SBAS)* being developed as part of the BeiDou Navigation Satellite System to provide horizontal and vertical navigation throughout China.

**Best Linear Unbiased Estimator (BLUE)**
The estimator with the best precision, i. e., smallest variance, of all linear unbiased estimators. Linear unbiased estimators are linear functions of the observables that have an expectation equal to the to-be-estimated unknown parameter vector.

**Best Linear Unbiased Predictor (BLUP)**
The predictor having the smallest mean square prediction error (best) of all linear unbiased predictors. Linear unbiased predictors are linear functions of the observables that have an expectation equal to the expectation of the to-be-predicted random parameter vector.

**Between-receiver Difference**
Difference between (code or carrier-phase) GNSS observations or parameters at the same frequency for two receivers tracking the same satellite.

**Between-satellite Difference**
Difference between (code or carrier-phase) GNSS observations or parameters at the same frequency of two satellites that are tracked by the same receiver.

**Bias**
In estimation, *bias* denotes the difference between the expected value of an estimator and the true value being estimated. Biases are often the consequence of an improper modeling of measurement processes, such as the neglect of non-negligible systematic errors. More loosely and generally, the term is often used to describe a systematic error or offset in a measurement.

**Bias-to-noise Ratio (BNR)**
A dimensionless measure of bias significance. The influential-BNR drives the probability of hazardous occurrence, while the testable-BNR drives the probability of missed detection.

**Binary Offset Carrier (BOC) Modulation**
An extension of ► *binary phase shift keying (BPSK) modulation*, in which the modulated signal is multiplied by an additional sine or a cosine square wave sub-carrier. Instead of a single lobe, the spectrum of a BOC-modulated signal exhibits two main lobes symmetrically shifted relative to the main carrier frequency. Therefore, BOC modulation is also known as a split-spectrum modulation. The separation of the two lobes is determined by the sub-carrier frequency. In GNSS, BOC signals are applied in order to fulfill spectral separation requirements between non-interoperable signals of different systems.

**Binary Phase Shift Keying (BPSK) Modulation**
A modulation scheme for radio navigation signals, in which the phase of the carrier is shifted by 0° or 180° depending on the binary value of the modulated signals (i. e., ranging code and navigation data).

**Bit Error Correction**
The process carried out within a GNSS receiver to identify and correct incorrectly received ► *navigation message* bits. This process requires the navigation message to contain redundant bits.

**Bit Synchronization**
The process carried out within a GNSS receiver to identify the epochs of navigation data bit/symbol transitions if the bit/symbol duration exceeds the primary code duration.

**Blunder**
A gross error in a measurement that is neither systematic nor of random nature.

**Block**
Different generations of Global Positioning System (GPS) satellites built by different manufacturers are commonly termed *blocks*. The second generation is further divided into Block II, IIA, IIR, IIR-M, and IIF satellites.

**Boresight Angle**
The angle between the line-of-sight direction and the symmetry axis of an antenna.

**Boundary Layer**
The lowermost atmospheric layer directly affected by the Earth's surface.

**Box-wing Model**
A simplified description of geometrical and optical (reflection/emission) properties of a GNSS satellite for the modeling of ► *radiation pressure* effects.

**Broadcast Ephemeris**
The ► *ephemeris* transmitted by a GNSS satellite as part of its ► *navigation message* to enable computation of the satellite positions within a receiver.

**Broadcast Group Delay (BGD)**
Alternative name for ► *Timing Group Delay (TGD)*.

## C

**C-band**
The part of the spectrum of electromagnetic waves with carrier frequencies in the range from 4 GHz to 8 GHz

**C/A-code**
The ► *pseudo-random noise (PRN)* sequence used as coarse and acquisition ranging code within the Global Positioning System GPS. Each C/A-code has a length of 1023 chips and is transmitted in 1 ms. An entire family of C/A-codes has been defined for GPS as well as other radio navigation systems such as SBAS and QZSS. The serial number assigned to each code known as the PRN number and commonly used to identify the transmitting GPS satellite.

**Cadastral Surveying**
A form of land surveying for the determination, or marking-out of land property boundaries.

**Carrier**
A periodic electromagnetic wave on which the ranging code and navigation data of a radio navigation satellite system are modulated. GNSS signals are commonly located in the ► *L-band* and employ frequencies in a range of about 1100–1600 MHz.

**Carrier Phase**
The instantaneous phase (expressed in radians or cycles) of a periodic electromagnetic wave. In GNSS the term is commonly related to the beat phase of the received carrier after mixing with the nominal signal frequency, which represents a measure of the range variation between the transmitting satellite and the receiver.

**Carrier Phase Ambiguity**
The measurement of the ► *carrier phase* inside a GNSS receiver includes an arbitrary cycle count introducing an integer-cycle ambiguity. Depending on the specific tracking technique, half-cycle biases may also arise. The measured carrier phase range is furthermore affected by satellite or receiver specific biases causing a float-valued ambiguity in the measured carrier phase range.

**Carrier-to-noise Density Ratio ($C/N_0$)**
The ratio of the power level of the carrier signal to the noise power within a 1 Hz bandwidth.

**Celestial Coordinates**
Spherical coordinates of celestial objects with respect to a celestial reference system, called ► *right ascension* and ► *declination*, analogous to longitude and latitude, respectively.

**Celestial Ephemeris Pole**
The reference pole for ► *nutation* and ► *polar motion* that was adopted by the 1980 IAU theory of nutation. By definition, it is a pole that exhibits no nearly diurnal motions in either the celestial or terrestrial reference frames.

**Celestial Intermediate Pole**
The reference pole for ► *nutation* and ► *polar motion* that was adopted by the 2000 IAU theory of nutation. It extends the definition of the ► *celestial ephemeris pole* by clarifying the distinction between nutation and polar motion. Motion of the celestial intermediate pole within the celestial reference frame that has a frequency between -0.5 cycles per sidereal day (cpsd) and +0.5 cpsd is defined to be nutation. Motion of the celestial intermediate pole outside this frequency band is defined to be polar motion. The polar motion parameters reported by Earth rotation measurement services give the location of the celestial intermediate pole within the rotating, body-fixed terrestrial reference frame.

**Celestial Sphere**
An imaginary sphere of infinite radius on which radial direction are projected. The center of the celestial sphere may be viewed as being geocentric or barycentric, depending on the definition of the associated coordinate system.

**Central Synchronizer**
The master clock of the GLONASS system. It comprises four ► *hydrogen maser* frequency standards and contributes to the mathematical GLONASS System Time steered to UTC(SU).

**Certification**
A process applied by a regulating body to determine whether an object has been manufactured according to an approved design and that the design ensures compliance with previously specified requirements. The requirements are often specified in ► *Minimum Operating Performance Standards (MOPS)* and related documents.

**Cesium Beam Frequency Standard**
A signal generator based on the hyperfine frequency of the cesium atom's ground state of 9 192 631 770 Hz. Typically, the cesium atoms are thermally formed into a beam and magnetically separated into the ground state for interrogation.

**Chandler Period**
A characteristic period in the oscillation of the Earth's rotation axis relative to its axis of figure discovered by S.C. Chandler. Due to the non-rigid structure of the Earth, the Chandler period may vary in a range of about 412–442 days.

**Chapman Profile**
An analytical model describing the height-dependent electron density variation in the ionosphere or its individual layers based on simplifying assumptions of the atmospheric structure as well as the ionization and recombination processes.

**Chinese Area Positioning System (CAPS)**
A positioning system developed in China, which transfers ground-generated navigation signals to users via communication satellites.

**Choke-ring Antenna**
An ► *antenna* composed of the sensitive antenna element and a surrounding, corrugated ground plane, which is typically made up of multiple concentric conductive rings. Choke ring antennas offer superior ► *multipath* suppression and are commonly used for

the highest accuracy user applications such as for geodetic surveys or ► *continuously operating reference stations*.

**Circular Error Probable (CEP)**
The radius of a circle centered on the true value that contains 50% of the actual measurements.

**Clock Ensemble**
A collection of clocks, not necessarily in the same physical location, operated together in a coordinated way to maximize the performance (time accuracy and frequency stability) and/or the availability of a time scale. Typically, the relative value of each clock is weighted, so that the best clocks contribute the most to the average.

**Clock Offset**
The offset between the reading of a satellite or receiver clock involved in the timing of GNSS measurements and a given reference time scale, such as the system time maintained by the GNSS control segment.

**Coarse/Acquisition (C/A) Code**
► *C/A-code*

**Code Bias**
A receiver and transmitter specific hardware ► *group delay* affecting the ► *pseudorange* (i. e., code observation) generation.

**Code Division Multiple Access (CDMA)**
A multiple access scheme that allows different transmitters to access the transmission channel simultaneously using the entire available bandwidth where the transmitter is identified by a unique code assigned to it. CDMA signals form the basis of most navigation satellite systems in use today.

**Code Phase**
The instantaneous phase of the ranging code modulated on a GNSS signal as sensed by a receiver. It can be expressed as the number of full and fractional code chips, or, alternatively as a time or distance value. The code phase is a measure of the transmission time (modulo the code duration) and used together with the current receiver time to form a ► *pseudorange* measurement.

**Code Shift Keying (CSK)**
A specific scheme used to increase the rate of navigation data in a GNSS signal. The ranging code is shifted relative to a nominal starting point by an amount that is determined by the encoded data word. Code shift keying is, for example, employed in the E6 signal of the Japanese ► *Quasi-Zenith Satellite System (QZSS)* to transmit high-rate correction data for ► *precise point positioning* to its users.

**Coherent Integration Time**
The time period chosen by a GNSS receiver to compute correlation values of the received signal with internal replica signals.

**Cold Start**
Activation of a GNSS receiver with no prior information on time, user position, and satellite orbit/clock data.

**Compatibility**
The ability of two navigation signals to be transmitted and used along each other without causing harmful interference for their users.

**Conductive Test**
Testing a receiver by directly connecting a signal source to the receiver.

**Constrained Maximum Success-rate (CMS) Test**
An ambiguity acceptance test which has the largest success rate for a given user-defined failure rate. This test requires the ► *integer least-squares (ILS)* solution as its input.

**Construction Surveying**
Land surveying that addresses the different positioning requirements of civil engineers and building professionals during the construction phase for any engineered structure.

**Conterminous (or Contiguous) United States (CONUS)**
The 48 adjoining US states and Washington, DC. CONUS is the portion of the United States that excludes Alaska, Hawaii, and all offshore territories.

**Continental Drift**
► *plate motion*

**Continuity**
The probability that a user is able to determine its position with the specified accuracy and is able to monitor the integrity of its determined position over the time interval applicable for the corresponding phase of flight. Assuming the service is available at the start of an operation, this is the probability of it becoming unavailable over a specified time interval linked to the duration of the operation.

**Continuously Operating Reference Stations (CORS)**
A GNSS receiver and antenna established on a permanent and stable site that serves as a ► *control point* of a geodetic network or reference station for ► *differential GNSS* systems.

**Controlled Flight into Terrain (CFIT)**
The situation when a normally functioning aircraft under the complete control of the pilot is inadvertently flown into an obstacle.

**Control Point**
A marker or monument used for surveying, typically with known coordinates in the local or national geodetic ► *datum*. May also be a ► *base station* if a GNSS receiver is operated at that point.

**Control Segment**
The ground infrastructure used to operate a global or regional navigation satellite system.

**Coordinated Universal Time**
► *Universal Time Coordinated (UTC)*

**Coordinate Time (TCB,TCG)**
A set of fundamental relativistic time scales with rates based on the SI second in the respective reference frames, i. e., at the Solar System's center of gravity for Barycentric Coordinate Time (TCB) and the Earth's center for Terrestrial Coordinate Time (TCG).

**Correlation**
A measure of agreement between two statistical values or time series. In estimation, correlation is

defined as a normalized form of the ► *covariance*. In GNSS signal processing, the correlation describes how well two signals or ► *pseudo-random noise* codes match each other.

**Correlator**
A device used inside a GNSS receiver to measure the ► *correlation* of the incoming signal and a receiver-generated replica. The correlator values serve as input for the ► *tracking loops*, which aim to continuously align the replica code and phase with the incoming signal. In order to best measure the instantaneous code offset, a combination of an *early* and a *late* correlator is used, which employ time shifted code replicas. The early-minus-late difference of the correlator outputs can then be used as a ► *discriminator* to sense the tracking error.

**Correlator Spacing**
The spacing (in units of PRN chips) between the early and late ► *correlators* in a conventional ► *delay lock loop*.

**Coseismic**
means *during an earthquake*. The term is most commonly used to describe displacements that result from an earthquake.

**COSPAS-SARSAT**
An international satellite-based search and rescue system.

**Costas Loop**
A special form of a ► *phase lock loop* developed by J.P. Costas that uses a two-quadrant phase discriminator to track a signal with ► *binary phase shift keying (BPSK) modulation* without being affected by data bit transitions.

**Covariance**
A measure of how much two random variables change together. ► *Correlation* is the normalized version of covariance. It is obtained by dividing the covariance by the standard deviations of the two random variables.

**Cramer Rao Lower Bound (CRLB)**
A lower bound on the variance of unbiased estimators of deterministic parameters. Named after H. Cramer and C.R. Rao

**Cross-correlation**
Operation on two (real or complex) Doppler and delay-aligned signals to estimate their temporal coherence, as a function of the relative delay. Such function is termed waveform.

**Cycle Slip**
An unknown discontinuity in the measured ► *carrier phase* usually resulting from a temporary loss-of-lock (e.g., due to shading) in the carrier tracking loop of a GNSS receiver.

## D

**Data Bit**
The basic information unit of the navigation message modulated on a GNSS signal. This unit is called symbol, if the navigation message employs a ► *forward error correction* scheme. Otherwise it is called bit.

**Data Channel**
A GNSS signal component used to broadcast navigation data. For improved measurement performance, the data channel is complemented by a ► *pilot signal* in modern GNSS signals.

**Data Demodulation**
The process carried out within a GNSS receiver to extract a data bit or data symbol from a received GNSS signal.

**Data Snooping**
A procedure to identify the observations contaminated with gross errors.

**Data Symbol**
► *data bit*

**Datum**
A set of parameters and conventions that defines and realizes a coordinate system for geodetic control on a national or global scale. Nowadays realized by the 3-D Cartesian coordinates or 2-D geodetic coordinates of a network of ► *control points*.

**Decision Altitude or Height (DA/H)**
The altitude or height during an instrument approach procedure where the pilot must decide to either continue the approach to land or initiate the missed approach procedure. The decision is based on the availability of the required visual references. The decision altitude is measured above mean sea level and a decision height is above the ground. The DA/H is the point at which a missed approach is initiated and does not preclude the aircraft from descending below this height before the aircraft starts to climb.

**Declination**
The angle, at right-angles to the ► *equator*, measured between the equator and a celestial body. Together with ► *right ascension*, declination forms the equatorial system of coordinates.

**Deflection of the Vertical**
The angle between the tangent to the plumb line (direction of gravity) and the normal to the ellipsoid at a point.

**Deformation**
Any displacement that changes the shape of a body, as opposed to rigid body motion. Active tectonic and volcanic processes cause both recoverable and permanent deformation of the Earth.

**Delay Lock Loop (DLL)**
A controller used within a GNSS receiver to align a replica of the ranging code with the incoming signal after removal of the carrier. The DLL combines a steerable code generator with a code ► *discriminator* to sense the tracking error and a loop filter to reduce the tracking noise.

**Differential Code Bias (DCB)**
Difference of either receiver or satellite hardware biases on the code (or ► *pseudorange*) observations of two frequencies.

**Differential GNSS (DGNSS)**
GNSS positioning technique based on the principle that common biases between receivers can be eliminated or significantly reduced by processing multi-receiver code (pseudorange) and/or carrier-phase data simultaneously tracked from the same satellites. At least two receivers are needed; one is the reference and the other rover. This technique can be implemented either by differencing the observations of reference and rover, or by transmitting corrections determined at the reference to the rover.

**Dilution of Precision (DOP)**
A scalar measure that captures the impact of the instantaneous receiver-satellite geometry on the precision of ► *single point positioning*. It is computed as the square root of the sum of those diagonal elements of the variance matrix excluding the variance factor for which the DOP needs to be evaluated (e.g., Position DOP based on the diagonal elements for east, north and up and horizontal DOP when only the diagonal elements for east and north are involved, etc.).

**Direct Conversion**
A method to digitize a radio frequency signal without prior down-conversion.

**Direction Cosine**
the cosine of the angle formed by a vector in space and a reference direction.

**Discriminator**
A function of ► *correlator* values used to measure the code, phase, or frequency offset between the incoming GNSS signal and the replica generated in the receiver.

**Dispersive Medium**
A medium in which an electromagnetic wave propagates for which the magnetic constant (permeability) and/or the dielectric constant (permittivity) depend on frequency. Therefore, the phase velocity as well as the group velocity of an electromagnetic wave in a dispersive medium also depend on frequency.

**Displacement**
The change in position of a point. All points on the Earth's surface are displaced slowly and steadily by plate motions, but sudden displacements also can occur due to events such as earthquakes. Seasonal movements of mass cause quasi-periodic displacements due to loading.

**Disposal Orbit**
An orbit for satellites that are beyond the end of their service life, which is designed to minimize the probability of a collision with any other satellites or space debris.

**Distance Measuring Equipment (DME)**
A combination of ground and airborne equipment which provides a continuous slant range distance-from-a ground station by measuring the propagation delay of a signal transmitted by the aircraft to the station and responded back. The ground equipment is a VHF transmitter and receiver (called the transponder) and the airborne equipment is called the interrogator.

**Doppler/Delay Alignment**
Operation to compensate the delay experienced by a signal due to the relative motion of the transmitter and the receiver. For a short time interval the relative motion can be modeled using two quantities, the initial relative delay and the initial relative Doppler.

**Doppler Delay Map (DDM)**
An evaluation of the ► *cross-correlation* function of the received signal with a replica signal expressed as a function of code delay and ► *Doppler shift*.

**Doppler Effect**
► *Doppler Shift*.

**Doppler Range**
The range of frequency offsets from the nominal signal frequency considered by a GNSS receiver in the signal search to account for the Doppler shift due to the relative motion of transmitter and receiver as well as the frequency error of the local oscillator.

**Doppler Shift**
The frequency shift experienced by an electromagnetic (or acoustic) wave due the relative motion of the transmitter and receiver. Named after the Austrian nineteenth-century physicist Christian Doppler.

**Double-difference**
Difference between either two ► *between-receiver differenced* observations/parameters that correspond to different satellites, or two ► *between-satellite differenced* observations/parameters that correspond to different receivers.

**Down-conversion**
A method to convert the frequency of a radio-frequency signal to a reduced intermediate frequency by mixing it with a harmonic signal. Down-conversion facilitates the analog-to-digital conversion and the subsequent signal processing.

**Draconitic Period**
The time that elapses between two passages of the orbiting object through its ► *ascending node*.

**Draconitic Year**
The repeat period of the orientation of a GNSS constellation with respect to the Sun, e.g., 351.5 days for GPS.

**Dual-frequency**
The use of GNSS measurements on two different signal frequencies, e.g., to eliminate the impact of ionospheric path delays.

**Dynamical Time (TDB, TDT)**
A relativistic time scale having a rate that matches the SI second at the Earth's surface, defined as a re-scaling of the ► *Coordinate Time scales TCG and TCB*. In 1991 it was agreed by the International Astronomical Union that Terrestrial Dynamical Time (TDT) should just be called ► *Terrestrial Time (TT)*.

## E

**Early-minus-late Correlator**
► *correlator*

**Earth-centered Earth-fixed (ECEF)**
Refers to a coordinate system or frame that is fixed to the Earth's crust with a conventional orientation and whose origin is at the Earth's center of mass. The axes of the ► *International Terrestrial Reference Frame* provide a possible choice of an ECEF coordinate system.

**Earth-centered Inertial (ECI)**
A non-accelerating, non-rotating frame aligned with the ► *Earth-centered Earth-fixed (ECEF)* frame at a specific instant of time. Various approximate ECI frames may be convenient for analysis. For example, the non-rotating ECI frame origin may be assumed to coincide with the ECEF origin, which is approximate because the ECEF origin is accelerating.

**Earth Model PZ-90**
► *Parametry Zemli 1990 (PZ-90)*

**Earth Oblateness**
The oblateness or ► *flattening* is a measure of how much the Earth's elliptical shape differs from a sphere.

**Earth Orientation Parameters**
A set of parameters that relate an Earth-centered Inertial coordinate system to an Earth-centered Earth-fixed coordinate system and vice versa. It consists of the small angles that define the motion of the ► *Celestial Intermediate Pole* (approximately Earth's instantaneous spin axis) with respect to the terrestrial reference system (► *polar motion*) and its motion relative to the celestial reference system (► *precession* and ► *nutation*).

**Earthquake Cycle**
The roughly cyclic buildup of stress and strain and their release in earthquakes is termed the earthquake cycle. The shallow part of most faults is stuck together (locked) by friction most of the time, while the deeper part continues to creep at a nearly steady rate. This causes an increase in the stress around the locked fault zone and results in elastic strain energy being stored in the crust. When the driving stress exceeds the frictional resistance, the fault slips and an earthquake occurs. Earthquakes are never perfectly periodic in occurrence, so this should not be understood to be a periodic process.

**Earth Radiation Pressure**
The non-gravitational force acting on a satellites due to radiation reflected/emitted by the Earth's surface (► *Albedo*).

**Earth Rotation Angle**
The angle between the origins on the intermediate terrestrial and celestial equators; it is proportional to the time associated with Earth's rate of rotation.

**Ecliptic**
The imaginary great circle representing the intersection of the plane of the Earth's orbit with the celestial sphere.

**Effective Isotropic Radiated Power (EIRP)**
The amount of power radiated by an antenna in a particular direction as referenced to the amount of power fed to an idealized lossless isotropic antenna that would produce the same power density.

**Elevation**
The angle measured from the observer's horizontal plane with respect to the station-satellite line-of-sight. May also refer to a station's height in metric units with respect to the zero datum level, or synonymous with ► *ellipsoidal height*.

**Elevation Mask**
A threshold controlling the allocation of GNSS for tracking in the receiver or for processing in the positioning. Only satellites exceeding the defined minimum angle above the ► *horizon* (or alternatively the antenna ground plane) will be considered.

**Ellipsoid**
In geodesy, it generally refers to a geometric figure defined by rotating an ellipse about its minor axis and whose parameters (size and flattening) are chosen to yield a good approximation to the geoid. It is the mapping surface for horizontal geodetic control. It is also called a spheroid to distinguish it from a more general tri-axial ellipsoid.

**Ellipsoidal Height**
The distance along the perpendicular (normal) to an ellipsoid starting from the ellipsoid. Ellipsoidal height is positive for points outside the ellipsoid and negative for points inside the ellipsoid, being zero on the ellipsoid.

**Elongation**
The angle between two bodies, as seen by an observer.

**Empirical CODE Orbit Model (ECOM)**
A model for solar ► *radiation pressure* developed at the Astronomical Institute of the University Bern, a member of the Center for Orbit Determination in Europe (CODE). The radiation pressure is modeled with constant and sine/cosine terms in a Sun-oriented system.

**Ephemeris**
Based on a Greek expression (*for a single day*), the term is widely used for astronomical tables giving the daily coordinates of a planet or other solar system body. In GNSS, ephemerides are likewise tabular positions and clock offsets of the GNSS satellites (resulting, e.g., from a ► *precise orbit determination*). Furthermore, the term ephemeris is used for a set of orbital parameters transmitted by a GNSS satellite as part of its ► *navigation message* to enable computation of the satellite positions within a receiver.

**Ephemeris Time (ET)**
An astronomical time defined by the orbital motions of the Earth, Moon, and planets. Ephemeris Time was introduced in 1952 to be provide a time scale independent of the irregular, unpredictable variations in the rotation of the Earth, inherent to the ► *Universal Time* in use beforehand. Within the framework of relativistic theories of motion, Ephemeris Time has been replaced by ► *Terrestrial Time (TT)*.

**Equator**
An imaginary great circle on the celestial sphere, which is perpendicular to the Earth's axis of rotation. The equator separates the northern and southern

celestial hemispheres, and is simultaneously the reference plane for the equatorial system of coordinates, which uses the coordinates ► *right ascension* and ► *declination*. It defines the plane that is orthogonal to the polar axis of a global coordinate system. For the Earth it is the circle on the ellipsoid at zero latitude.

**Equatorial Coordinates**
Coordinates referred to the ► *equator* (► *right ascension*, ► *declination*).

**Equinox**
► *vernal equinox*.

**Euler Angles**
A set of three angles that define the orientation of a rigid body. The Euler angles define a sequence of three consecutive rotations that enable aligning any two arbitrarily rotated orthogonal frames.

**Euler Axis and Angle**
The rotation axis and rotation angle of a body in space relative to an initial or reference orientation. Any rotation of a rigid body in space can be described in terms of an axis-angle parameterization.

**European Geostationary Navigation Overlay Service (EGNOS)**
A ► *satellite-based augmentation system (SBAS)* developed by the European Space Agency, the European Commission, and EUROCONTROL to provide horizontal and vertical navigation throughout Europe. It has provided safety-of-life service since 2011.

**Expandable Slot**
In the GPS constellation, one of three orbital positions that can each be divided into a pair of positions when the constellation has more than the nominal number (24) of satellites.

**Extended Kalman Filter (EKF)**
The ► *Kalman filter* applied to the linearized versions of non-linear state space measurement and dynamic models.

## F

**Fading Frequency**
The phase rate-of-change (known simply as phase rate) of a multipath signal relative to the direct-path signal.

**Fixed Solution**
► *ambiguity fixed solution*

**Fixed Failure Rate Ratio Test**
An ambiguity acceptance test that is computed as a ► *ratio test*, but that has a guaranteed failure rate. The required failure rate can be set by the user.

**Flächenkorrekturparameter (FKP)**
Original German designation of area correction parameters (horizontal gradients) of regional models for distance-dependent biases transmitted to the users as part of ► *network RTK corrections*.

**Flattening**
The geometric parameter of an oblate ► *ellipsoid* defined by the ratio of the difference between semi-major and semi-minor axes of an ellipsoid to its semi-major axis.

**Flicker Noise**
A type of noise in electronic systems (e.g., oscillators), which exhibits a power spectral density inversely proportional to the frequency.

**Flight Management System (FMS)**
An aircraft computer system with multiple functions for managing a flight. The FMS includes navigation and guidance functions and contains a database allowing flight plans and routes to be pre-programmed.

**Flight Technical Error (FTE)**
The difference between the estimated position and the defined path. It serves as a measure of how well the pilot or the avionics can follow the guidance information provided by the navigation system.

**Float Solution**
► *ambiguity float solution*.

**Footprint**
The region beneath a satellite that can receive and utilize its signal. A navigational satellite footprint is often depicted as a circular region directly below the satellite representing a set of users whose line of sight to the satellite is at least 5° above their local horizon.

**Forecast**
A forecast describes the future state and/or development of characteristic system parameters like the temperature in the troposphere or the electron density in the ionosphere based on the current state and additional information.

**Forward Error Correction (FEC)**
A technique used to minimize bit errors in data transmission which introduces redundant information into the data stream. Other than simple parity checksums, FEC enables not only detection but also correction of errors.

**Frame Bias**
A small constant angular offset between the current kinematic ICRF pole and origin (in right ascension) and the dynamic pole and equinox of J2000.

**Frame synchronization**
The process carried out within a GNSS receiver to identify the beginning of the navigation data message.

**Free-space Loss**
The change in signal power of an electromagnetic wave emerging from an isotropic radiator when propagating in free space. The free-space loss grows with the square of the distance and is inversely proportional to the square of the wavelength.

**Frequency**
The rate of a repetitive event, i. e., the inverse of its repeat period. In the SI system of units the period is expressed in seconds (s), and the frequency is expressed in Hertz (Hz).

**Frequency Lock Loop (FLL)**
A controller used to align the frequency of a carrier replica inside a GNSS receiver with that of the incoming signal. It comprises a ► *numerically controlled oscillator (NCO)*, a frequency

► *discriminator* that senses the instantaneous tracking error and a loop filter that provides a smoothed estimate of the frequency error for feedback to the NCO.

**Frequency Division Multiple Access (FDMA)**
A multiple access scheme that allows different transmitters to access the channel simultaneously but using slightly different frequencies within the specified overall bandwidth. For global satellite navigation systems, FDMA signals are presently only used by ► *GLONASS*

**Friis Formula**
A formula named after the electrical engineer H.T. Friis, which is widely used in communications to calculate the total noise factor of a cascaded stage radio frequency ► *frontend* of which each stage is represented by a noise factor and a gain.

**Frontend**
The combination of different modules that convert the incoming ► *baseband signal*, on the transmitter side, to the specified radio frequency before passing it on to the antenna. A receiver frontend does the opposite.

## G

**Galileo**
The European global navigation satellite system.

**Galileo-GPS Time Offset (GGTO)**
As GPS and Galileo use different reference time systems, there is a system time offset between the two systems, the Galileo-GPS time offset. This offset can be several tens of nanoseconds or tens of meters. Users can correct their data for the offset, since the GGTO is broadcast as part of the navigation messages.

**Geocentric Coordinates**
Coordinates referred to the center of the Earth.

**Geodetic Coordinates**
Coordinates of latitude, longitude, and height associated with a particular ► *ellipsoid*. The geodetic latitude is the angle of the ellipsoid normal for a point relative to the Equator. The geodetic longitude is the same as the spherical longitude. See also ► *ellipsoidal height*.

**Geodetic-grade Receiver**
Top-of-the-line GNSS receiver able to make ► *carrier phase* and ► *pseudorange* measurements on multiple L-band frequencies broadcast by several GNSS constellations.

**Geodetic Reference System 1980 (GRS80)**
The current internationally defined reference ellipsoid and associated gravitational field for geodetic applications.

**Geographic Coordinates**
A general name that refers to coordinates associated with the spherical shape of the Earth

**Geographic Information System (GIS)**
A software system that manages, analyses, displays spatial data that has been organized in *layers*. For the purpose of creating special feature maps, undertaking spatial analysis, assist in decision-making, and more. Sometimes the term may also refer to the spatial datasets themselves.

**Geoid**
A surface on which the Earth's gravity potential is a constant (equipotential or level surface) and that closely approximates global mean sea level.

**Geoid Height**
The ► *ellipsoidal height* of the ► *geoid*; also known as the geoid undulation.

**Geoid Model**
Representation of the ► *geoid height* across a local area, a region, or the globe. May be in the form of geoid height contours on the ► *reference ellipsoid*, as point values, or gridded data, or various mathematical functions – the most common being in the form of spherical harmonics.

**Geoid Undulation**
Same as ► *geoid height*.

**Geostationary Earth Orbit (GEO)**
A circular orbit at approximately 36 000 km altitude above the Earth's equator with an orbital period equal to the Earth's rotational period. A satellite in a geostationary Earth orbit will appear to be in a fixed position in the sky for terrestrial observers.

**Geostationary Satellite**
A satellite in a ► *geostationary Earth orbit*. Often used for communication and for ► *satellite-based augmentation systems*.

**Global Navigation Satellite System (GNSS)**
A navigation system that can provide a positioning solution anywhere in the world. The term is currently used collectively for GPS, Galileo, GLONASS, and BeiDou.

**Global'naya Navigatsionnaya Sputnikova Sistema (GLONASS)**
Global navigation satellite system of the Russian Federation, providing global permanent positioning, navigation and timing service for land, air and space users worldwide. GLONASS is a dual-use system providing both authorized and open access services.

**Global Positioning System (GPS)**
A global navigation satellite system owned and operated by the United States Air Force.

**Gold Code**
A family of ► *pseudo-random noise (PRN)* sequences with good auto and cross-correlation properties proposed by Robert Gold. Gold codes are, for example, employed for the GPS coarse and acquisition (► *C/A*) code.

**GPS Aided GEO Augmented Navigation (GAGAN)**
A ► *satellite-based augmentation system (SBAS)* developed by the Indian Space Research Organization, the Airports Authority of India, and the Directorate General of Civil Aviation to provide horizontal and vertical navigation throughout India. It has provided safety-of-life service since 2014.

**GPS Time**
The timescale used by GPS, which began at midnight ► *Universal Time Coordinated (UTC)* on January 5/6, 1980 and is not adjusted by leap seconds.

**GPS Week**
The integer number of weeks elapsed since the start of ► *GPS time*. GPS weeks start at midnight from Saturday (day-of-week 6) to Sunday (day-of-week 0). In accordance with the 10-bit representation of the GPS week in the legacy GPS ► *navigation message*, its value is often given modulo 1024, resulting in roll-overs in August 22, 1999 and April, 7 2019. RBL,OM)

**Greenwich Mean Time (GMT)**
A 24-hour time keeping system whose hours, minutes, and seconds represent the time-of-day at the Earth's prime meridian (0° longitude) located near Greenwich, England. GMT was adopted as the world's first global time standard in 1884. GMT no longer exists, since it was replaced by other astronomical time scales many years ago, which in turn were subsequently replaced by the atomic time scale UTC.

**Greenwich Hour Angle**
The angle at a specified epoch between the *x*-axes of the ► *Earth-centered inertial* and ► *coordinate systems*.

**Grid Ionospheric Vertical Error (GIVE)**
A parameter broadcast by SBAS to indicate the possible magnitude of the vertical delay error for a specific ionospheric grid point delay estimate. GIVE is determined from a broadcast 4-bit number, called the GIVE indicator or GIVEI. A look up table is used to convert the indicator to a 1-sigma overbound value (► *overbound*) called the $\sigma_{\mathrm{GIVE}}$. By tradition, GIVE itself is a 99.9% number or $3.29 \times \sigma_{\mathrm{GIVE}}$. A relevant set of $\sigma$GIVEs is used to interpolate the corresponding User Ionospheric Vertical Error overbound, $\sigma_{\mathrm{UIVE}}$. This vertical overbound is finally multiplied by the obliquity factor to obtain the complete User Ionospheric Range Error overbound, $\sigma_{\mathrm{UIRE}}$.

**Ground-based Augmentation System (GBAS)**
A local area differential GNSS augmentation system using multiple airport-based reference receivers that provide corrections and integrity information to users via a very-high frequency (VHF) data link known as the ► *VHF data broadcast (VDB)*. GBAS supports aircraft performing precision approach and landing operations as well as other operations near GBAS-equipped airports.

**Ground Plane**
An electrically conducting flat surface at the *bottom* of an ► *antenna* that reflects electromagnetic waves. Optimum antenna properties (such as ► *multipath resistance*) are obtained if the dimension of the ground plane is large compared to the ► *wavelength*.

**Ground Segment**
A major component of a ► *global navigation satellite system* providing satellite control and constellation keeping, as well as orbit and clock data calculation for mission operations.

**Ground Station**
A terrestrial radio station enabling communication with a satellite. Depending on the specific application, one may distinguish between various functions: telemetry stations for reception of satellite data on the ground, telecommand (or uplink) stations for sending control commends to the spacecraft, or tracking stations providing range, range rate or angular measurements for ► *orbit determination*.

**Group Delay**
is a measure of the propagation time of the amplitude envelope of an electromagnetic signal through a device or medium. In the context of GNSS, it describes the delay experienced by the code modulation upon signal propagation through a dispersive medium such as the ionosphere or parts of the signal generating, transmitting, or receiving equipment.

**Group Velocity**
Speed of propagation of the envelope, i. e., the code signal of navigation signals, of a modulated electromagnetic wave. It is a measure for the speed of movement of the wave energy.

## H

**Hand-Over Word (HOW)**
The second 30-bit word within every GPS legacy navigation data 300-bit sub-frame. HOW includes a time stamp.

**Harmonic**
A signal whose frequency is an integer multiple of some other signal's frequency. Nonlinearity in any one of several stages involved in radio frequency transmission generates (typically undesired) power at harmonics of the transmission frequency.

**Hatanaka Compression**
A loss less technique used to compress GNSS data files in ► *Receiver Independent Exchange (RINEX)* format.

**Helmert Transformation**
A 7-parameter similarity transformation named after the geodesist and mathematician F. R. Helmert. It relates two frames through a shift vector, a rotation and a scale factor.

**Higher-order Ionospheric (HOI) Terms**
Contributions to the ionospheric delay of a GNSS signal, which depend on higher than second-order terms of the frequency and cannot by eliminated by the ► *ionosphere-free combinations* of two observations.

**Horizon**
The imaginary line of intersection between a plane tangent to the surface of the Earth at the observer and the celestial sphere. The horizon is the reference plane for the ► *horizontal system* with coordinates ► *azimuth* and ► *altitude*.

**Horizontal System**
A coordinate system related to the local horizon of an observer, and where the coordinates used are ► *azimuth* and ► *elevation*.

**Hot Start**
Activation of a GNSS receiver with prior information on the approximate time and user position as well as

the broadcast ephemeris of the GNSS satellites to speed up the signal search and acquisition and to enable an immediate computation of the navigation solution after collection of valid ► *pseudorange* measurements.

**Hour Angle**
Difference between the local ► *sidereal time* and the ► *right ascension* of a star. The hour angle measures the sidereal time that has passed since the last culmination.

**Hydrogen Maser**
A signal generator based on the hyperfine transition of the neutral hydrogen atom at 1420.405752 MHz.

**Hydrographic Surveying**
A form of surveying in support of offshore engineering (such as associated with pipelines, undersea cables, breakwaters, harbor works, dredging, etc.) and sea floor charting.

**Hydrostatic Delay**
The dry component of the ► *slant total delay*.

**Hypothesis Testing**
is a formalized decision rule of rejecting or not rejecting the null hypothesis. The null hypothesis, representing the model one believes to be true, is thereby compared to one or more alternative hypotheses.

## I

**IF-level Simulator**
A simulator that generates intermediate frequency (IF) samples of GNSS signals similar to those expected at the output of the receivers' front end. These samples can be processed directly by the digital processor of a receiver, or, with a digital-to-analog converter and an up-converter, can be converted to RF signals for conductive or rebroadcast testing.

**Inclined Geosynchronous Orbit (IGSO)**
An orbit synchronous with the Earth'S rotation period of about 24 h but inclined with respect to the Earth's equator. IGSO satellites are commonly used for regional navigation satellite systems as a complement to strictly ► *geostationary satellites*.

**Inertial Measurement Unit**
An electronic measurement device combining accelerometers and gyros to measure the specific force and angular rate of the body to which the sensor is attached.

**Inertial System/Frame**
A non-rotating system or frame in free fall with respect to the ambient gravitational field. *Pseudo* or *quasi* are sometimes appended to distinguish it from the original Newtonian concept of a frame at rest or having only constant rectilinear motion.

**Influential Bias**
A ► *bias* that propagates into the parameter estimator; such bias lies in the range space of the design matrix. A non-testable bias is always influential.

**In-phase (I) Component**
GNSS signals frequently use ► *quadrature phase shift keying* to transmit two orthogonal signal components. such as a civil and a military signal, on one frequency. In the case of GPS L5, the in-phase (I) component transmits the navigation data (► *data channel*), while the quadrature (Q) component (which is 90° out of phase) carries a dataless ► *pilot signal*.

**Integer Ambiguity**
The unknown number of wavelengths (cycles) that is contained in the measured carrier phase range from the receiver to satellite antenna.

**Integer Ambiguity Resolution**
The procedure by which the unknown double-differenced carrier-phase ambiguities are estimated and validated as integers. Once these ambiguities can be considered known, the corresponding carrier-phase measurements will act as very precise pseudorange measurements.

**Integer Bootstrapping (IB)**
Integer estimation that is based on a combination of ► *integer rounding* and sequential conditional least-squares estimation. The success rate of integer bootstrapping is never smaller than that of integer rounding and never larger than that of ► *integer least-squares*.

**Integer Least-squares (ILS)**
Integer estimation that is based on the principle of least-squares. The ILS estimator has the largest success rate of all integer estimators. Its success rate is invariant for ► *Z-transformations*. In contrast to ► *integer rounding* and ► *integer bootstrapping*, the ILS-estimation requires an integer search.

**Integer Rounding (IR)**
Integer estimation that is based on scalar rounding to the nearest integer. The success rate of integer rounding is never larger than that of ► *integer bootstrapping* or ► *integer least-squares*.

**Integrity**
A measure of the trust that can be placed in the correctness of the position solution. Integrity includes the ability of a system to provide timely and valid warnings (alerts) to the user.

**Inter-channel Bias (ICB)**
Difference in code or phase biases of GLONASS ► *FDMA* signals transmitted on different frequency channels.

**Interface Control Document (ICD)**
A document describing the interfaces between the GNSS ► *space segment* and the ► *user segment*. It provides a description of the signal structure and modulation, the format and contents of the navigation data, as well as relevant algorithms for using these data in the positioning.

**Interference**
Radio frequency power in one or more GNSS bands that degrades a GNSS receiver's ability to acquire and track GNSS signals. Interference may be structured, as in GNSS ► *spoofing*, or unstructured, as in wideband Gaussian noise jamming. It may be intentional, as in deliberate jamming, or unintentional, as in noise generated by electronics surrounding a GNSS receiver.

**Inter-frequency Bias (IFB)**
Difference in code or phase hardware biases of signals with different frequencies.

**Intermediate Frequency (IF)**
A frequency lower than the carrier frequency to which the modulated GNSS signal is shifted to facilitate processing in the signal generation or processing chain.

**International Atomic Time (TAI)**
A time scale realized by a weighted average of the time kept by over 400 atomic clocks worldwide. It is the basis for ► *Coordinated Universal Time (UTC)*, which is used for civil timekeeping all over the Earth's surface. TAI is computed monthly by the International Bureau of Weights and Measurements (BIPM).

**International Celestial Reference System (ICRS)**
A system of coordinates and conventions that define coordinates of objects in inertial space. It is defined and maintained by the International Earth Rotation and Reference Systems Service (IERS).

**International Celestial Reference Frame (ICRF)**
A reference frame that realizes the ► *International Celestial Reference System* by means of coordinates of objects accessible directly by radio-astronomical observations.

**International Terrestrial Reference System (ITRS)**
A system of coordinates and conventions that define coordinates of points tied to the Earth. It is defined and maintained by the International Earth Rotation and Reference Systems Service (IERS).

**International Terrestrial Reference Frame (ITRF)**
A reference frame that realizes the ► *International Terrestrial Reference System* at a particular epoch by means of coordinates of definite points that are accessible directly by occupation or by observation. The IERS is responsible for computing the coordinates of this global network in order to realize the ITRF.

**Interoperability**
The ability of jointly using two independent navigation systems for with a resulting benefit over the use of each individual system. ► *Compatibility* of their signals is a prerequisite for the interoperability of two systems.

**Interplex**
A special case of a phase-shift-keyed/phase-modulated (PSK/PM) multichannel system that is characterized by high power efficiency for a number of components.

**Inter-seismic**
Between earthquakes. The inter-seismic period is the time period between major earthquakes on a given fault. In most models of the earthquake cycle, the rate of deformation is expected to be constant or varying only slowly for most of the inter-seismic period.

**Inter-system Bias (ISB)**
Difference in receiver hardware biases between signals of two GNSS constellations plus the offset between the time scales of the two systems.

**Inter-satellite Type Bias (ISTB)**
Difference in receiver hardware biases between signals transmitted by different satellite types within a constellation. In the case of BDS, the existence of inter-satellite type biases has been demonstrated for signals of geostationary satellites that are combined with those of other (IGSO, MEO) satellites.

**Inter-Signal Correction (ISC)**
Correction values in the GPS modernized navigation message to enable a consistent processing of different navigation signals using a single set of clock offset values. ISCs represent a specific form of ► *differential code biases*.

**Ionosphere**
The ionized part of the upper atmosphere from 50 km up to about 1000 km height. The ionospheric plasma is primarily produced by electromagnetic and particle radiation transmitted from the Sun. Consequently, the ionization level depends strongly on geographic location, season and local time. Spatial structure and dynamics of the ionospheric plasma are strongly coupled with other geospheres such as thermosphere and magnetosphere causing a high variability of the plasma density.

**Ionosphere-free Combination**
A linear combination of two GNSS observations, which eliminates the dominant contributions of ionospheric path delays that vary with the inverse square of the signal frequency.

**Ionospheric Correction Models**
In a first-order approach the ionospheric delay or range error is proportional to the ► *total electron content (TEC)* along the ray path. Therefore, to reduce ionospheric range errors in single frequency GNSS applications, ionospheric electron density models (► *NeQuick* for Galileo) or simple TEC models (e.g., ► *Klobuchar* model for GPS or NTCM) can be used.

**Ionospheric Gradient**
Steep variations in time and space of the ionosphere electron content, which cause large delays in the GNSS differential observations even for small baselines.

**Ionospheric Grid Point (IGP)**
A specific reference location on an imaginary thin shell above the Earth's surface. In ► *satellite-based augmentation systems (SBAS)* a set of IGPs is used to describe the ionosphere by transmitting ionospheric delay values for a fixed set of locations over the region of interest.

**Ionospheric Perturbations**
There exist several types of ► *space weather* driven temporal and spatial electron density perturbations in the ionosphere and plasma sphere that may impact GNSS in different ways. Besides radio ► *scintillations* caused by small scale electron density irregularities also medium scale and large scale ► *traveling ionospheric disturbances* (MSTIDs, LSTIDs) or solar flare induced sudden ionospheric disturbances (SIDs) may degrade the GNSS

performance in precision and safety of live applications.

**Ionospheric Pierce Point (IPP)**
A location, often specified by latitude and longitude, between the user and a satellite where the line of sight between the two intersects an imaginary thin shell above the Earth's surface, a shell in which all electrons are assumed to be concentrated. Most commonly the thin shell is specified to have a constant height of 350 km above the reference ► *ellipsoid* of the 1984 release of the ► *World Geodetic System (WGS-84)*

**Ionospheric Refraction**
The signal propagation delay and signal path bending induced by free electrons in the upper part of the atmosphere. Besides the plasma density along the ray path, ionospheric refraction depends on the radio wave frequency (dispersion) and the geomagnetic field vector along the ray path (anisotropy).

## J

**J2000**
A standard epoch representing midday on January 1, 2000 (2000 Jan. 1.5 = JD 2451545.0).

**Julian Day**
A time unit of ► *dynamic time*. It is exactly 1/36525 of a Julian century.

**Julian Day (JD) Number**
An integer day number obtained by counting days from the starting point of noon on January 1, 4713 BC (Julian Day zero).

## K

**Kalman Filter**
A recursive algorithm to obtain a ► *minimum mean squared error (MMSE) estimate* of the state vector of a linear dynamic system based on a time series of past and current observations. Each cycle of the recursion consists of a time-update and a measurement update. In the time-update the dynamic model is used to predict the state vector from the previous epoch, while in the measurement-update the measurements of the current epoch are used to improve upon the estimate of the predicted state vector.

**Keplerian Elements**
A set of six orbital elements used to describe the shape and spatial orientation of the orbit, typically comprising the semi-major axis, eccentricity, inclination, longitude of the ascending node, argument of perigee, and mean anomaly.

**Keplerian Orbit**
The trajectory of a satellite around a central point mass, for the special case of an attracting force proportional to the inverse square of the distance. Bound Keplerian orbits are ellipses confined to a fixed ► *orbital plane*.

**Klobuchar Model**
An empirical model used to describe the ionospheric time delay in single-frequency GNSS measurements. The Klobuchar ionospheric model was first adopted by the Global Positioning System but is also used by various other GNSSs in the same or slightly modified form. It comprises eight parameters that are broadcast by the GNSS satellites with at least daily updates.

**Kinematic Positioning**
Estimation of epoch-wise coordinates for a moving or non-moving GNSS receiver from observations covering a given data arc.

**Korean Augmentation Satellite System (KASS)**
A ► *satellite-based augmentation system (SBAS)* being developed by the Ministry of Land, Infrastructure, and Transport to provide horizontal and vertical navigation throughout the Korean peninsula.

## L

**Laser Time Transfer (LTT)**
A technique for synchronization of space and ground clocks through the exchange of laser pulses. It combines ► *satellite laser ranging* with onboard measurements of the arrival time using a photo-detector on the satellite.

**Latency**
Delay in time after ► *differential GNSS* corrections are generated by the reference receiver or the network and the time they arrive and are applied by the user. Also: delay in the provision of precise orbit and clock products relative to the epoch of the GNSS observations used in their generation.

**L-band**
The band of the radio spectrum covering frequencies of 1–2 GHz.

**Leap Second**
An intentional time step of one second used to adjust ► *Universal Time Coordinated (UTC)* in order to ensure approximate agreement with UT1. An inserted second is called a positive leap second, and an omitted second is called a negative leap second.

**Least-squares Ambiguity Decorrelation Adjustment (LAMBDA)**
Method for the efficient computation of the integer least-squares ambiguity estimator. It makes use of a decorrelating ► *Z-transformation* to speed up the integer search and to compute an improved integer bootstrapping estimator as first approximation.

**Least-squares Estimation**
An estimation principle for solving an overdetermined system of equation by minimizing its (weighted) sum of squared residuals (the differences between input data and their estimated values).

**Length-of-day**
The rotational period of the solid Earth. The angular velocity of the solid Earth, and hence its period of

rotation, changes in response to the torques acting on it.

**Light-time**
The time that it takes an electromagnetic signal to pass the distance between the transmitter and receiver.

**Linear Feedback Shift Registers (LFSR)**
A shift register whose input binary state (0 or 1) is a linear function of its previous states. An *n*-stage shift register consists of *n* consecutive two-state stages (flip-flops) driven by a clock. At each pulse of the clock the state of each stage is shifted to the next stage in line to the right of the register. In order to convert the *n*-stage shift register into a sequence generator a feedback loop is incorporated, which calculates a new term for the left-most stage, based on the states of the *n* previous states. At the right-most stage of the register the generated sequence is output.

**Line-of-sight (LOS)**
Typically refers to the straight line between a GNSS satellite and the antenna of a GNSS receiver. The LOS signal is also referred to as the direct-path signal.

**Line-of-sight Vector**
Vector of unit length pointing from the receiver position to the satellite position.

**Line Quality Factor**
The ratio of the frequency of an atomic transition and the width of the resonance line. The ► *Allan Deviation* of an atomic clock is inversely proportional to the line quality factor, i. e., the clock stability improves with increasing quality factor.

**Link budget**
A budget of gains and losses in a telecommunication system. GNSS link budgets typically comprise the transmit power, the transmit and receive ► *antenna* gains, the ► *free-space loss* as well as atmospheric and cable losses.

**Loading**
The surface forces acting on the Earth from the movement of mass, and the deformation of the solid Earth in response to changing loading forces. Loading most commonly refers to water and atmospheric loading, but erosion and sedimentation can also produce measurable deformation where they are concentrated enough and involve a sufficiently large movement of mass.

**Local Coordinates**
Cartesian coordinates, often in a left-handed system, with the third axis along the local vertical.

**Low Earth Orbit (LEO)**
A satellite orbit with a representative altitude of about 300–1400 km that is commonly used for remote sensing missions.

**Low-noise amplifier (LNA)**
An electronic device to amplify electromagnetic signals, which is specifically designed to add only little noise and can thus be used for very weak signals.

## M

**Mapping Function**
The ratio between the propagation delay through the atmosphere at a specified elevation angle and the propagation delay in the ► *zenith direction*.

**Maser**
A device producing coherent electromagnetic waves through *Microwave Amplification by Simulated Emission of Radiation (MASER)*. Hydrogen Masers are used as atomic clocks, characterized by a very good short-term stability.

**Master-auxiliary Concept (MAC)**
Method of providing ► *Network RTK* corrections to the rover, where absolute corrections from one of the reference stations of the network (i. e., the master) and differential corrections from other (auxiliary) reference stations are transmitted to the rover.

**Master Clock**
A precision clock that provides timing signals to synchronize slave clocks as part of a clock network.

**Master Station**
A processing facility that collects measurements from multiple ► *reference stations* and makes determinations on the performance of the GNSS satellites (and perhaps the ► *ionosphere*). A master station may calculate orbits, satellite clock states, differential corrections, confidence bounds, and/or integrity evaluations.

**Matched Filter**
A technique to reveal a weak signal of known structure by ► *correlation* with a replica.

**Maximum Likelihood Estimator (MLE)**
A parameter estimator of which the outcome maximizes the respective likelihood function. A likelihood function is a parameter function that gives the probability or probability density for the occurrence of a corresponding observation or sample.

**M-code**
The modernized GPS military signals that are broadcast at center frequencies of 1575.42 MHz and 1227.6 MHz on Block IIR-M and subsequent GPS satellites.

**Meaconing**
A specialized spoofing attack in which an entire segment of radio frequency spectrum is captured and replayed. The term *meacon* is a portmanteau of *masking beacon*.

**Mean Solar Time**
An astronomical time scale that is based on the average length of the day, called the mean solar day. The length of an average day is different from a true or apparent solar day, due to daily variations, over the span of a year, in the Sun's apparent angular speed across the sky when viewed by an observer on Earth. Thus, the length of an average or mean solar day is used for a more uniform system of timekeeping.

**Mean Tide System**
A system (such as for coordinates) in which all

temporal tidal effects except the mean tidal effect have been removed.

**Measurement-level Simulator**
A simulator that generates pseudorange, carrier-phase, and/or Doppler measurements for computing the position and other relevant parameters in software. Typically used for testing the ability of a receiver or a third-party software to compute a correct solution.

**Medium Altitude Earth Orbit (MEO)**
An orbit with altitudes above ► *low Earth orbits* and below ► *geostationary orbits*. GNSS medium altitude Earth orbits are usually located at altitudes of about 20 000 km.

**Meridian**
An imaginary great circle on the celestial sphere that defines the plane that is parallel to the polar axis and contains a local vertical vector. The astronomic meridian plane contains the tangent to the local plumb line, and the geodetic meridian plane contain the local normal to the ellipsoid.

**Minimal Detectable Bias (MDB)**
The smallest bias that a test can detect for a given level of significance and ► *power*.

**Minimum Descent Altitude or Height (MDA/H)**
The lowest altitude or height to which a descent is authorized when an aircraft performs a ► *Non-precision Approach* procedure. Unlike a ► *Decision Altitude or Height* an aircraft must not descend below the MDA/H. The pilot may descend to this height and maintain it until reaching the missed approach point, where the missed approach must be initiated if the required visual references are not available.

**Minimum Mean Penalty (MMP) Test**
This ambiguity acceptance test penalizes certain ambiguity outcomes. The penalties (e.g., costs) are chosen by the user and can be made dependent on the application at hand. It is optimal in the sense that it minimizes the average of the assigned penalties.

**Minimum Mean Square Error (MMSE) Estimator**
The estimator that has the smallest mean-square-error of all estimators from a particular class. Often the class is restricted to the class of linear functions. The mean of the squared error is the mathematical expectation of the squared error.

**Minimum Operating Performance Standards (MOPS)**
A document describing the necessary requirements for an object to be awarded an airworthiness certificate. Federal advisory committees, operated by RTCA Inc., develop and document these requirements and the MOPS form the basis for Federal Aviation Administration (FAA) regulatory requirements.

**Modified Julian Day Number**
The ► *Julian day number* minus 2400000.5. The Modified Julian Date (MJD) has a starting point of midnight on November 17, 1858.

**Modulation**
The process of mapping ► *baseband* information to a high-frequency carrier for the purpose of transmission. This takes place by either varying amplitude, phase, or frequency of the carrier signal to be transmitted.

**Monitoring Station**
► *reference station*

**Moore's Law**
An empirical relation named after a founder of Intel Co., who observed that the number of transistors in integrated circuits was almost doubled every 2 years.

**Multi-function Satellite Augmentation System (MSAS)**
A ► *satellite-based augmentation system (SBAS)* developed by the Japanese Civil Aviation Bureau to provide horizontal navigation throughout the Japanese airspace. It has provided safety-of-life service since 2007.

**Multipath**
The phenomenon whereby a transmitted GNSS signal is received at the receiver via multiple paths due to reflection and diffraction in addition to the direct-path signal. The received superposition of direct and non-direct-path signals (also known as the non-line-of-sight signals) results in errors in the signal tracking.

**Multipath-to-direct (M/D) Ratio**
The amplitude of a multipath signal relative to the direct-path signal.

**Multiplexed Binary Offset Carrier (MBOC) Modulation**
A variant of the ► *BOC* modulation, in which two sub-carriers of different frequency and different amplitude are used concurrently (composite BOC or CBOC) or in which the two sub-carriers have equal amplitude but alternate times slots (► *time multiplexed BOC or TMBOC*). The addition of the high-frequency sub-carrier component aims at an improved multipath resistance without a notable increase of the spectral width.

**Multivariate Constrained-least-squares Ambiguity Decorrelation Adjustment (MC-LAMBDA)**
A method for the computation of the integer least-squares ambiguity estimator subject to nonlinear constraints, based on the ► *Least-squares Ambiguity Decorrelation Adjustment (LAMBDA)* method.

## N

**Nadir**
The direction towards the center of the Earth, i. e., opposite to the ► *zenith*.

**Notice Advisory to Navstar Users (NANU)**
Notifications issued by the ► *Global Positioning System (GPS)* to alert users of non-nominal situations such as signal outages or special operations that may result in service interruptions. Similar notifications (NAGUs, NAQUs) are provided by ► *Galileo* and the ► *Quasi-Zenith Satellite System*.

**Narrow-lane Observable**
A linear combination of carrier-phase observations on two frequencies that is formed as the sum of the individual phase values expressed in cycles. It exhibits

a small effective wavelength, e.g., 10.7 cm for GPS L1 and L2.

**Navigation**
The estimation process for determining the system ► *pose* as it maneuvers. Also, the process of determining and implementing a trajectory for an autonomous system.

**Navigation Message**
The set of auxiliary parameters such as satellite orbit and clock information, ionospheric correction data, and time offset parameters, which are transmitted by a GNSS satellite to enable computation of a position fix from the ► *pseudorange* measurements.

**Navigation Message Authentication**
A GNSS signal authentication technique whereby unpredictable (to the public) but verifiable data are inserted into a GNSS signal's navigation data stream. The properties of unpredictability and verifiability can be achieved by means of a digital signature, which is generated by a secret (private) key but can be verified by a public key. Besides injecting verifiable randomness into the navigation data stream, the digital signature serves to authenticate all data in the stream as originating with the holder of the private key (e.g., the control segment for a particular GNSS constellation).

**Navigation System Error (NSE)**
The difference between the true position and the estimated position. This error is linked to the navigation system providing the position estimation.

**NeQuick**
An empirical model used to describe the ionospheric electron density. A specific version known as NeQuick-G has been adopted by the Galileo system. Here, the modeled electron density is integrated along the signal path and used to correct single-frequency code measurements. The NeQuick-G model parameters are broadcast by the Galileo satellites with at least a daily update interval.

**Networked Transport of RTCM via Internet Protocol (NTRIP)**
Protocol for the streaming of ► *differential GNSS* corrections in ► *RTCM* format via the Internet.

**Network RTK (NRTK)**
A ► *differential GNSS* positioning technique that extends the operational distance of the ► *real-time kinematic (RTK) positioning* technique from 10 km to about 100 km from the reference receiver. This is realized by employing a network of reference receivers that produces precise correction models of the distance-dependent biases (atmosphere, orbit).

**Neuman-Hofman (NH) Code**
A specific type of ► *secondary code* used in ► *pilot signals* of the modern GNSS navigation signals.

**Noise**
Random fluctuations in a measured signal.

**Non-directional Beacon (NDB)**
A radio beacon operating in the medium or low-frequency bandwidths used for aircraft navigation. NDBs transmit a signal of equal strength in all directions. ► *Automatic Direction Finding (ADF)* equipment on board aircraft uses bearings from NDBs for navigation purposes.

**No-net-rotation**
The conventional requirement that subsequent realizations of a reference system are parallel.

**Non-precision Approach (NPA)**
An aircraft approach procedure using lateral guidance to bring the aircraft to a point where the runway is in view and a visual landing can be performed. NPA procedures do not include vertical guidance and include a ► *Minimum Descent Altitude/Height*.

**Notice to Airmen (NOTAM)**
A notice containing information concerning the establishment, condition, or change in any aeronautical facility, service, procedure, or hazard, the timely knowledge of which is essential to personnel concerned with flight operations.

**Null Hypothesis**
► *Hypothesis testing*

**Numerically Controlled Oscillator (NCO)**
A digital signal generator used to generate a harmonic wave of desired frequency, and, optionally, phase. It is used inside a ► *phase lock loop* or ► *frequency lock loop* to track the incoming carrier signal and to measure its phase and ► *Doppler shift*.

**Nutation**
An oscillation of the Earth's axis about its mean position, which is superimposed on precession and driven by the luni-solar gravitational torque. The nutation movement is the resultant of oscillations with different periods of which the more important is 18.6 years, corresponding to one rotation of the Moon's ascending node.

## O

**Obliquity**
The angle between the equatorial and orbital planes of some body. For the Earth, the angle between the plane of the Earth's equator and the plane of the Earth's orbit about the Sun. The mean obliquity of the ecliptic is about 23.4°.

**Obliquity Factor**
The ratio between a slant path passing through a thin slab above the Earth to a vertical path passing through the same location in the slab. The obliquity factor (or ► *mapping function*) is used to convert a vertical ionospheric delay estimate into a slant delay estimate corresponding to the elevation angle of the path. For the thin shell model that assumes an ► *ionosphere* 350 km above the Earth, the obliquity factor ranges from 1 (for a satellite directly over head) to just over 3 (for a satellite close to the horizon).

**Observation Session**
The length of time a non-moving receiver makes sufficient observations (adequate change in satellite–receiver geometry) for reliable ► *static positioning*. It may be many hours in length for a long ► *baseline* and/or an ► *ambiguity float solution*, to as

short as a few seconds if the ambiguities have already been resolved.

**Occultation**
► *Radio Occultation*

**Orbit**
The trajectory of a natural or artificial satellite around a central body – the Sun in the case of planets in the solar system, or the Earth in the case of artificial Earth-orbiting satellites.

**Orbital Plane**
The plane to which the motion of a satellite is confined in a central gravity field. In the presence of perturbations an ► *osculating* ► *orbit plane* is defined by the instantaneous position and velocity vector.

**Orbit Determination**
The process of estimating a set of parameters (including the initial position and velocity as well as various force mode parameters) describing the future motion of a satellite through a corresponding dynamical trajectory model.

**Orbit Perturbations**
Deviations of the orbital motion of a satellite around a central body from an idealized ► *Keplerian orbit*. Such perturbations are, e.g., caused by the aspherical gravity field of the Earth, the luni-solar gravitational attraction, atmospheric drag, and solar ► *radiation pressure*.

**Oscillator**
A device providing a periodical signal with a given frequency.

**Outlier**
A measurement that, relative to the assumed measurement noise probability distribution, is so rare that its validity is questionable.

**Overbound**
A probability distribution whose likelihood of having an error magnitude greater than some value is at least as large as the likelihood that the true error magnitude is greater than that value. The overbound is most commonly specified as a 1-sigma value for a zero-mean Gaussian distribution. The overbound is used to conservatively describe a true error distribution.

**Overall Model Test**
A test that tests the null hypothesis (► *hypothesis testing*) against the most relaxed alternative. This test is used for detecting unspecified modeling errors in the null hypothesis.

**Overlay Code**
► *Secondary code*

## P

**Parametry Zemli 1990 (PZ-90)**
An Earth model maintained by the Military Topography Agency of the General Staff of the Armed Forces of the Russian Federation. The definition of PZ-90 comprises fundamental geodetic constants, parameters of the Earth's ellipsoid, and the Earth's gravity field parameters, as well as the geocentric reference system, which is defined in accordance with common conventions of the International Earth Rotation and Reference Systems Service (IERS) and Bureau International de l'Heure (BIH). PZ-90 serves as the ► *datum* for ► *GLONASS* ► *single-point positioning*.

**Partial Ambiguity Resolution (PAR)**
Ambiguity resolution when only a part of the ambiguities are resolved as integers. PAR can be applied in case the GNSS model is not strong enough to enable successful ambiguity resolution of all ambiguities. PAR is usually applied after the ambiguities have been re-parameterized with a proper ► *Z-transformation*.

**Parts-per-million (ppm)**
A relative accuracy measure defined as the ratio of accuracy to ► *baseline* length scaled by one million. For example, 1 ppm is 1 cm accuracy between two GNSS receivers separated by 10 km, or 10 cm over 100 km, etc. Parts-per-billion (ppb) is obtained as ppm × 1000. For example, 10 ppb is 1 cm accuracy between two GNSS receivers separated by 1000 km.

**P-code**
The precision (P) ranging code modulated onto both L1 and L2 carriers in GPS and GLONASS. The GPS P-code is referred to as the Y-code if it is encrypted. In the case of GPS, only authorized receivers are capable of directly tracking the Y-code. Civilian receivers use ► *semi-codeless tracking* techniques to obtain P(Y)-code pseudorange measurements.

**Performance-based Navigation (PBN)**
► *Area navigation* based on performance requirements for aircraft operating along an air traffic service route, on an instrument approach procedure or in a designated airspace. Airborne performance requirements are expressed in navigation specifications in terms of ► *accuracy*, ► *integrity*, ► *continuity*, and functionality needed for the proposed operation in the context of a particular airspace concept. Within the airspace concept, the availability of GNSS signal-in-space (SIS) or that of some other applicable navigation infrastructure has to be considered in order to enable the navigation application.

**Perifocal Coordinates**
Position of a celestial body relative to its orbital plane and the line of apsides.

**Perigee**
The closest point of an artificial satellite's orbit around the Earth.

**Phase Bias**
The signal hardware delay at receiver and transmitter side associated with the carrier phase signal generation.

**Phase Center Offset (PCO)**
The separation vector between the ► *antenna reference point* and the ► *antenna phase center*.

**Phase Center Variation**
Deviations of the antenna radiation pattern from a perfect sphere about the ► *antenna phase center*.

**Phased-array Antenna**
An array of antennas in which the relative phases of the signals coming to the antennas are combined in such a way that the effective radiation pattern of the array is reinforced in a desired direction and suppressed in undesired directions.

**Phase-range Corrections**
Corrections determined at a (network of) reference receiver(s) that are transmitted to a rover receiver in order to enable carrier-phase-based ► *differential GNSS* or ► *real-time kinematic positioning*.

**Phase Lock Loop (PLL)**
A controller used to align the phase of a carrier replica inside a GNSS receiver with that of the incoming signal. It comprises a ► *numerically controlled oscillator*, a phase ► *discriminator* that senses the instantaneous tracking error, and a loop filter that provides a smoothed estimate of the phase error for feedback to the NCO.

**Phase Unlock**
Failure to maintain phase tracking lock in a carrier phase tracking loop, resulting in a single ► *cycle slip* or a succession of cycle slips.

**Phase Velocity**
The speed of propagation of the carrier signal of an electromagnetic wave at a single frequency. It describes the velocity of movement of the phase front.

**Phase Wind-up**
The change in the received signal phase due to rotational changes in the relative orientation between receiver and transmitter antenna in the direction of signal propagation.

**Pilot Signal**
A GNSS signal component that does not contain data and is only modulated with a ranging code. Pilot signals allow for extended integration times for improved tracking sensitivity and robustness. Often, a ► *tiered code* is used for pilot signals in which a medium length primary ranging code is combined with a short ► *secondary code*.

**Pivot Receiver/Satellite**
Receiver or satellite that is selected as reference for forming ► *between-receiver* or ► *between-satellite differences*, respectively.

**Plate Boundary Zone**
The boundaries between tectonic plates are observed to be diffuse and often involve deformation spread out over regions hundreds to even 1000 km wide. Within a plate boundary zone, several active faults may take up the relative plate motion between the major plates, sometimes with large undeforming regions inside the plate boundary zone.

**Plate Motion**
The surface of the Earth is broken up into a set of tectonic plates, which are rigid except near their edges and which are all moving relative to each other. Plate motions are steady with time, changing only over long timescales, like hundreds of thousands of years. Plate motions are described in terms of rotations on the surface of a sphere about a geocentric axis.

**Polarization**
The direction of the oscillation of the electromagnetic field as a function of time. GNSS signals are circularly polarized, i. e., the field vector rotates along the propagation direction.

**Polar Motion**
The motion of the ► *celestial intermediate pole* with respect to the crust and mantle of the Earth. Can also refer to the motion of some other pole, such as the rotation pole, with respect to the crust and mantle of the Earth.

**Pose**
The position and attitude of an entity.

**Positioning**
Determination of the position coordinates of a location (in a reference frame) by means of measurement techniques in which the instrument is either placed on the position to be determined, or where the instrument measures the location of which the position has to be determined.

**Position Dilution of Precision (PDOP)**
► *Dilution of Precision*

**Postseismic**
Immediately after an earthquake. Transient deformation processes are observed to occur immediately after large earthquakes. These processes may cause very rapid deformation for a short time after the earthquake, and the rate of deformation decays with time back to a background, interseismic rate.

**Power (statistical)**
One minus the ► *probability of missed detection*.

**Preamble**
A well-defined bit sequence used to identify the start of data frames in the GNSS navigation message.

**Precession**
The slow variations in the directions of the Earth's instantaneous spin axis and of the ► *vernal equinox* relative to the celestial sphere due to the gravitational actions of the Sun, Moon, and planets on the Earth's orbit and its non-spherical shape and non-homogeneous constitution.

**Precise Orbit Determination (POD)**
A technique that combines methods and strategies to derive precise (typically of sub-decimeter accuracy) satellite positions using either a dynamic (relying on accurate modeling of forces acting on a satellite) or kinematic (trajectory through epoch-wide representation) approach.

**Precise Point Positioning (PPP)**
A technique that makes use of pseudorange and carrier phase observations of only a single receiver along with precise orbit and clock information of the GNSS satellites for determining the position of the receiver antenna.

**Precise Point Positioning Real-time Kinematic (PPP-RTK)**
Extension of the ► *precise point positioning (PPP)* technique by including satellite phase bias corrections such that the single-station carrier-phase ambiguities can be resolved to integers and, consequently, the PPP precision can be improved to centimeter level.

**Precise Positioning Service (PPS)**
One of two services provided by GPS that is intended for authorized (e.g., military) users only and based upon the ► *P(Y)-code* signals on two frequencies, GPS L1 and L2.

**Precision**
A measure for the reproducibility of measured or estimated quantity when measurement or estimation is repeated under similar circumstances.

**Precision Approach**
an instrument approach procedure using precise lateral and vertical guidance flown to a ► *decision altitude/height*.

**Prediction (statistical)**
Estimation of the outcome or realization of a random variable or vector. An observable random vector is used to guess the outcome of another non-observed random vector.The non-observable vector may comprise model parameters to be predicted in time or in space, but also signal and/or noise parameters.

**Probability of False Alarm**
The chance of rejecting the null hypothesis (► *hypothesis testing*) while it is true. It is also known as the significance level and it is usually denoted by $\alpha$.

**Probability of Hazardous Missed Detection**
The product of the ► *probability of hazardous occurrence* and ► *probability of missed detection*

**Probability of Hazardous Occurrence**
Probability of having the outcome of the GNSS parameter estimator lie outside a pre-defined, non-hazardous parameter region. This probability increases as the influential ► *bias-to-noise ratio* gets larger.

**Probability of Missed Detection**
The chance of not rejecting the null hypothesis (► *hypothesis testing*) while it is false. It is usually denoted by $\beta$. This probability gets smaller as the testable ► *bias-to-noise ratio* gets larger.

**Proper Time**
The time scale associated with an observer at rest in a local frame.

**Protection Level**
The maximum possible positioning error that may be present for a navigation system at the current time, for a specified probability level. Usually, the protection level is compared to a corresponding ► *alert limit* to determine whether the navigation system meets the operational requirements at that time.

**PRN Number**
A number used to identify a GPS satellite based on the transmitted signal. More specifically, the PRN number denotes the serial number assigned to the ► *C/A-code* ► *pseudo-random noise sequence*.

**Pseudolite**
A device that transmits GNSS-like ranging signals from a known location to augment or replace the signals broadcast by GNSS satellites. The word is a contracted form of the composite term *pseudo-satellite*.

**Pseudo-random (PR) Binary Sequence**
► *Pseudo-random noise*

**Pseudo-random Noise (PRN)**
A quasi-random bit sequence of limited length with good cross and autocorrelation properties. PRN sequences are commonly used as ranging codes in GNSS systems.

**Pseudorange**
A distance-like measurement obtained from the time difference between transmission and reception of a radio signal and the known speed-of-light. Due to time offsets between the local clocks measuring the two times, the measurement differs from the true distance and includes a contribution related to these clock offsets. It is hence called a *pseudo*range.

**Pseudorange Corrections**
Corrections determined at a (network of) reference receiver(s) that are transmitted to a rover receiver in order to enable code-based ► *differential GNSS (DGNSS)* positioning.

**Pull-in Region**
Region in which every float ambiguity vector is pulled to the same integer vector. Pull-in regions are translational invariant regions that cover the ambiguity space without gaps and overlap. The shape of the pull-in region is defined by the type of integer estimator chosen.

**P-value**
A measure of strength-of-evidence on which the ► *hypothesis testing* decision to *reject* or *not reject* is made. Given the data, it is the smallest significance level at which the test rejects the null hypothesis.

**P(Y)-code**
A 10.23 MHz chipping rate, spread-spectrum signal broadcast by the GPS satellites on two frequencies, 1575.42 MHz and 1227.6 MHz. The precision (P)-code is unencrypted. For many years, the P-code has been encrypted into what is referred to as the ► *Y-code*. In common usage, P(Y)-code refers to the 10.23 MHz chipping rate GPS signals whether they are being broadcasted encrypted or unencrypted.

## Q

**Quadrature (Q) Component**
A signal component transmitted with a 90° phase shift relative to the ► *in-phase component* of a compound navigation signal.

**Quadrature Phase Shift Keying (QPSK)**
A modulation scheme for radio navigation signals, in which two superimposed carriers with a 90° shift (known as in-phase and quadrature channel) are each modulated with a binary signal using ► *binary phase shift keying (BPSK)*.

**Quadrifilar Helix**
A GNSS antenna made up of four wires arranged in a fractional-turn helix configuration and fed with progressive quadrature phase shifts.

**Quantization**
The process of converting a signal defined on a continuous range of values to one on a finite range of discrete values. The analog radio frequency signal received by a GNSS signal may be quantized to two, three, four, or more discrete quantization levels. Higher quantization resolution resulting from a larger number of quantization levels reduces signal distortion due to quantization.

**Quartz Crystal Oscillator**
A harmonic signal generator comprised of an specially cut quartz crystal device in a tuned circuit designed to produce a specific frequency signal. Design variations are employed to compensate for environmental effects on the crystal device that may cause frequency changes.

**Quasi-Zenith Satellite System (QZSS)**
A regional Japanese navigation system, which uses slightly eccentric ► *inclined geosynchronous orbits* to ensure that at least one satellite is always visible at high elevations for users in the service area.

**Quaternion**
A real-valued, four-component entity that extends the space of complex numbers by defining a hypercomplex mathematical object. A subset of the space of quaternions (quaternion with unit norm) can be used to parameterize a rotation.

## R

**Radiation Pressure**
The pressure caused by the absorption or reflection of photons impinging on the surface of a satellite. For GNSS satellites with large solar panels, radiation pressure is a dominant source of ► *orbital perturbations*. Aside from the direct solar radiation pressure, reflected solar radiation of the Earth (► *albedo*) or the Earth's infrared radiation contribute to the total acceleration.

**Radio-determination Satellite Service (RDSS)**
A service defined by the International Telecommunications Union (ITU) for location determination and reporting of mobile users using radio signals in the L-band (uplink) and S-band (downlink).

**Radio Occultation**
A radio technique that measures the change of radio wave parameters such as signal strength and phase at grazing incidence when the radio wave continuously approaches the surface of a planet until the radio wave finally disappears. The technique has been widely used to explore planetary atmospheres such as Venus and Mars. The GNSS radio occultation technique uses the changing refraction of GNSS signals while approaching the Earth's atmosphere to retrieve vertical profiles of the electron and neutral gas densities of the ionosphere and troposphere, respectively.

**Radome**
A dome that covers, e.g., a ► *choke-ring antenna*, as typically used for geodetic surveying applications or at a ► *reference station*.

**Ranging Code**
A binary sequence modulated on a carrier wave to enable ► *(pseudo)range* measurements. GNSS uses ► *pseudo-random noise (PRN)* sequences as ranging code.

**Ratio Test**
An ambiguity test to decide whether or not to accept the estimated ► *integer ambiguity vector*. The test is based on the ratio of two quadratic forms, measuring the closeness of the float ambiguity vector to the estimated integer vector and the next nearest integer vector.

**Ray Tracing**
The reconstruction of the signal path through different media.

**Real-time Kinematic (RTK) Positioning**
► *Differential GNSS* positioning technique that is driven by carrier-phase data based on a baseline set up between a reference and rover receiver. Essential to high-precision RTK positioning is carrier-phase integer ambiguity resolution. Code (pseudorange) data are used in addition to the phase data to strengthen the RTK positioning model. For sufficiently short baselines (e.g., less than 10 km) the differential atmospheric biases can be neglected and very fast integer ambiguity resolution is feasible.

**Rebroadcast Test**
Testing a receiver by broadcasting GNSS signals (usually simulated) toward the device under test from one or more transmitter positions. Typically conducted when the antenna is integrated into the device under test, or when it is necessary to include the antenna in the test chain.

**Receiver Autonomous Integrity Monitoring (RAIM)**
A testing procedure whereby the redundant observations available at the GNSS receiver are autonomously processed to monitor the integrity of the GNSS signals with the purpose of providing relevant warnings.

**Receiver Independent Exchange Format (RINEX)**
The receiver independet exchange format is an ASCII-based format for GNSS observation and navigation data, as well as meteorological data.

**Record-and-playback System**
A system capable of recording received GNSS signals as intermediate frequency samples and, at a later time, up-converting the replayed signals for input to a GNSS receiver.

**Redundancy**
The total number of available observations minus the number of observations that are strictly needed to solve the system of equations. For a linear system of

observation equations it equals the difference between the number of observations and the rank of the system matrix.

**Reference Ellipsoid**
That ► *ellipsoid* adopted for a particular national or global ► *datum* or ► *reference frame*, such as the ITRF. The ► *Geodetic Reference System 1980 (GRS80)* ellipsoid is an internationally recognized reference ellipsoid.

**Reference Frame**
The realization of a ► *reference system* by means of coordinates of ► *control points* or ground marks that are accessible directly by occupation or by observation; for example, the ► *International Terrestrial Reference Frame (ITRF)*.

**Reference Station**
A GNSS receiver at a precisely surveyed antenna location (i. e., with known coordinates expressed in a ► *reference frame*), whose measurements are used to monitor, and possibly correct, any observable satellite signal errors. The reference station can act as the coordinate fixed point for baseline solutions or relative positioning determination with GNSS techniques such as ► *differential positioning (DGNSS)* or ► *real-time kinematic (RTK)* positioning.

**Reference System**
A set of prescriptions and conventions together with the modeling required to define at any time a triad of Cartesian coordinate axes.

**Reflectometry**
Method to establish properties of a reflecting surface by comparing the properties of incident (or a replica) and reflected electromagnetic signals.

**Refraction**
The deflection of GNSS signals in the Earth's atmosphere.

**Regional Argumentation**
The provision of additional parameters derived from regional GNSS observations to support ► *Precise Point Positioning (PPP)*

**Relative Positioning**
► *Differential GNSS*

**Required Navigation Performance (RNP)**
A form of ► *Area Navigation (RNAV)* with the addition of an on-board performance monitoring and alerting capability.

**RF-level Simulation**
A simulator that generates radio-frequency (RF) signals similar to those expected at the input of an antenna. Typically used for conductive testing, but rebroadcast testing is also possible.

**Right Ascension**
The longitude in a ► *celestial coordinate* system. Right ascension is the angle between the reference direction (at or close to the ► *vernal equinox*) and the projection of a bodies position on the equatorial plane, measured in an eastern direction.

**RINEX**
► *Receiver independent exchange format*

**Rodrigues Vector**
A vector of ► *attitude parameters* derived from the elements of a ► *quaternion*.

**Rotation Poles**
The two points, the north rotation pole and the south rotation pole, defined by the intersection of the Earth's rotation axis with the surface of the Earth.

**RTCM Message Format**
Standardized format for the exchange of GNSS observations, ephemerides, and correction data as defined and published by the Radio Technical Commission for Maritime Services Special Committee 104 (RTCM SC-104).

**Rubidium Atomic Frequency Standard**
A signal generator that produces a stable signal based on optically pumping the hyperfine frequency of Rubidium 87 at 6.834682611 GHz, where the Rubidium is suspended in a gas cell.

## S

**S-band**
A part of the spectrum of electromagnetic waves with carrier frequencies in the range of 2–4 GHz.

**Sagnac Correction**
In the context of GNSS, the Sagnac or Earth-rotation correction denotes a (non-relativistic) correction of the satellite positions that must be applied in the computation of the navigation solution when working in a rotating, Earth-fixed reference frame, to properly account for the Earth's rotation during the signal propagation time.

**Sample Rate**
The frequency at which a signal is measured.

**Satellite-based Augmentation System (SBAS)**
A wide area differential GNSS augmentation system using a regional monitoring network to collect data from core constellations and providing a navigation message to users via satellites in ► *geostationary orbit*. Examples include the US ► *Wide Area Augmentation System (WAAS)*, the ► *European Geostationary Navigation Overlay Service (EGNOS)*, the Japanese ► *Multi-function Satellite Augmentation System (MSAS)*, and the Indian ► *GPS Aided GEO Augmented Navigation (GAGAN)* system.

**Satellite Laser Ranging (SLR)**
A geodetic technique that provides distance measurements between satellites and a ground station based on the signal turn-around time of laser pulses.

**Scintillation**
Temporal fluctuations in phase and intensity caused by electron density irregularities along a transionospheric signal's propagation path. Scintillation effects may lead to severe signal fading (e.g., deep power fades $> 15$ dB) associated with loss of lock and extremely enhanced phase noise.

**Search and Rescue (SAR)**
A secondary mission for some GNSS constellations, which involves the detection of internationally standardized distress signals from emergency beacons

and relaying of this information to government authorities.

**Second**
The duration of 9 192 631 770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of the cesium-133 atom. The definition was added to the International System (SI) of units in 1967.

**Secondary Code**
A short binary pattern that is applied to subsequent repetitions of a fast, medium-length, primary spreading code to form a long ► *tiered code* that enables long integration times. Also referred to as an overlay or synchronization code.

**Selective Availability (SA)**
An intentional degradation of the clock phase to limit the accuracy of the ► *standard positioning service* of the ► *Global Positioning System (GPS)* for civil users to approximately 150 m. Selective availability was finally abandoned by presidential order in May 2000.

**Semi-codeless Tracking**
A special technique to track the encrypted ► *Y-code* signal of the GPS satellites without full knowledge of the signal. It is based on the assumption that the Y-code results from the known ► *P-code* by multiplication with an unknown low rate (≈ 500 kHz) *W-code*.

**Semi-kinematic Positioning**
► *Differential GNSS* positioning technique in which carrier-phase (and pseudorange) data are collected for a rover receiver that is moving with respect to a stationary reference receiver. The rover receiver collects data during a short time (a few minutes) and then moves to the next point, continuously tracking the signals. To avoid a long observation time span during which the rover cannot move (as with conventional static positioning), special measurement procedures have been developed (i. e., revisiting of stations, starting from a known baseline, with antenna swap).

**Semi-major Axis**
Half the *large diameter* of an ellipse, i. e., the radius of an encompassing circle. For an elliptic satellite orbit, the semi-major axis denotes the mean value of the minimum and maximum orbital distance from the central body.

**Shapiro Effect**
The gravitational time delay experienced by an electromagnetic signal due to the presence of a massive body close to the signal transmission path.

**Shielding Chamber**
A chamber or cabinet designed to contain radio-frequency signals. Typically used for broadcast testing of radio-frequency equipment when the device under test must be shielded from external signals and/or when the broadcast signals are in a protected or restricted band.

**Sidereal Day**
The interval of time between two consecutive upper transits of the ► *vernal equinox* across some ► *meridian*. The mean sidereal day is 86 164.09054 s long and is a measure of the rotation of the Earth with respect to the stars.

**Sidereal Time**
The time associated with Earth's rotation relative to the celestial sphere, where 15° of rotation equals 1 h of sidereal time.

**Signal-in-space Range Error (SISRE)**
The user range error contributed by both the ► *space segment* and ► *ground segment*, but excluding ionosphere, troposphere, multipath errors, and receiver noise contributions. Usually applied to define the navigation service quality of the system itself.

**Signal-to-noise Ratio (SNR)**
A signal power to noise power ratio. It compares the level of a desired signal to the level of background noise.

**Signal-to-interference-plus-noise ratio (SINR)**
A signal power to noise-plus-interference power ratio.

**Significance Level**
The ► *probability of false alarm*.

**SINEX**
► *Solution independent exchange format*

**Single-difference**
► *Between-receiver difference* or ► *between-satellite difference* of GNSS observations and parameters.

**Single Point Positioning (SPP)**
An absolute GNSS positioning technique that is based on pseudorange measurements of at least four satellites with known positions and clocks offsets.

**Slant Total Delay**
The extra time needed for a signal propagating through the neutral atmosphere in a given (slant) direction compared to the propagation time in vacuum. It is often expressed in units of length, using the speed of light in vacuum for the conversion. For practical reasons, the slant total delay (STD) is divided into a slant hydrostatic delay (SHD) and a slant wet delay (SWD). A special case is the delay in the zenith direction. This zenith total delay (ZTD) is also divided into a zenith hydrostatic delay (ZHD) and a zenith wet delay (ZWD). The ZHD is approximately 2.3 m at sea level and proportional to the ground pressure. The ZWD can be anything between 0–40 cm, depending on the climate zone and the specific weather conditions.

**Software Defined Radio (SDR)**
A radio communication system implemented by means of software running on a processing system instead of typical implementation in hardware.

**Solar Day**
The interval of time between two consecutive transits of the Sun across some ► *meridian*. The nominal solar day is 86 400 s long and is a measure of the rotation of the Earth with respect to the Sun. The length of the solar day differs from that of the ► *sidereal day* by about 4 min because of the orbital motion of the Earth about the Sun.

**Solar Radiation Pressure**
The non-gravitational force acting on a satellite due to the direct radiation of the Sun (► *radiation pressure*).

**Solar Radio Burst**
An intense outburst of radio emissions from the Sun, with spectral power ranging from 3 MHz to above the L-band. A burst is typically associated with solar flares, which are caused by the acceleration of electrons in the solar atmosphere and whose rate of occurrence follows the 11-year sunspot cycle.

**Solution Independent Exchange Format (SINEX)**
An ASCII-based format for normal equation or variance/covariance matrices and related information. SINEX files computed by different analysis/combination centers are, e.g., the input for the computation of the ► *International Terrestrial Reference Frame*.

**Space Segment**
A key part of a ► *global navigation satellite system*, comprising the constellation of satellites with proper orbital geometry which transmits the navigation signals.

**Space Vehicle Number (SVN)**
A consecutive number assigned to different satellites of the Global Positioning System (GPS). Other than the pseudo-random noise (PRN) number the SVN is unique for a given spacecraft and does not change throughout its lifetime.

**Space Weather**
characterizes the energy, intensity, and composition of the electromagnetic and corpuscular solar radiation, galactic cosmic rays, and the associated state and coupling processes of the magnetosphere, ionosphere/plasmasphere, and thermosphere.

**Specific Force**
The non-gravitational force per unit of mass.

**Spoofing**
The act of generating a signal whose structure adheres closely enough to a GNSS signal specification that it can be misconstrued by a GNSS receiver as authentically broadcast by a GNSS satellite. Spoofing can be intentional, as in a deliberate attempt to manipulate the position, velocity, or time readout of a target GNSS receiver, or unintentional, as in an errant GNSS simulator or repeater signal that could be misinterpreted as originating from a GNSS satellite.

**Standard Positioning Service (SPS)**
One of two services provided by GPS that is intended for civilian use and is based upon the ► *C/A-code* signal on one frequency, GPS L1 (1575.42 MHz).

**Static Positioning**
Estimation of a single set of coordinates for a non-moving receiver from observations covering an extended observation data collection session (typically 1 or more hours). Referred to as rapid static positioning when the ► *observation session* is of the order of a few tens of minutes.

**Stochastic Orbit Parameter**
Empirical parameters such as accelerations or impulsive velocity increments that are introduced into the equation of motion of a satellite and adjusted in the orbit determination process to compensate for imperfections of the employed force model.

**Stratosphere**
is the layer in the Earth's atmosphere above the ► *troposphere*. It starts in about 8–13 km, but the actual value depends on the weather conditions and varies systematically with the latitude and the season. The top is at a height around 50 km.

**Surface Acoustic Wave (SAW) Filter**
A bandpass filter for radio frequency signals based on an electromechanical device that converts electrical signals to a mechanical wave and then back to electrical signals.

**Surplus Satellite**
An extra satellite in a GNSS constellation that is not operational (e.g., because it is older than its design life and suffers some performance degradation), but could be reactivated if needed.

**System of Differential Correction and Monitoring (SDCM)**
A ► *satellite-based augmentation system (SBAS)* being developed by the Russian Federation to provide horizontal and vertical navigation throughout Russia.

## T

**Terrestrial Time (TT)**
Terrestrial Time is the relativistic timescale that replaced ► *Ephemeris Time (ET)* as the time reference for apparent geocentric ephemerides (► *Dynamical Time*). For practical purposes both time scales may be considered to be equivalent. Its origin is defined by the following relation to TAI: TT = TAI + 32.184 s on January 1, 1977, 0 h TAI. TT is a theoretical ideal, which real clocks can only approximate; its best realization is TT(BIPM) provided on a yearly basis by the BIPM from a set of atomic clocks also used for TAI.

**Testable Bias**
Bias that propagates into the test statistic; such bias lies in the orthogonal complement of the design matrix range. A non-influential bias is always testable.

**Test statistic**
A function of the observables that is used to test hypotheses.

**Thermal Noise**
Broadband noise originating in an electrical conductor due to the random thermal motion of electrons. In a radio system such as a GNSS receiver, thermal noise originates primarily in the first amplifiers through which received signals pass. It can be accurately modeled as spectrally flat with an intensity proportional to temperature and having a Gaussian amplitude distribution.

**Tides**
Earth deformations induced by the luni-solar gravitational attraction and resulting in periodic ground motions (body tides) of several tens of centimeters, inducing periodic displacement of the liquids at the surface of the Earth (ocean tides).

Besides changing the position of points on the surface of the Earth, tides also cause small variations of the Earth's gravity field.

**Tide-free System**
A system (such as for coordinates) in which all tidal effects have been removed.

**Tiered Code**
A combination of a primary ranging code and a short ► *secondary code* commonly used in ► *pilot channels* of modern GNSS signals.

**Time Division Multiple Access (TDMA)**
A multiple access scheme, where channel users (satellites) occupy the complete available bandwidth but at different times, i. e., transmitting in turn in assigned time slots.

**Time Multiplexed Binary Offset Carrier (TMBOC) Modulation**
A modulation in which different ► *binary offset carrier modulations* pulse shapes are used for different chips of the pseudo-random binary sequence. For example, a mixture of BOC(1,1) and BOC(6,1) modulations is used for the ► *pilot component* of the GPS L1 civil (L1C) signal.

**Time Scale**
A continuous realization of a (conventional) reference frequency

**Time-to-first-fix (TTFF)**
The time between activation of a GNSS receiver and the first computation of a navigation solution. It is determined by the time required to search and for a sufficient number of satellites, to reliably track them and to decode the relevant parts of the navigation message. TTFF may vary from a few seconds for a ► *hot start*, to tens of seconds for a ► *warm start*, or even up to a few minutes for a receiver ► *cold start*.

**Time-to-alert (TTA)**
A maximum time allowed when a system that was previously declared safe for use can no longer assure that it meets all its integrity requirements for a given operation.

**Time Transfer**
The transfer of a precise reference time needed for remote synchronization. In scientific metrology, the time transfer is also used for remote comparisons of atomic clocks.

**Timing Group Delay (TGD)**
Scaled value of a satellite ► *differential code bias* as transmitted in the satellite's navigation message.

**Tomography**
Tomography refers to imaging of an object by penetrating waves whose modifications are measured after leaving the target. As an example, ground and space-based GNSS signals can be used to image the electron density distribution in the ionosphere and the water vapor distribution in the troposphere by measuring code and/or carrier phase changes.

**Total Electron Content (TEC)**
Integral of the electron density along a given ray path through the ionized atmosphere. Since each ray path has a specific geometry in concrete applications, TEC must be specified by both ends of the ray path and the elevation angle. In ground-based GNSS applications it is convenient for distinguishing between the slant TEC (STEC) along the entire ray path and the geometry free vertical TEC (VTEC) that describes the vertical electron content from the bottom of the ionosphere up to GNSS orbit heights and is commonly used as reference. TEC is usually measured in units of $10^{16}$ electrons per $m^2$ that is equivalent to 1 TEC unit (TECU).

**Total Station**
A survey instrument set up on a tripod over a ground mark that electronically measures the horizontal and vertical angles of the telescope when pointed at a target, as well as the distance to a reflecting prism (or reflective surface) using an infrared laser. Used to transfer geodetic coordinates from the ground mark to a target.

**Tracking**
The continuous alignment of a replica signal generated inside a GNSS receiver to the received signal. Based on the tracking process, which is initiated after the initial signal ► *acquisition*, measurements of code delay, carrier phase, and carrier can be obtained by the receiver.

**Tracking Loop**
A controller used to align a replica of the carrier or ranging code in a GNSS receiver with the incoming signal. A ► *phase lock loop (PLL)* or ► *frequency lock loop (FLL)* for carrier tracking is combined with a ► *delay lock loop (DLL)* to track the ranging signal.

**Traveling Ionospheric Disturbance**
Ionospheric perturbation of electron density characterized by a horizontal scale length of a few hundred kilometers that travel at velocities in the order of a few hundred meters per second. TIDs are often generated by ► *space weather* events, in particular at high latitudes due to the interaction of solar wind with the Earth's magnetosphere, causing enhanced ionization and heating. Here the enhanced solar energy input causes perturbation-related thermospheric winds and electromagnetic forces from the magnetosphere, which may move plasma perturbations, e.g., towards lower latitudes.

**Traveling Wave Tube Amplifier (TWTA)**
A traveling wave tube integrated with a regulated power supply and protection circuits used to produce high-power radio frequency signals.

**Triple-difference**
The time difference of ► *double-difference* GNSS observations.

**Troposphere**
is the lowest layer of the Earth's atmosphere, where the temperature on the average decreases with height. It ends at the tropopause, which is located in the range from 8 km to 13 km, depending on the weather conditions, and varies systematically with latitude and season. The troposphere contains the weather, e.g., clouds and precipitation.

**Tropospheric Refraction**
Describes the signal propagation delay and bending induced by the electromagnetic neutral part of the atmosphere (► *slant total delay*). The ► *wet delay* and ► *hydrostatic (dry) delay* components are typically separately modeled or accounted for in GNSS measurement processing.

**Two-body Problem**
The task of calculating the motion of two bodies under the influence of their mutual gravitational attraction. The two-body problem is a simplified representation of the motion of a satellite around the Earth, where all perturbations are neglected. The solution of the two-body problem is also termed a ► *Keplerian orbit*.

**Two-way Satellite Time and Frequency Transfer (TWSTFT)**
A high-precision long distance time and frequency transfer mechanism used for clock offset determination or time synchronization between two stations.

## U

**Uniformly Most Powerful Invariant (UMPI) Test Statistic**
A test statistic that has uniformly the largest ► *power of all invariant statistics*

**Universal Time (UT)**
An irregular time scale based upon the rotation of the Earth. UT0 is a local time scale determined from observations taken at a single observing station. UT1 is UT0 corrected for the change in longitude of the observing station caused by polar motion. UT2 is UT1 corrected for seasonal variations. UT1 is proportional to the angle through which the Earth has rotated in space. The angular velocity of the Earth is proportional to the time rate-of-change of UT1.

**Universal Time Coordinated (UTC)**
Coordinated Universal Time is an atomic time aligned on the long-term on the Universal Time, i. e., the Earth's rotation. It is constructed by adding to the TAI, when needed, a leap second to keep the difference between UTC and UT less than 0.9 s. The difference between UTC and TAI is, therefore, always an integral number of seconds.

**User Differential Range Error (UDRE)**
A parameter broadcast by a ► *satellite-based augmentation system (SBAS)* to indicate the possible magnitude of the signal-in-space error for a specific satellite after applying the SBAS corrections. UDRE is determined from a broadcast 4-bit number, called the UDRE indicator or UDREI. A look up table is used to convert the indicator to a 1-sigma ► *overbound value* called the $\sigma_{\mathrm{UDRE}}$. By tradition, UDRE itself is a 99.9% number or $3.29 \times \sigma_{\mathrm{UDRE}}$.

**User Equipment Error (UEE)**
Contributions to the pseudorange measurement and modeling errors that relate to the user equipment (such as multipath and receiver noise). Atmospheric errors such as residual tropospheric and ionospheric delays not taken into account by models or eliminated in a dual-frequency combination are also commonly attributed to the UEE.

**User Equivalent Range Error (UERE)**
The statistical error of the difference between observed and modeled pseudoranges that are used for computing a GNSS position solution. UERE is commonly split into contributions of the space and control segment (► *Signal-in-space Range Error, SISRE*) as well as contributions related to the user equipment and atmosphere (► *User Equipment Error, UEE*). Multiplication of UERE with the ► *dilution of precision* yields the statistical positioning error.

**User Segment**
The user equipment for tracking GNSS signals and for determining position, velocity, and time.

## V

**Vector Tracking Architecture**
A GNSS signal tracking architecture in which the local code and carrier replica generators are driven not by single-channel local feedback, as in a traditional *scalar* tracking architecture, but by the state estimate of a consolidated position, velocity, and timing estimator that takes in data from all active channels. A vector architecture benefits from the mutual information in code phase, carrier phase, and Doppler measurements between channels and can thus provide more accurate and robust tracking than a scalar architecture.

**Vernal Equinox**
The point of intersection of the ► *ecliptic* and the ► *equator*, at which the Sun crosses the Equator from south to north, during its yearly passage along the ecliptic. This currently occurs on about March 21 each year. Historically, the vernal equinox served as origin of the measurement of ecliptic longitude as well as right ascension in the ► *celestial coordinate system*.

**Very Long Baseline Interferometry (VLBI)**
A space geodetic technique utilizing microwave signals from extragalactic radio sources (quasars). Basically, the signal travel time difference between two radio telescopes is measured. VLBI is the only technique to determine ► *Universal Time UT1* and ► *nutation* parameters, and is used to realize the ► *International Celestial Reference System*.

**VHF Data Broadcast (VDB)**
The transmission of ► *Ground-based Augmentation System (GBAS)* differential corrections and integrity information using the ILS localizer's VHF frequency band (108–118 MHz) and a time division multiple access (TDMA) data format defined in the GBAS ► *ICD*.

**VHF Omnidirectional Range (VOR)**
An aircraft navigation system operating in the very-high frequency (VHF) band. VORs broadcast a VHF radio composite signal that allows airborne receiving equipment to derive the magnetic bearing

from the station to the aircraft. This line of position is called a *radial*.

**Virtual Clock**
A technique used by ► *Chinese Area Positioning System* to implement satellite navigation. With the satellite virtual atomic clocks, the time at which the signals are transmitted from the ground can be delayed into the time that the signals are transmitted from the satellites, and the pseudorange measuring can be fulfilled as in GPS.

**Virtual Reference Station (VRS) Approach**
An approach that presents the data of a network of multiple reference stations to the user or rover as if coming from a single reference station, referred to as the virtual reference station.

**Viterbi Decoder**
A device or software for decoding a navigation message encoded with a convolutional code for ► *forward error correction*. It builds on algorithms for optimal decoding first published by A.J. Viterbi in 1967.

## W

**Wavelength**
The spatial separation between consecutive maxima or minima of an electromagnetic wave at a given instant of time.

**Walker Constellation**
A specific arrangement of multiple satellites in circular orbits around the Earth that enables good coverage and visibility conditions. Following J. G. Walker, the constellation geometry is described by the total number of satellites, the number of orbital planes, and the along-track shift of corresponding satellites in neighboring planes. All satellites within a plane exhibit identical spacing and the same applies for the ► *ascending nodes* of the individual orbital planes.

**Warm Start**
Activation of a GNSS receiver with prior information on the approximate time and user position, as well as the coarse orbit of GNSS satellites to speed up the signal search and acquisition.

**W-Code**
A low rate code used to encrypt the ► *P-code* of the GPS L1 and L2 signal. The product of the W- and P-codes yields the so-called ► *Y-code*.

**Wet Delay**
The wet component of the ► *slant total delay*.

**Wide Area Augmentation System (WAAS)**
A ► *satellite-based augmentation system (SBAS)* developed by the US Federal Aviation Administration (FAA) to provide horizontal and vertical navigation throughout North America. It has provided safety-of-life service since 2003.

**Wide-lane Observable**
A linear combination of carrier-phase observations on two frequencies that exhibits a large effective wavelength. It is formed as the difference of the two carrier-phase observations expressed in cycles. For GPS L1 and L2 the wide-lane combination yields a wavelength of about 86 cm.

**Wind-up**
► *Phase wind-up*

**World Geodetic System 1984 (WGS84)**
A conventional terrestrial ► *reference frame* defined and maintained by the US Department of Defense. Nominally the ► *datum* for GPS ► *single point positioning*.

***w*-test Statistic**
A ► *uniformly most powerful invariant (UMPI) test statistic* to test for the presence of one-dimensional biases. A special form of the w-test statistic is used in ► *data snooping* for the identification of observations contaminated with gross errors.

## Y

**Yaw-steering**
The continuous control of a GNSS satellite's attitude around the Earth-pointing (yaw) axis to keep the solar panel axis perpendicular to the satellite–Sun direction.

**Y-code**
An encrypted version of the precise ranging code (P-code) transmitted by the GPS satellites on the L1 and L2 frequencies.

## Z

**Zenith**
An imaginary point on the celestial sphere that is the projection of a local vertical direction. The astronomic zenith is the projection of the tangent to the local plumb line; the geodetic zenith is the projection of the local ellipsoid normal.

**Zenith Total Delay**
► *Slant Total Delay*

**Zero-baseline**
A setup of two or more GNSS receivers sharing a single antenna through a signal splitter.

**Zero-tide System**
A system specifically for the gravitational potential, in which all tidal effects except that of the permanent (mean) tidal deformation have been removed.

**Z-tracking**
An advanced technique for ► *semi-codeless tracking* of the GPS P(Y)-code on the L1 and L2 frequencies. The encryption signal bit is estimated separately in each frequency and fed to the other frequency to remove the encryption code from the signal. In this way, the code ranges and full wavelength L1 and L2 carrier phases are obtained. However, this method results in a signal-to-noise ratio degradation in comparison to the direct code correlation method.

***Z*-transformation**
An integer preserving ambiguity transformation. A matrix is integer preserving if and only if all its

entries and those of its inverse are integer. Such transformations are used, e.g., in the ► *least-squares ambiguity decorrelation adjustment (LAMBDA)* method, to re-parameterize ambiguities so that they can be estimated with higher precision and less correlation.

**Springer Handbook of Spacetime** (2014)
ed. by Ashtekar, Petkov, 887 p., 978-3-642-41991-1

**Springer Handbook of Bio-/Neuro-Informatics** (2014)
ed. by Kasabov, 1230 p., 978-3-642-30573-3

**Springer Handbook of Nanomaterials** (2013)
ed. by Vajtai, 1222 p., 978-3-642-20594-1

**Springer Handbook of Lasers and Optics (2nd)** (2012)
ed. by Träger, 1694 p., 978-3-642-19408-5

**Springer Handbook of Geographic Information** (2012)
ed. by Kresse, Danko, 1120 p., 978-3-540-72678-4

**Springer Handbook of Medical Technology** (2011)
ed. by Kramme, Hoffmann, Pozos, 1500 p., 978-3-540-74657-7

**Springer Handbook of Metrology and Testing (2nd)** (2011)
ed. by Czichos, Saito, Smith, 1229 p., 978-3-642-16640-2

**Springer Handbook of Crystal Growth** (2010)
ed. by Dhanaraj, Byrappa, Prasad, Dudley, 1816 p., 978-3-540-74182-4

**Springer Handbook of Nanotechnology (3rd)** (2010)
ed. by Bhushan, 1961 p., 978-3-642-02524-2

**Springer Handbook of Automation** (2009)
ed. by Nof, 1812 p., 978-3-540-78830-0

**Springer Handbook of Mechanical Engineering** (2009)
ed. by Grote, Antonsson, 1576 p., 978-3-540-49131-6

**Springer Handbook of Experimental Solid Mechanics** (2008)
ed. by Sharpe, 1096 p., 978-0-387-26883-5

**Springer Handbook of Speech Processing** (2007)
ed. by Benesty, Sondhi, Huang, 1176 p., 978-3-540-49125-5

**Springer Handbook of Experimental Fluid Mechanics** (2007)
ed. by Tropea, Yarin, Foss, 1557 p., 978-3-540-25141-5

**Springer Handbook of Electronic and Photonic Materials** (2006)
ed. by Kasap, Capper, 1406 p., 978-0-387-26059-4

**Springer Handbook of Engineering Statistics** (2006)
ed. by Pham, 1120 p., 978-1-85233-806-0

**Springer Handbook of Atomic, Molecular, and Optical Physics (2nd)** (2005)
ed. by Drake, 1506 p., 978-0-387-20802-2
